DUTTON'S ORTHOPAEDIC EXAMINATION, EVALUATION, AND INTERVENTION

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. T e authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. T is recommendation is of particular importance in connection with new or infrequently used drugs.

For my parents,
Ron and Brenda, who have always helped, guided, and inspired me
and to my two daughters, Leah and Lauren, who provide me with such joy.

Your Legacy

Will you have earned the respect of your peers and the admiration of your critics?

Will you have acted humbly during success and gracefully in the face of adversity?

Will you be remembered for how often you brought smiles to the hearts of others?

Will you have looked for the very best, and done your utmost to build worth, in others?

Will you have left this world a better place by the life you have lived?

Preface

T e fourth edition of this book is an update of information and bibliography provided in the previous versions together with a reorganization of various chapters.

T e United States currently spends more money on healthcare per person than any other country in the world, with current projections indicating that 20% of the gross domestic product of the United States will be spent on healthcare by the year 2019.[1] As the population continues to age, the treatment of musculoskeletal conditions, and their subsequent expenses, will also increase. T is will place an increasing burden on the clinician to provide value for money—the achievement of a health outcome relative to the costs incurred. Gone are the days when a clinician can rely on an expensive shotgun approach to treatment. Instead, emphasis is now placed on outcomes such as patient satisfaction and accurate measures of clinical outcomes, for it is the consistent measurement and reporting of clinical outcomes that is the most powerful tool in moving toward a value-based system.[2]

To that end, the aim of this book is to provide the reader with a systematic and evidence-based approach to the examination and intervention of the orthopaedic patient. Such an approach must be eclectic because no single method works all of the time. T us, this book attempts to incorporate the most reliable concepts currently available.

I hope that this book will be seen as the best available textbook, guide, review, and reference for healthcare students and clinicians involved in the care of the orthopaedic population.

Mark Dutton, P*T*

Acknowledgments

From inception to completion, the various editions span almost 12 years. Such an endeavor cannot be completed without the help of many. I would like to take this opportunity to thank the following:

- The faculty of the North American Institute of Manual and Manipulative Therapy (NAIOMT)—especially, Jim Meadows, Erl Pettman, Cliff Fowler, Diane Lee, and the late Dave Lamb.
- The exceptional team at McGraw-Hill, for their superb guidance throughout this object. Thank you especially to Michael Weitz for his advice and support and to other members of the initial lineup. Special thanks also to Brian Kearns.
- To the production crew of Aptara, especially the project manager Amit Kashyap.
- Bob Davis for his creative eye and the excellent photography.
- Leah for agreeing to be the photographic model.
- The staff of Human Motion Rehabilitation, Allegheny General Hospital including Troy Baxendell, Susan Berger, Diane Ferianc, Leslie Fisher, Keith Galloway, Dave Hahn, Dean Hnaras, John Karp, Ronald Klingensmith, Randi Marshak, Dan McCool, Renee Nacy, Dan Norkiewicz, Darcy Skrip, Jodi Weiher, Melissa Willis, and Joe Witt.
- To the countless clinicians throughout the world who continually strive to improve their knowledge and clinical skills.

Introduction

"T e very f rst step towards success in any occupation is to become interested in it."

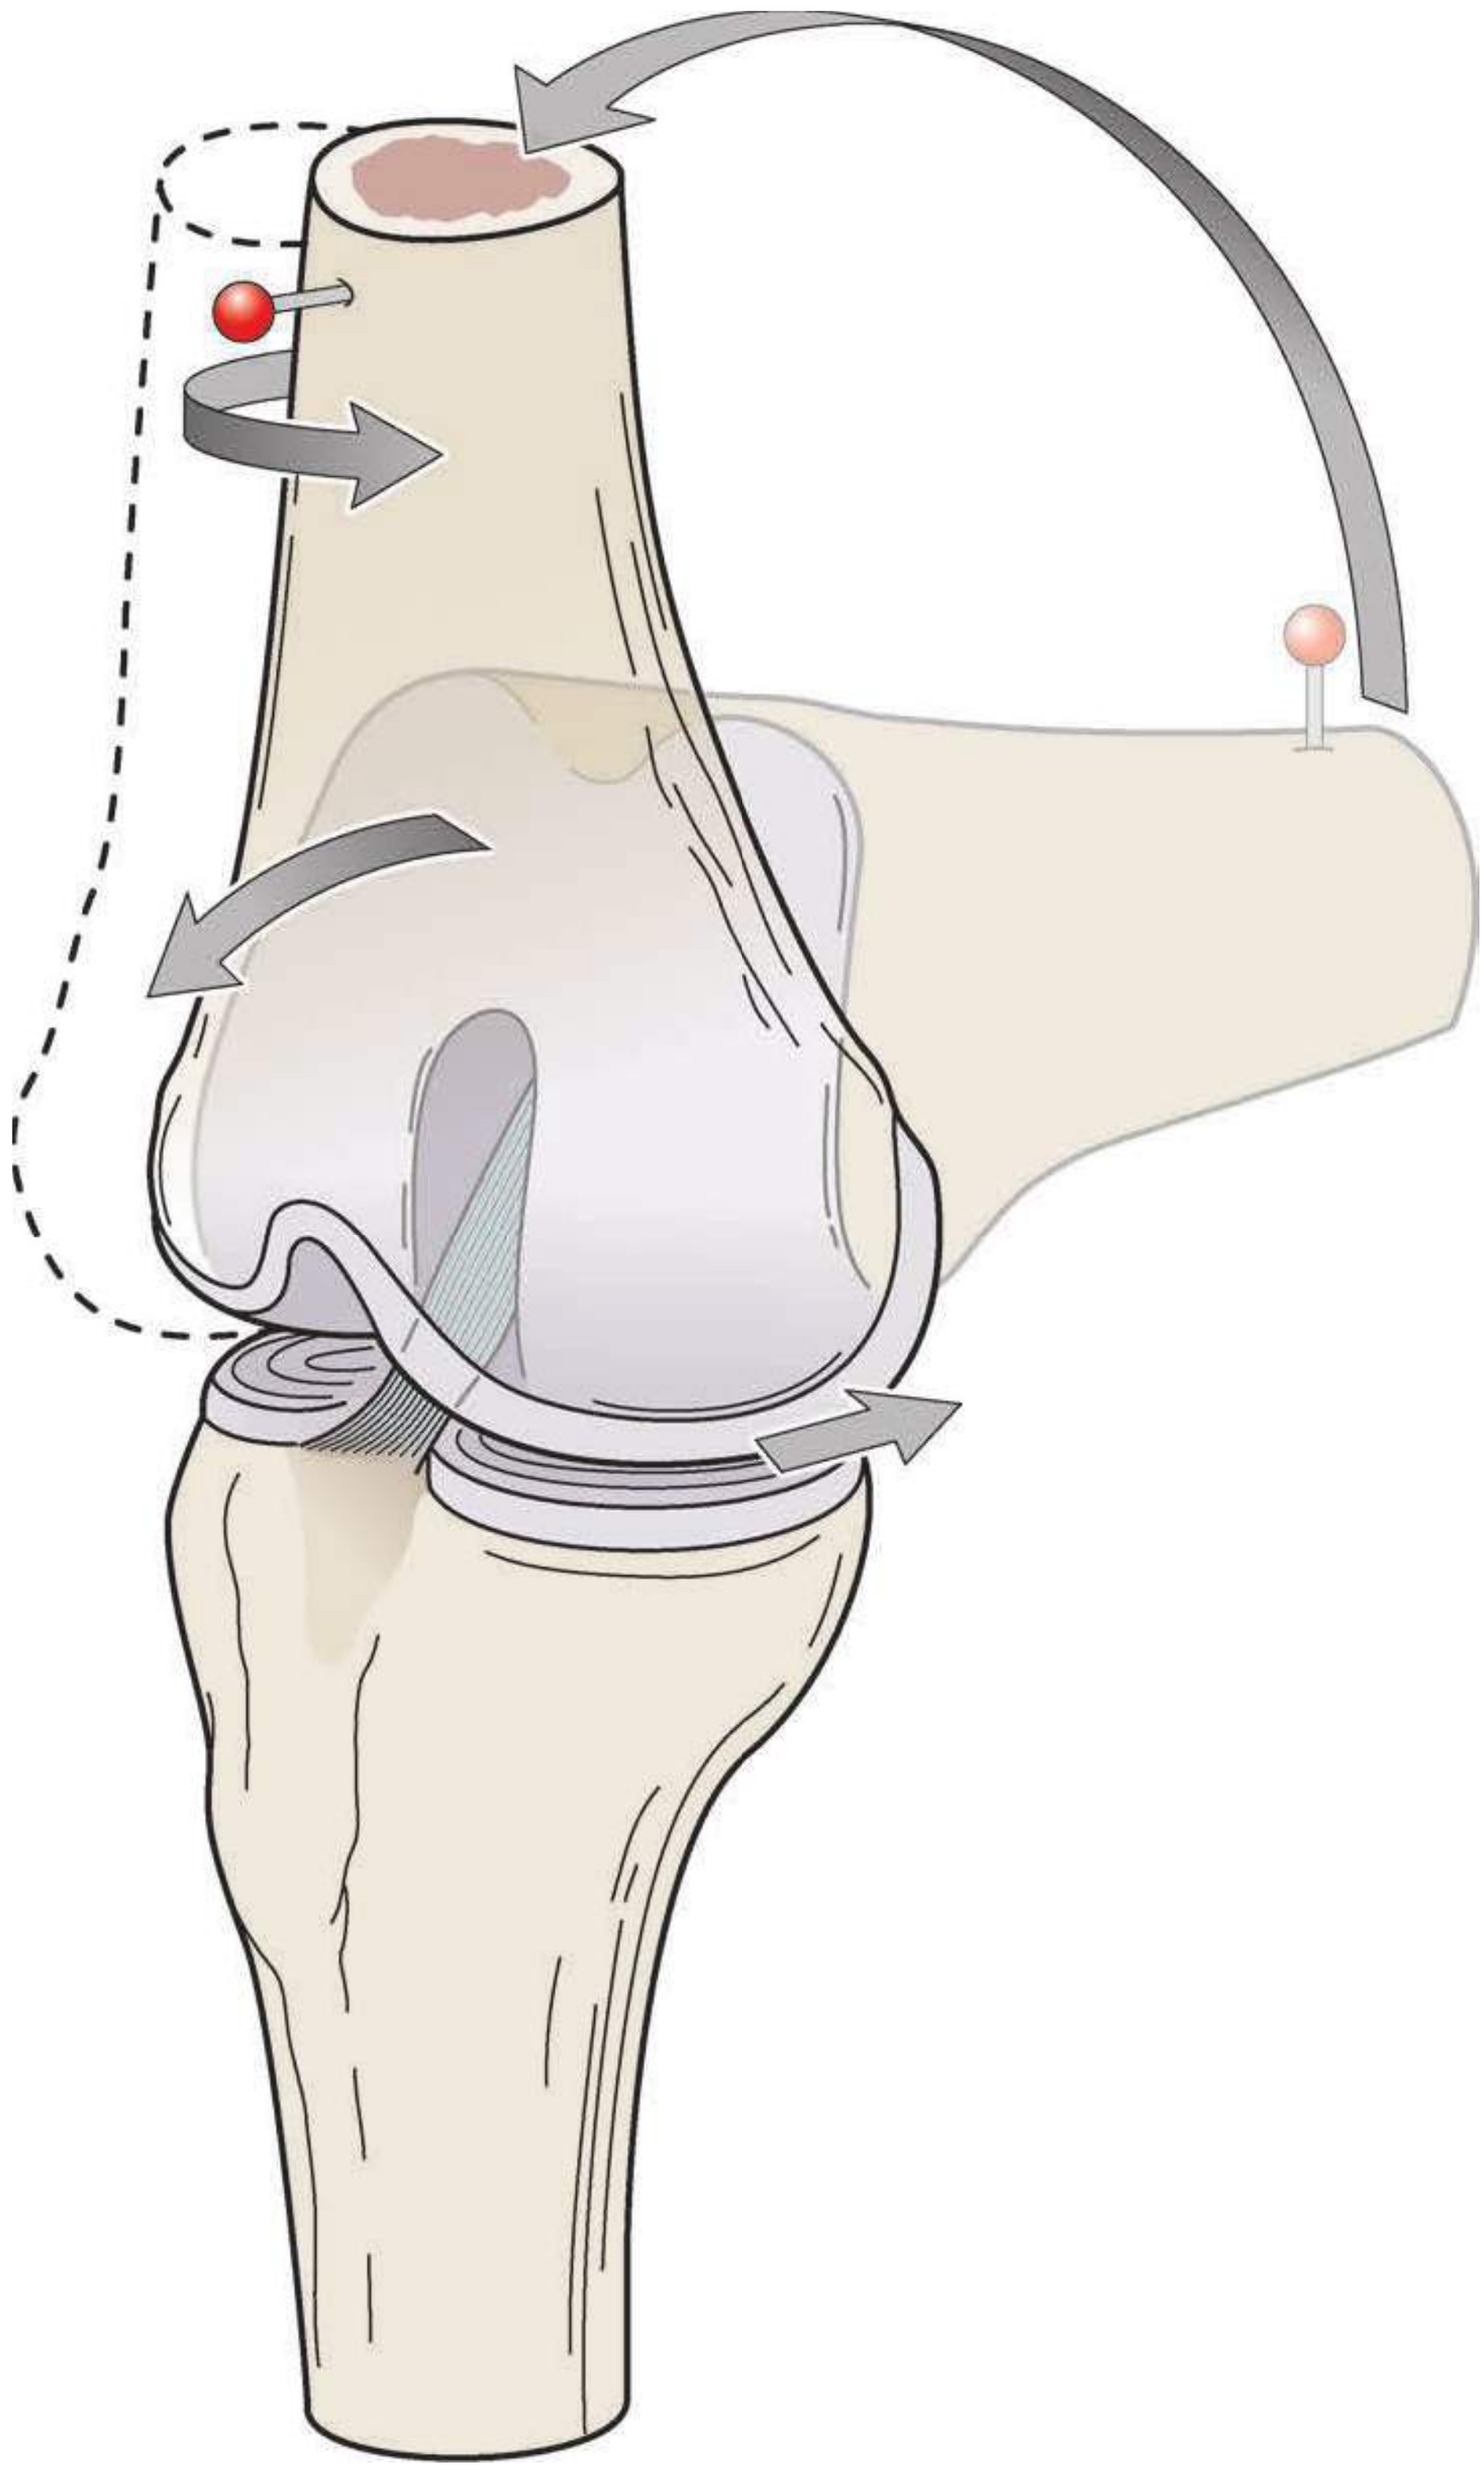
—Sir William Osler (1849–1919)

Until the beginning of the last century, knowledge about the mechanism of healing and the methods to decrease pain and suffering were extremely limited. Although we may scoff at many of the interventions used in the distant past, many of the interventions we use today, albeit less radical, have still to demonstrate much more in the way of effectiveness. T at may soon change with the recent emphasis within many healthcare professions on evidence-based clinical practice. T e process of evidence-based practice is outlined in Table I-1. When combining clinical expertise with the best available external clinical evidence, clinicians can make informed decisions regarding patient management, including the selection and interpretation of the most appropriate evaluation procedures. Also, intervention strategies based on the best available evidence will have a greater likelihood of success with the least associated risk.[3,4]

TABLE I-1 The Process of Evidence-Based Practice

1. Identify the patient problem. Derive a specif c question.
2. Search the literature.
3. Appraise the literature.
4. Integrate the appraisal of literature with your clinical expertise, experience, patient values, and unique circumstances.
5. Implement the f ndings.
6. Assess outcome and reappraise.

Data from Sackett DL, Strauss SE, Richardson WS, et al. Evidence Based Medicine: How to Practice and Teach EBM. 2nd ed. Edinburgh, Scotland: Churchill Livingstone; 2000.



T e goal of every clinician should be to enhance patient/client satisfaction, increase ef ciency, and decrease unproven treatment approaches.[4] T e management of the patient/client is a complex process involving an intricate blend of experience, knowledge, and interpersonal skills. Obtaining an accurate diagnosis requires a systematic and logical approach. Such an approach should be eclectic because no single method works all of the time. For any intervention to be successful, an accurate diagnosis must be followed by a carefully planned and specific rehabilitation program to both the affected area and its related structures. In this book, great emphasis is placed on the appropriate use of manual techniques and therapeutic exercise based on these considerations. Electrotherapeutic and thermal/cryotherapeutic modalities should be viewed as adjuncts to the rehabilitative process. T e accompanying DVD to this book contains numerous video clips of manual techniques and therapeutic exercises, which the reader is encouraged to view. T e following icon is used throughout the text to indicate when such clips are available. [VIDEO]

SECTION I

ANATOMY

CHAPTER 1 The Musculoskeletal System

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the various types of biological tissue of the musculoskeletal system.
2. Describe the tissue mechanics and structural differences and similarities between muscle, tendons, fascia, and ligaments.
3. Describe the different types of joints and their various characteristics.
4. Define the various terminologies used to describe the joint position, movements, and relationships.
5. Give definitions for commonly used biomechanical terms.
6. Describe the different planes of the body.
7. Define the body's center of mass and its location.
8. Describe the different axes of the body and the motions that occur around them.
9. Define the terms osteokinematic motion and arthrokinematic motion.
10. Differentiate between the different types of motion that can occur at the joint surfaces.
11. Describe the basic biomechanics of joint motion in terms of their concave–convex relationships.
12. Define the terms close-packed and open-packed.

OVERVIEW

The correct embryonic development of the musculoskeletal system requires a coordinated morphogenesis of the fundamental tissues of the body. Throughout the human body, there are four major types of tissues:

- Epithelial. Covers all internal and external body surfaces and includes structures such as the skin and the inner lining of the blood vessels.
- Connective. Connective tissue (CT), which includes four different classes: connective tissue proper, bone, cartilage, and blood tissue. In the embryo, muscle tissue and its fascia form as a differentiation of the paraxial mesoderm that divides into somites on either side of the neural tube and notochord. The cartilage and bone of the vertebral column and ribs develop from the sclerotome which is the anterior (ventral) part of the somite.[1] The dermomyotome, which is the posterior (dorsal) part of the somite, gives rise to the overlying dermis of the back and the skeletal muscles of the body and limbs.[1] Connective tissue provides structural and metabolic support for other tissues and organs of the body.
- Muscle. Muscles are classified functionally as either voluntary or involuntary, and structurally as either smooth, striated (skeletal), or cardiac. There are approximately 430 skeletal muscles in the body, each of which can be considered anatomically as a separate organ. Of these 430 muscles, about 75 pairs provide the majority of body movements and postures.[2]
- Nervous. Nervous tissue provides a two-way communication system between the central nervous system (brain and spinal cord) and muscles, sensory organs, and various systems (see Chapter 3).

CONNECTIVE TISSUE

CT proper has a loose, flexible matrix, called ground substance. The most common cell within CT proper is the fibroblast. Fibroblasts produce collagen, elastin, and reticular fibers:

- Collagen is a group of naturally occurring proteins. The collagens are a family of extracellular matrix (ECM) proteins that play a dominant role in maintaining the structural integrity of various tissues and in providing tensile strength to tissues. The ECM is formed from glycosaminoglycans (GAGs) subunits, long polysaccharide chains containing amino sugars, and are strongly hydrophilic to allow rapid diffusion of water-soluble molecules and easy migration of cells. Proteoglycans, which are a major component of the ECM, are macromolecules that consist of a protein backbone

to which the GAGs are attached. There are two types of GAGs: chondroitin sulfate and keratin sulfate.[3,4] A simple way to visualize the proteoglycan molecule is to consider a test tube brush, with the stem representing the protein core and the GAGs representing the bristles.[5,6] Glycoproteins, another component of the ECM, consist of fibronectin and thrombospondin and function as adhesive structures for repair and regeneration.[7]

- Elastic fibers are composed of a protein called elastin. As its name suggests, elastin provides elastic properties to the tissues in which it is situated.[8] Elastin fibers can stretch, but they normally return to their original shape when the tension is released. Thus, the elastic fibers of elastin determine the patterns of distention and recoil in most organs, including the skin and lungs, blood vessels, and CT. Bundles of collagen and elastin combine to form a matrix of CT fascicles. This matrix is organized within the primary collagen bundles as well as between the bundles that surround them.[9]
- Reticular fibers are composed of a type of collagen, which is secreted by reticular cells. These fibers crosslink to form a fine meshwork, called reticulin, which acts as a supporting mesh in bone marrow, and the tissues and organs of the lymphatic system, and the liver.

The various characteristics of collagen differ depending on whether it is loose or dense collagen. The anatomic and functional characteristics of loose and dense collagen are summarized in Table 1-1. Collagenous and elastic fibers are sparse and irregularly arranged in loose CT but are tightly packed in dense CT.[10]

The various types of CT, as they relate to the musculoskeletal system, are described as follows:

Fascia

Fascia, for example, the thoracolumbar fascia and the plantar fascia, is viewed as a loose CT that provides support and protection to a joint, and acts as an interconnection between tendons, aponeuroses, ligaments, capsules, nerves, and the intrinsic components of muscle.[11,12] Fascia may be categorized as fibrous or nonfibrous, with the fibrous components consisting mainly of collagen and elastin fibers, and the nonfibrous portion consisting of amorphous ground substance.[13] Three different types of fascia have been identified, namely, superficial, deep, and visceral fascia. Various three-dimensional biomechanical models of the human fascial system have been developed, which correlate dysfunctional movement with various interrelated abnormal amounts of tension throughout the network of fascia. In particular, deep fascia has been implicated in being involved with the deep venous return, in having a possible role in proprioception, and responding to mechanical traction induced by muscular activity in different regions.[14] Histological studies of deep fascia in the limbs show that it consists of elastic fibers and undulated collagen fibers arranged in layers.[15] Each collagen layer is aligned in a different direction, and this permits a certain degree of stretch as well as a capacity to recoil.[16]

Tendons

Tendons are dense, regularly arranged connective tissues, composed of 70% water and 30% dry mass that attach muscle to the bone at each end of the muscle. Tendons produce joint motion by transferring force from muscle to bone, and, when stretched, store elastic energy that contributes to movement. Also, tendons enable the muscle belly to be an optimal distance from the joint upon which it is acting. The collagen fibers of tendons (70–80% of the collagen in tendons is type I, with the remaining 20–30% of dry weight composed of proteoglycans, GAGs, elastin, and other collagens—being type III, V, and VII) are arranged in a quarter-stagger arrangement, which gives it a characteristic banding pattern and provides high strength and stability.[17] Tenoblasts, or immature tendon cells, transform into tenocytes that synthesize collagen and components of the ECM network.[7] The ECM surrounds collagen and tenocytes and is composed of several components for specific functions (e.g., glycoproteins, and Tenascin-C, which may play a role in collagen fiber orientation and alignment). Tendon structure is highly regular with collagen-forming triple helices (tropocollagen), which pack together to form microfibrils, which interdigitate to form fibrils, which coalesce to form fibers, which combine to form fascicles, which are bundled together to form a tendon.[18] The thickness of each tendon varies and is proportional to the size of the muscle from which it originates. Vascularity within the tendon is relatively sparse and corresponds with the lower metabolic/turnover rate of these tissues. Within the fascicles of tendons, which are held together by loose CT called endotenon, the collagen components are oriented in a unidirectional way. Endotenon contains blood vessels, lymphatics, and nerves and permits longitudinal movements of individual fascicles when tensile forces are applied to the structure. The CT surrounding groups of fascicles, or the entire structure, is called the epitenon. The epitenon contains the vascular, lymphatic, and nerve supplies to the tendon. A peritendinous sheath (paratenon), which is composed of loose areolar connective tissue in addition to sensory and autonomic nerve fibers, surrounds the entire tendon.[19] This sheath consists of

TABLE 1-1 Loose and Dense Collagen

Joint Type	Anatomic Location	Fiber Orientation	Mechanical Specialization
Dense irregular connective tissue	Composes the external fibrous layer of the joint capsule, forms ligaments, bone, aponeuroses, and tendons	Parallel, tightly aligned fibers	Ligament: binds bones together and restrains unwanted movement at the joints; resists tension in several directions Tendon: attaches muscle to bone
Loose irregular connective tissue	Found in capsules, muscles, nerves, fascia, and skin	Random fiber orientation	Provides structural support

two layers: an inner (visceral) layer and an outer (parietal) layer with occasional connecting bridges (mesotenon). If there is synovial fluid between these two layers, the paratenon is called tenosynovium; if not, it is termed tenovagium.[9]

Tendons are metabolically active and are provided with a rich and vascular supply during development.[20] Tendons receive their vascular supply through the musculotendinous junction (MTJ), the osteotendinous junction, and the vessels from the various surrounding tissues including the paratenon and mesotenon.[18] Tendons in different areas of the body receive different amounts of blood supply, and tendon vascularity can be compromised by the junctional zones and sites of friction, torsion, or compression—a number of tendons are known to have reduced tendon vascularity, including the supraspinatus, the biceps, the Achilles, the patellar, and the posterior tibial tendon.[18]

T e mechanical properties of tendon come from its highly oriented structure. Tendons display viscoelastic mechanical properties that confer time- and rate-dependent effects on the tissue. Specifically, tendons are more elastic at lower strain rates and stiffer at higher rates of tensile loading (see Chapter 2). Tendons deform less than ligaments under an applied load and are able to transmit the load from muscle to bone.[9] Material and structural properties of the tendon increase from birth through maturity and then decrease from maturity through old age.[18] Although tendons withstand strong tensile forces well, they resist shear forces less well and provide little resistance to a compression force (see Chapter 2).

A tendon can be divided into three main sections:[21]

- T e bone–tendon junction. At most tendon–bone interfaces, the collagen fibers insert directly into the bone in a gradual transition of material composition. T e physical junction of tendon and bone is referred to as an enthesis,[22] and is an interface that is vulnerable to acute and chronic injury.[23] One role of the enthesis is to absorb and distribute the stress concentration that occurs at the junction over a broader area.
- T e tendon midsubstance. Overuse tendon injuries can occur in the midsubstance of the tendon, but not as frequently as at the enthesis.
- MTJ. T e MTJ is the site where the muscle and tendon meet. T e MTJ comprises numerous interdigitations between muscle cells and tendon tissue, resembling interlocked fingers. Despite its viscoelastic mechanical characteristics, the MTJ is very vulnerable to tensile failure (see Chapter 2).[24,25]

Ligaments

Skeletal ligaments are fibrous bands of dense CT that connect bones across joints. Ligaments can be named for the bones into which they insert (coracohumeral), their shape (deltoid of the ankle), or their relationships to each other (cruciate).[26] T e gross structure of a ligament varies according to location (intra-articular or extra-articular, capsular), and function.[27] Ligaments, which appear as dense white bands or cords of CT, are composed primarily of water (approximately 66%), and of collagen (largely type I collagen [85%], but with small amounts of type III) making up most of the dry weight. T e collagen in ligaments has a less unidirectional organization than it does in tendons, but its structural framework still provides stiffness (resistance to deformation—see Chapter 2).[28] Small amounts of elastin (1% of the dry weight) are present in ligaments, with the exception of the ligamentum flavum and the nuchal ligament of the spine, which contain more. T e cellular organization of ligaments makes them ideal for sustaining tensile loads, with many containing functional subunits that are capable of tightening or loosening in different joint positions.[29] At the microscopic level, closely spaced collagen fibers (fascicles) are aligned along the long axis of the ligament and are arranged into a series of bundles that are delineated by a cellular layer, the endoligament, and the entire ligament is encased in a neurovascular biocellular layer referred to as the epiligament.[26] Ligaments contribute to the stability of joint function by preventing excessive motion,[30] acting as guides or checkreins to direct motion, and providing proprioceptive information for joint function through sensory nerve endings (see Chapter 3) and the attachments of the ligament to the joint capsule.[31–33] Many ligaments share functions. For example, while the anterior cruciate ligament of the knee is considered the primary restraint to anterior translation of the tibia relative to the femur, the collateral ligaments and the posterior capsule of the knee also help in this function (see Chapter 20).[26] T e vascular and nerve distribution to ligaments is not homogeneous. For example, the middle of the ligament is typically avascular, while the proximal and distal ends enjoy a rich blood supply. Similarly, the insertional ends of the ligaments are more highly innervated than the midsubstance.

Cartilage

Cartilage tissue exists in three forms: hyaline, elastic, and fibrocartilage.

- Hyaline cartilage, also referred to as articular cartilage, covers the ends of long bones and permits almost frictionless motion to occur between the articular surfaces of a diarthrodial (synovial) joint.[34] Articular cartilage is a highly organized viscoelastic material composed of cartilage cells called chondrocytes, water, and an ECM.

CLINICAL PEARL

Chondrocytes are specialized cells that are responsible for the development of cartilage and the maintenance of the ECM.[35] Chondrocytes produce aggrecan, link protein, and hyaluronan, all of which are extruded into the ECM, where they aggregate spontaneously.[4] The aggrecan forms a strong, porous-permeable, fiber-reinforced composite material with collagen. The chondrocytes sense mechanical changes in their surrounding matrix through intracytoplasmic filaments and short cilia on the surface of the cells.[27]

Articular cartilage, the most abundant cartilage within the body, is devoid of any blood vessels, lymphatics, and nerves.[5,6] Most of the bones of the body form first as hyaline cartilage, and later become bone in a process called endochondral ossification. T e normal thickness of articular cartilage is determined by the contact pressures across the joint—the higher the peak pressures, the thicker the

cartilage.[27] Articular cartilage functions to distribute the joint forces over a large contact area, thereby dissipating the forces associated with the load. T is distribution of forces allows the articular cartilage to remain healthy and fully functional throughout decades of life. T e patellar has the thickest articular cartilage in the body.

Articular cartilage may be grossly subdivided into four distinct zones with differing cellular morphology, biomechanical composition, collagen orientation, and structural properties, as follows:

- T e super*fi*cial zone. T e superficial zone, which lies adjacent to the joint cavity, comprises approximately 10–20% of the articular cartilage thickness and functions to protect deeper layers from shear stresses. T e collagen fibers within this zone are packed tightly and aligned parallel to the articular surface. T is zone is in contact with the synovial fluid and handles most of the tensile properties of cartilage.
- T e middle (transitional) zone. In the middle zone, which provides an anatomic and functional bridge between the superficial and deep zones, the collagen fibril orientation is obliquely organized. T is zone comprises 40–60% of the total cartilage volume. Functionally, the middle zone is the first line of resistance to compressive forces.
- T e deep or radial layer. T e deep layer comprises 30% of the matrix volume. It is characterized by radially aligned collagen fibers that are perpendicular to the surface of the joint, and which have a high proteoglycan content. Functionally the deep zone is responsible for providing the greatest resistance to compressive forces.
- T e tidemark. T e tidemark distinguishes the deep zone from the calcified cartilage, the area that prevents the diffusion of nutrients from the bone tissue into the cartilage.

- Elastic (yellow) cartilage is a very specialized CT, primarily found in locations such as the outer ear, and portions of the larynx.
- Fibrocartilage, also referred to as white cartilage, functions as a shock absorber in both weight-bearing and nonweight-bearing joints. Its large fiber content, reinforced with numerous collagen fibers, makes it ideal for bearing large stresses in all directions. Fibrocartilage is an avascular, alymphatic, and aneural tissue and derives its nutrition by a double-diffusion system.[36] Examples of fibrocartilage include the symphysis pubis, the intervertebral disk, and the menisci of the knee.

Bone

Bone is a highly vascular form of CT, composed of collagen, calcium phosphate, water, amorphous proteins, and cells. It is the most rigid of the CTs (Table 1-2). Despite its rigidity, bone is a dynamic tissue that undergoes constant metabolism and remodeling. T e collagen of bone is produced in the same manner as that of ligament and tendon but by a different cell, the osteoblast.[10] At the gross anatomical level, each bone has a distinct morphology comprising both cortical bone and cancellous bone. Cortical bone is found in the outer shell. Cancellous bone is found within the epiphyseal and metaphyseal regions of long bones, as well as throughout the interior of short bones.[24] Skeletal development occurs in one of the two ways:

- Intramembranous ossification. Mesenchymal stem cells within mesenchyme or the medullary cavity of a bone initiate the process of intramembranous ossification. T is type of ossification occurs in the cranium and facial bones and, in part, the ribs, clavicle, and mandible.

TABLE 1-2 General Structure of Bone

Site	Comment	Conditions	Result
Epiphysis	Mainly develops under pressure Apophysis forms under traction Forms bone ends Supports articular surface	Epiphyseal dysplasias Joint surface trauma Overuse injury Damaged blood supply	Distorted joints Degenerative changes Fragmented development Avascular necrosis
Physis	Epiphyseal or growth plate Responsive to growth and sex hormones Vulnerable prior to growth spurt Mechanically weak	Physeal dysplasia Trauma Slipped epiphysis	Short stature Deformed or angulated growth or growth arrest
Metaphysis	Remodeling expanded bone end Cancellous bone heals rapidly Vulnerable to osteomyelitis Affords ligament attachment	Osteomyelitis Tumors Metaphyseal dysplasia	Sequestrum formation Altered bone shape Distorted growth
Diaphysis	Forms shaft of bone Large surface for muscle origin Significant compact cortical bone Strong in compression	Fractures Diaphyseal dysplasias Healing slower than at metaphysis	Able to remodel angulation Cannot remodel rotation Involucrum with infection Dysplasia gives altered density and shape

Data from Reid DC. Sports Injury Assessment and Rehabilitation. New York, NY: Churchill Livingstone; 1992.

- Endochondral ossification. T e first site of ossification occurs in the primary center of ossification, which is in the middle of the diaphysis (shaft). About the time of birth, a secondary ossification center appears in each epiphysis (end) of long bones. Between the bone formed by the primary and secondary ossification centers, cartilage persists as the epiphyseal (growth) plates between the diaphysis and the epiphysis of a long bone. T is type of ossification occurs in the appendicular and axial bones.

T e periosteum is formed when the perichondrium, which surrounds the cartilage, becomes the periosteum. Chondrocytes in the primary center of ossification begin to grow (hypertrophy) and begin secreting alkaline phosphatase, an enzyme essential for mineral deposition. Calcification of the matrix follows, and apoptosis (a type of cell death involving a programmed sequence of events that eliminates certain cells) of the hypertrophic chondrocytes occurs. T is creates cavities within the bone. T e exact mechanism of chondrocyte hypertrophy and apoptosis is currently unknown. T e hypertrophic chondrocytes (before apoptosis) also secrete a substance called vascular endothelial cell growth *f*actor that induces the sprouting of blood vessels from the perichondrium. Blood vessels forming the periosteal bud invade the cavity left by the chondrocytes, and branch in opposite directions along the length of the shaft. T e blood vessels carry osteoprogenitor cells and hemopoietic cells inside the cavity, the latter of which later form the bone marrow. Osteoblasts, differentiated from the osteoprogenitor cells that enter the cavity via the periosteal bud, use the calcified matrix as a scaffold and begin to secrete osteoid, which forms the bone trabecula. Osteoclasts, formed from macrophages, break down the spongy bone to form the medullary cavity (bone marrow). T e function of bone is to provide support, enhance leverage, protect vital structures, provide attachments for both tendons and ligaments, and store minerals, particularly calcium. From a clinical perspective, bones may serve as useful landmarks during the palpation phase of the examination. T e strength of bone is related directly to its density. Of importance to the clinician, is the difference between maturing bone and mature bone. T e epiphyseal plate or growth plate of a maturing bone can be divided into four distinct zones:[37]

- Reserve zone: produces and stores matrix.
- Proliferative zone: produces matrix and is the site for longitudinal bone cell growth.
- Hypertrophic zone: subdivided into the maturation zone, degenerative zone, and the zone of provisional calcification. It is within the hypertrophic zone that the matrix is prepared for calcification and is here that the matrix is ultimately calcified. The hypertrophic zone is the most susceptible of the zones to injury because of the low volume of bone matrix and the high amounts of developing immature cells in this region.[38]
- Bone metaphysis: the part of the bone that grows during childhood.

Skeletal Muscle Tissue

T e microstructure and composition of skeletal muscle have been studied extensively. T e class of tissue labeled skeletal muscle consists of individual muscle cells or fibers that work together to produce the movement of bony levers. A single muscle cell is called a muscle *fi*ber or myo*fi*ber. As muscle cells differentiate within the mesoderm, individual myofibers are wrapped in a CT envelope called endomysium. Bundles of myofibers, which form a whole muscle (fasciculus), are encased in the perimysium (Fig. 1-1). T e perimysium is continuous with the deep fascia. T is relationship allows the fascia to unite all of the fibers of a single motor unit and, therefore, adapt to variations in form and volume of each muscle according to muscular contraction and intramuscular modifications induced by joint movement.[15] Groups of fasciculi are surrounded by a connective sheath called the epimysium (Fig. 1-1). Under an electron microscope, it can be seen that each of the myofibers consists of thousands of myo*fi*brils (Fig. 1-1), which extend throughout its length. Myofibrils are composed of sarcomeres arranged in series.[39]

CLINICAL PEARL

The sarcomere (Fig. 1-2) is the contractile machinery of the muscle. The graded contractions of a whole muscle occur because the number of fibers participating in the contraction varies. Increasing the force of movement is achieved by recruiting more cells into cooperative action.

All skeletal muscles exhibit four characteristics:[40]

1. Excitability, the ability to respond to stimulation from the nervous system.
2. Elasticity, the ability to change in length or stretch.
3. Extensibility, the ability to shorten and return to normal length.
4. Contractility, the ability to shorten and contract in response to some neural command. T e tension developed in skeletal muscle can occur passively (stretch) or actively (contraction). When an activated muscle develops tension, the amount of tension present is constant throughout the length of the muscle, in the tendons, and at the sites of the musculotendinous attachments to the bone. T e tensile force produced by the muscle pulls on the attached bones and creates torque at the joints crossed by the muscle. T e magnitude of the tensile force is dependent on a number of factors.

One of the most important roles of CT is to transmit mechanically the forces generated by the skeletal muscle cells to provide movement. Each of the myofibrils contains many fibers called myo*fi*laments, which run parallel to the myofibril axis. T e myofilaments are made up of two different proteins: actin (thin myofilaments) and myosin (thick myofilaments) that give skeletal muscle fibers their striated (striped) appearance (Fig. 1-2).[39]

T e striations are produced by alternating dark (A) and light (I) bands that appear to span the width of the muscle fiber. T e A bands are composed of myosin filaments, whereas

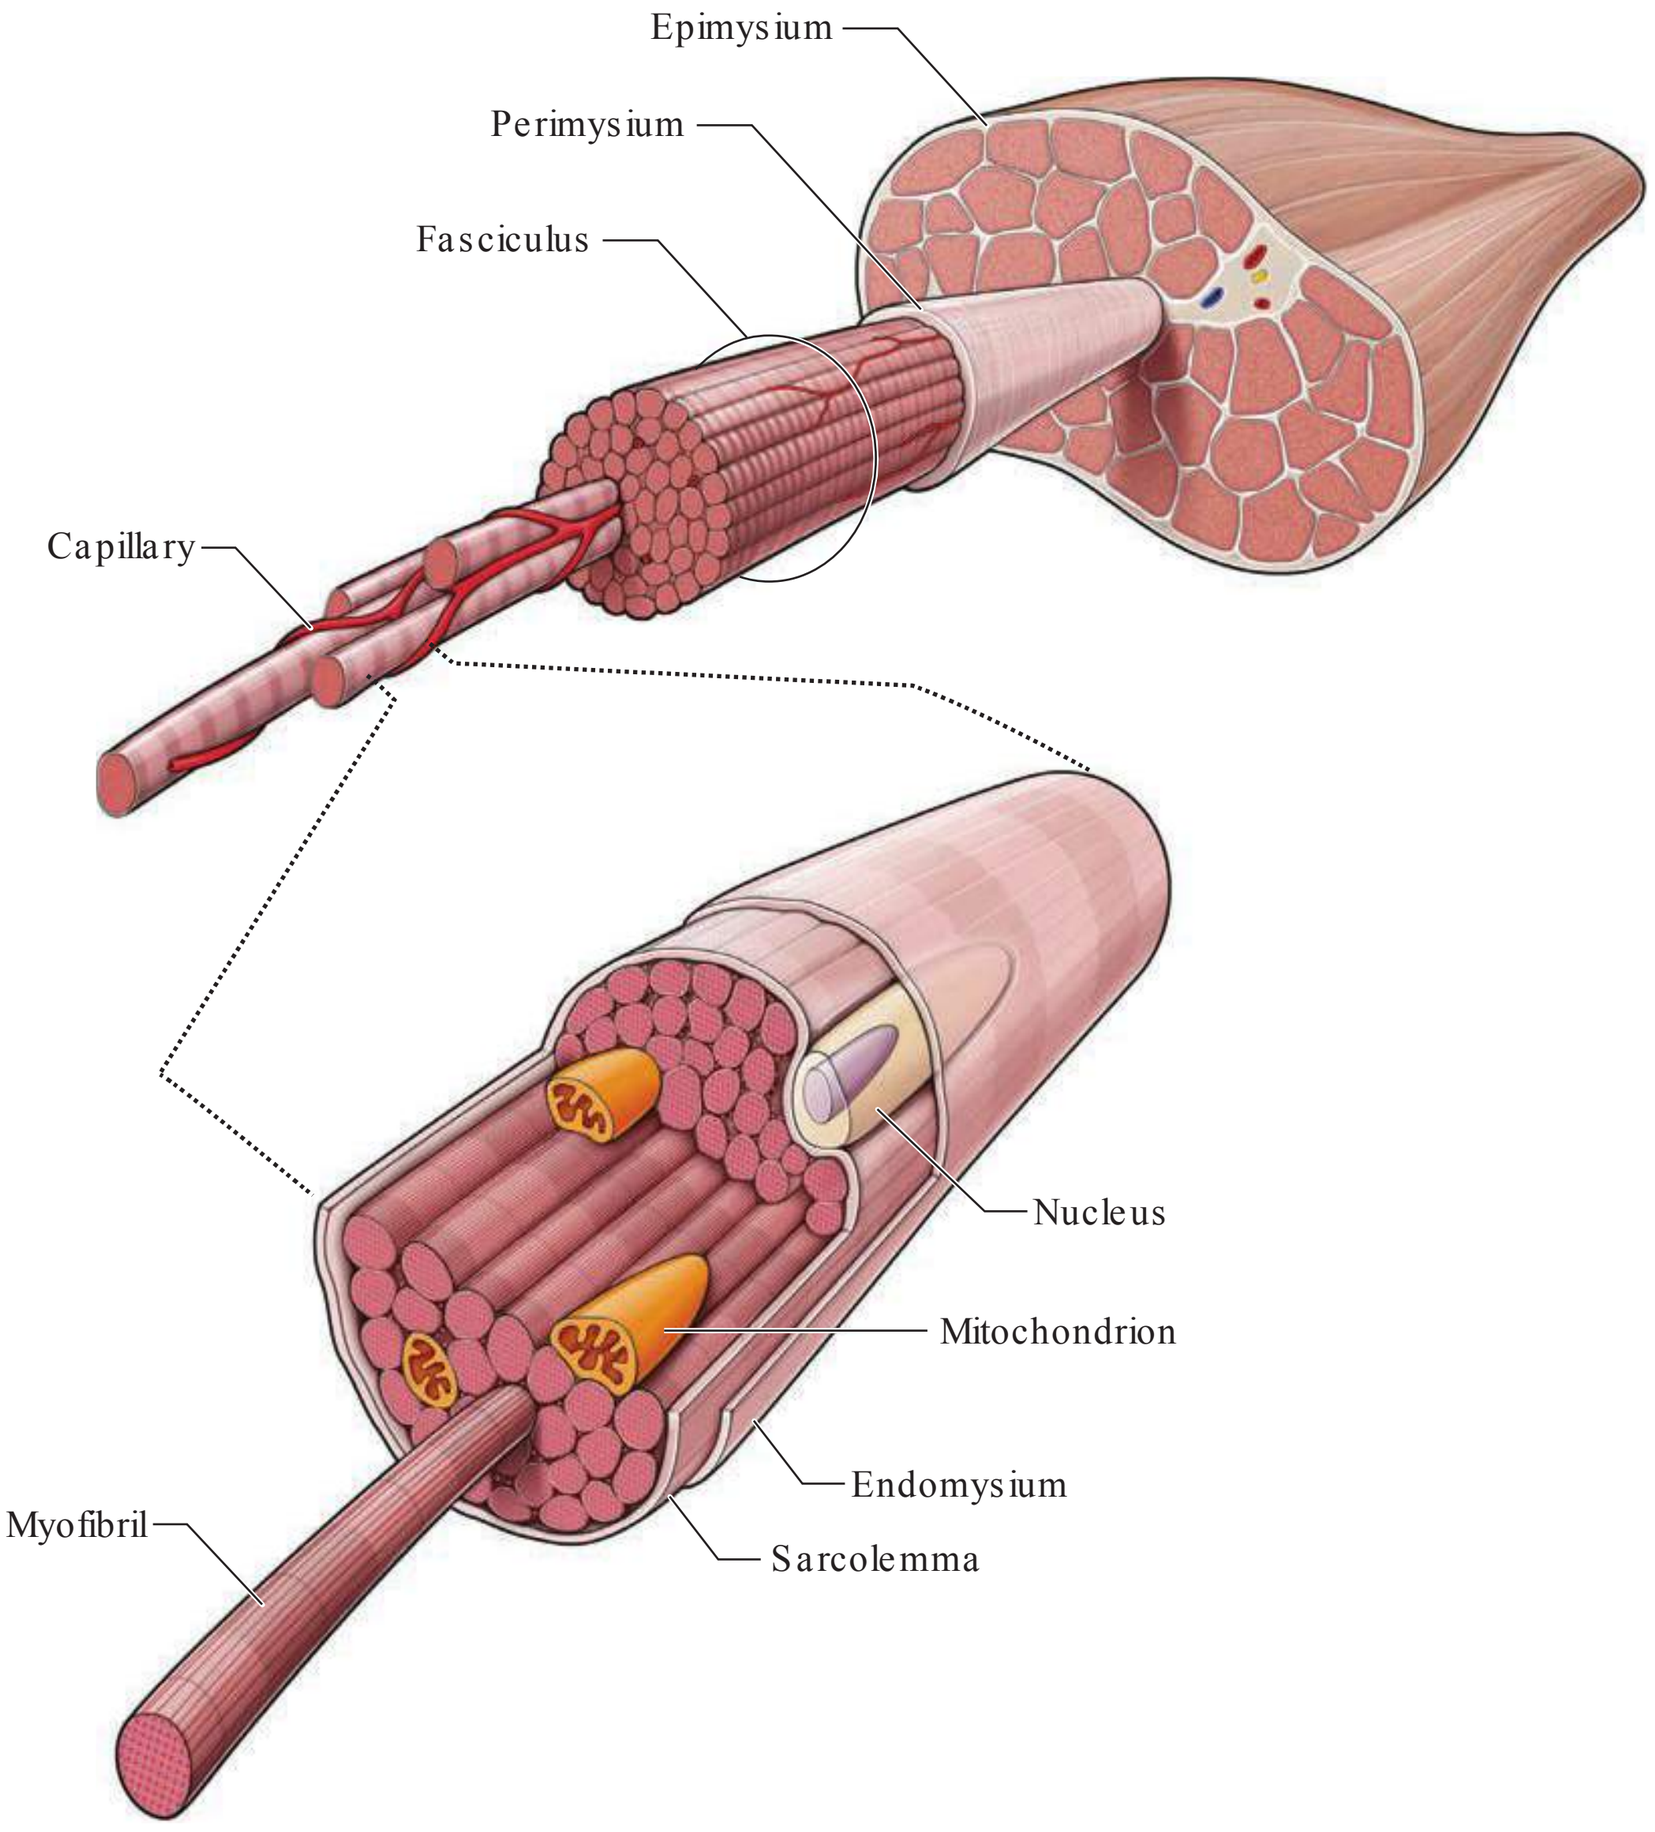

FIGURE 1-1 Microscopic structure of the muscle.

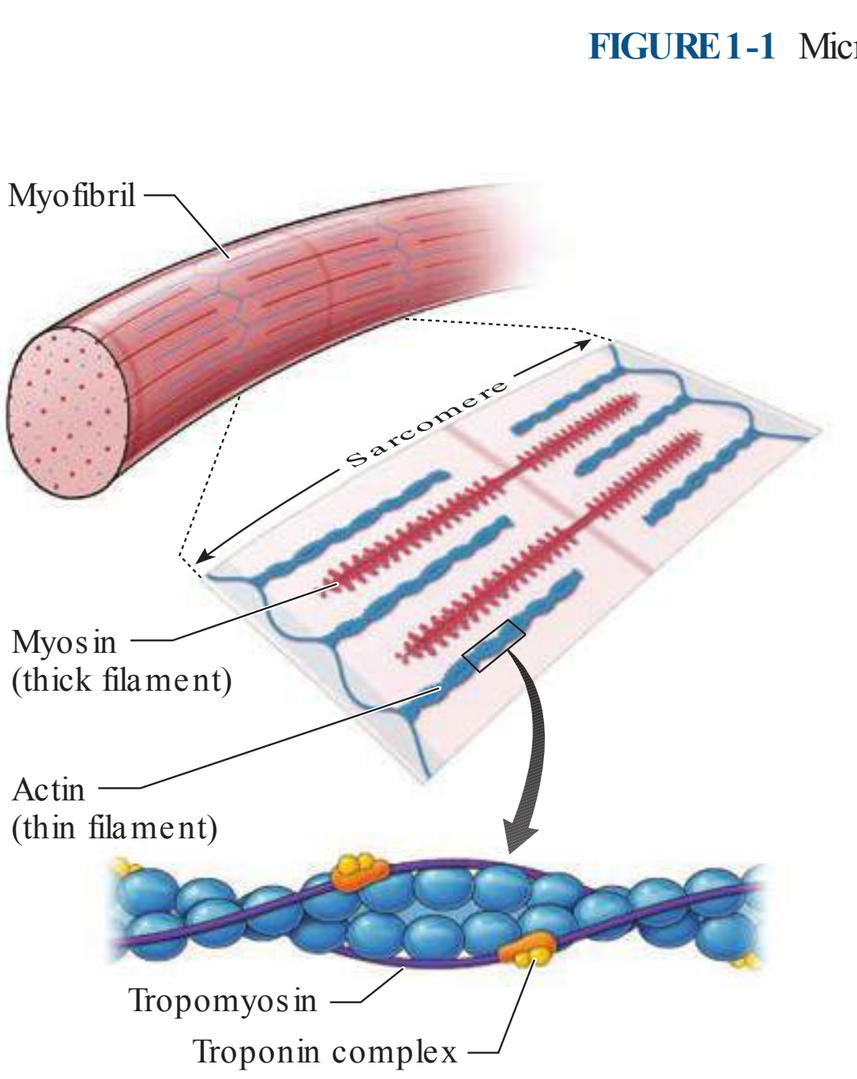

FIGURE 1-2 Troponin and tropomyosin action during a muscle contraction.

the I bands are composed of actin filaments. T e actin filaments of the I band overlap into the A band, giving the edges of the A band a darker appearance than the central region (H band), which contains only myosin. At the center of each I band is a thin, dark Z line. A sarcomere (Fig. 1-2) represents the distance between each Z line. Each muscle fiber is limited by a cell membrane called a sarcolemma (Fig. 1-1). T e protein dystrophin plays an essential role in the mechanical strength and stability of the sarcolemma.[41] Dystrophin is lacking in patients with Duchenne muscular dystrophy.

CLINICAL PEARL

The sarcoplasm is the specialized cytoplasm of a muscle cell that contains the usual subcellular elements along with the Golgi apparatus, abundant myofibrils, a modified endoplasmic reticulum known as the sarcoplasmic reticulum (SR), myoglobin, and mitochondria. Transverse tubules (T-tubules) invaginate the sarcolemma, allowing impulses to penetrate the cell and activate the SR.

The basic function of muscle is to contract. The word contraction, used to describe the generation of tension within muscle fibers, conjures up an image of shortening of muscle fibers during a resistance exercise. However, a contraction can produce shortening or lengthening of the muscle, or no change in the muscle length. Thus, three types of contraction are commonly recognized: isometric, concentric, and eccentric (see Chapter 12).

- Isometric contraction. Isometric exercises provide a static contraction with a variable and accommodating resistance without producing any appreciable change in muscle length.[42]
- Concentric contraction. A concentric contraction produces a shortening of the muscle. This occurs when the tension generated by the agonist muscle is sufficient to overcome an external resistance and to move the body segment of one attachment toward the segment of its other attachment.[42]
- Eccentric contraction. An eccentric contraction occurs when a muscle slowly lengthens as it gives in to an external force that is greater than the contractile force it is exerting.[42] In reality, the muscle does not lengthen, it merely returns from its shortened position to its normal resting length. Eccentric muscle contractions, which are capable of generating greater forces than either isometric or concentric contractions,[43–45] are involved in activities that require a deceleration to occur. Such activities include slowing to a stop when running, lowering an object, or sitting down. Because the load exceeds the bond between the actin and myosin filaments during an eccentric contraction, some of the myosin filaments probably are torn from the binding sites on the actin filament while the remainder are completing the contraction cycle.[46] The resulting force is substantially larger for a torn cross-bridge than for one being created during a normal cycle of muscle contraction. Consequently, the combined increase in force per cross-bridge and the number of active cross-bridges results in a maximum lengthening muscle tension that is greater than the tension that could be created during a shortening muscle action.[46,47]

CLINICAL PEARL

Both concentric and eccentric muscle action comprise the type of exercise called isotonic. An isotonic contraction is a contraction in which the tension within the muscle remains constant as the muscle shortens or lengthens.[42] This state is very difficult to produce and measure. Although the term isotonic is used in many texts to describe concentric and eccentric contractions alike, its use in this context is erroneous because in most exercise forms the muscle tension during exercise varies based upon the weight used, joint velocity, muscle length, and type of muscle contraction.[42]

Four other contractions are worth mentioning:

- Isokinetic contraction. An isokinetic contraction occurs when a muscle is maximally contracting at the same speed throughout the whole range of its related lever.[42] Isokinetic contractions require the use of special equipment that produces an accommodating resistance. Both high-speed/low-resistance and low-speed/high-resistance regimens result in excellent strength gains.[48–51] The major disadvantage of this type of exercise is its expense. Also, there is the potential for impact loading and incorrect joint axis alignment.[52] Isokinetic exercises may also have questionable functional carryover.[53]
- Econcentric contraction. This type of contraction combines both a controlled concentric and a simultaneous eccentric contraction of the same muscle over two separate joints.[54] Examples of an econcentric contraction include the standing hamstring curl, in which the hamstrings work concentrically to flex the knee while the hip tends to flex eccentrically, lengthening the hamstrings. When rising from a squat, the hamstrings work concentrically as the hip extends and work eccentrically as the knee extends. Conversely, the rectus femoris work eccentrically as the hip extends and work concentrically as the knee extends.
- Isolytic contraction. An isolytic contraction is an osteopathic term used to describe a type of eccentric contraction that makes use of a greater force than the patient can overcome. The difference between an eccentric contraction and an isolytic contraction is that, in the former, the contraction is voluntary whereas, in the latter, it is involuntary. The isolytic contraction can be used in certain manual techniques to stretch fibrotic tissue (see Chapter 10).

Structures called cross-bridges serve to connect the actin and myosin filaments. Increased synthesis of actin and myosin stimulates new myofibrils that are added to the external layers of the pre-existing myofibrils.[55] The myosin filaments contain two flexible, hinge-like regions, which allow the cross-bridges to attach and detach from the actin filament. During contraction, the cross-bridges attach and undergo power strokes, which provide the contractile force. During relaxation, the cross-bridges detach. This is attaching and detaching is asynchronous, so that some are attaching while others are detaching. Thus, at each moment, some of the cross-bridges are pulling, while others are releasing.

The regulation of cross-bridge attachment and detachment is a function of two proteins found in the actin filaments: tropomyosin and troponin (Fig. 1-2). Tropomyosin attaches directly to the actin filament, whereas troponin is attached to the tropomyosin rather than directly to the actin filament.

CLINICAL PEARL

Tropomyosin and troponin function as the switch for muscle contraction and relaxation. In a relaxed state, the tropomyosin physically blocks the cross-bridges from binding to the actin. For contraction to take place, the tropomyosin must be moved.

Each muscle fiber is innervated by a somatic motor neuron. One neuron and the muscle fibers it innervates constitute a motor unit or functional unit of the muscle. Each motor neuron branches as it enters the muscle to innervate a number of muscle fibers.

TABLE 1-3 Comparison of Muscle Fiber Types

Characteristics	Type I	Type II A	Type II B
Size (diameter)	Small	Intermediate	Very large
Resistance to fatigue	High	Fairly high	Low
Capillary density	High	High	Low
Glycogen content	Low	Intermediate	High
Twitch rate	Slow	Fast	Fast
Energy system	Aerobic	Aerobic	Anaerobic
Maximum muscle shortening velocity	Slow	Fast	Fast
Major storage fuel	Triglycerides	Creatine phosphate glycogen	Creatine phosphate glycogen

CLINICAL PEARL

The area of contact between a nerve and muscle fiber is known as the motor end plate, or neuromuscular junction (NMJ).

The release of a chemical acetylcholine from the axon terminals at the NMJ causes electrical activation of the skeletal muscle fibers. When an action potential propagates into the transverse tubule system (narrow membranous tunnels formed from and continuous with the sarcolemma), the voltage sensors on the transverse tubule membrane signal the release of Ca^{2+} from the terminal cisternae portion of the SR (a series of interconnected sacs and tubes that surround each myofibril).[56] The released Ca^{2+} then diffuses into the sarcomeres and binds to troponin, displacing the tropomyosin, and allowing the actin to bind with the myosin cross-bridges (Fig. 1-2). Whenever a somatic motor neuron is activated, all of the muscle fibers that it innervates are stimulated and contract with all-or-none twitches. Although the muscle fibers produce all-or-none contractions, muscles are capable of a wide variety of responses, ranging from activities requiring a high level of precision, to activities requiring high tension.

At the end of the contraction (the neural activity and action potentials cease), the SR actively accumulates Ca^{2+} and muscle relaxation occurs. The return of Ca^{2+} to the SR involves active transport, requiring the degradation of adenosine triphosphate (ATP) to adenosine diphosphate (ADP)*.[56] Because SR function is closely associated with both contraction and relaxation, changes in its ability to release or sequester Ca^{2+} markedly affect both the time course and magnitude of force output by the muscle fiber.[57]

CLINICAL PEARL

The SR forms a network around the myofibrils, storing and providing the Ca^{2+} that is required for muscle contraction.

*The most readily available energy for skeletal muscle cells is stored in the form of ATP and phosphocreatine (PCr). Through the activity of the enzyme ATPase, ATP promptly releases energy when required by the cell to perform any type of work, whether it is electrical, chemical, or mechanical.

On the basis of their contractile properties, two major types of muscle fiber have been recognized within skeletal muscle based on their resistance to fatigue: type I (tonic, slow-twitch fibers), and type II (phasic fast-twitch fibers). Type II muscle fibers are further divided into two additional classifications (Types IIA and IIB) (Table 1-3). Scott et al.[58] subdivide type II fibers into three classifications, including a type IIIC.

Type I fibers are richly endowed with mitochondria and have a high capacity for oxygen uptake. They are, therefore, suitable for activities of long duration or endurance (aerobic), including the maintenance of posture. In contrast, fast-twitch fibers, which generate a great amount of tension within a short period, are suited to quick, explosive actions (anaerobic), including such activities as sprinting. The type II (fast-twitch) fibers are separated based on mitochondria content into those that have a high complement of mitochondria (type IIA) and those that are mitochondria-poor (type IIB). This results in type IIB fibers having a tendency to fatigue more quickly than the type IIA fibers (Table 1-3).

CLINICAL PEARL

In fast-twitch fibers, the SR embraces every individual myofibril. In slow-twitch fibers, it may contain multiple myofibrils.[59]

Theory dictates that a muscle with a large percentage of the total cross-sectional area occupied by slow-twitch type I fibers should be more fatigue resistant than one in which the fast-twitch type II fibers predominate.

Different activities place differing demands on a muscle (Table 1-4).[59] For example, dynamic movement activities involve a predominance of fast-twitch fiber recruitment, whereas postural activities and those activities requiring stabilization entail more involvement of the slow-twitch fibers. In humans, most limb muscles contain a relatively equal distribution of each muscle fiber type, whereas the back and trunk demonstrate a predominance of slow-twitch fibers. Although it would seem possible that physical training may cause fibers to convert from slow twitch to fast twitch or the reverse, this has not been shown to be the case.[60] However, fiber conversion from type IIB to type IIA, and vice versa, has been found to occur with training.[61]

TABLE 1-4 Functional Division of Muscle Groups	
Movement Group	**Stabilization Group**
Primarily type IIa	Primarily type I
Prone to adaptive shortening	Prone to develop weakness
Prone to develop hypertonicity	Prone to muscle inhibition
Dominate in fatigue and new movement situations	Fatigue easily
Generally cross two joints	Primarily cross one joint
Examples	Examples
Gastrocnemius/Soleus	Fibularis (peronei)
Tibialis posterior	Tibialis anterior
Short hip adductors	Vastus medialis and lateralis
Hamstrings	Gluteus maximus, medius, and minimus
Rectus femoris	Serratus anterior
Tensor fascia lata	Rhomboids
Erector spinae	Lower portion of trapezius
Quadratus lumborum	Short/deep cervical flexors
Pectoralis major	Upper limb extensors
Upper portion of trapezius	Rectus abdominis
Levator scapulae	
Sternocleidomastoid	
Scalenes	
Upper limb flexors	

Data from Jull GA, Janda V. Muscle and motor control in low back pain. In: Twomey LT, Taylor JR, eds. Physical Therapy of the Low Back: Clinics in Physical Therapy. New York, NY: Churchill Livingstone; 1987:258–278.

The effectiveness of muscle to produce movement depends on some factors. These include the location and orientation of the muscle attachment relative to the joint, the limitations or laxity present in the musculotendinous unit, the type of contraction, the point of application, and the actions of other muscles that cross the joint.[2]

CLINICAL PEARL

Following the stimulation of muscle, a brief period elapses before a muscle begins to develop tension. The length of this period, the electromechanical delay (EMD), varies considerably among muscles. Fast-twitch fibers have shorter periods of EMD when compared with slow-twitch fibers.[62] EMD is affected by muscle fatigue, muscle length, muscle training, passive muscle stretching, and the type of muscle activation.[63] A tissue injury may increase the EMD and, therefore, increases the susceptibility to future injury if full healing does not occur.[64] One of the purposes of neuromuscular re-education (see Chapter 14) is to return the EMD to a normal level.[65]

Muscles serve a variety of roles depending on the required movement:

- Prime mover (agonist). This is a muscle that is directly responsible for producing a desired movement.
- Antagonist. This is a muscle that has an effect directly opposite to that of the agonist.
- Synergist (supporter). This is a muscle that performs a cooperative muscle function relative to the agonist. Synergists can function as stabilizers or neutralizers.
  - Stabilizers (fixators). Muscles that contract statically to steady or support some part of the body against the pull of the contracting muscles, against the pull of gravity, or against the effect of momentum and recoil in certain vigorous movements.
  - Neutralizers. Muscles that act to prevent an undesired action from one of the movers.

As previously mentioned, depending on the type of muscular contraction, the length of a muscle can remain the same (isometric), shorten (concentric), or "lengthen" (eccentric). The velocity at which muscle contracts significantly affects the tension that the muscle produces and subsequently affects a muscle's strength and power.[66]

- Concentric contractions. As the speed of a concentric contraction increases, the force it is capable of producing decreases.[43,45] The slower speed of contraction is thought to produce greater forces than can be produced by increasing the number of cross-bridges formed. This is relationship is a continuum, with the optimum velocity for the muscle somewhere between the slowest and fastest rates. At very slow speeds, the force that a muscle can resist or overcome rises rapidly up to 50% greater than the maximum isometric contraction.[43,45]
- Eccentric contractions. During a maximum-effort eccentric contraction, as the velocity of active muscle lengthening increases, force production in the muscle initially increases to a point, but then quickly levels off.[67–69] The following changes in force production occur during an eccentric contraction:
  - Rapid eccentric contractions generate more force than do slower eccentric contractions.
  - During slow eccentric muscle actions, the work produced approximates that of an isometric contraction.[43,45]

CLINICAL PEARL

The number of cross-bridges that can be formed is dependent on the extent of the overlap between the actin and myosin filaments.[70] Thus, the force a muscle is capable of exerting depends on its length. For each muscle cell, there is an optimum length, or range of lengths, at which the contractile force is strongest. At the optimum length of the muscle, there is a near-optimal overlap of actin and

myosin, allowing for the generation of maximum tension at this length.

- If the muscle is in a shortened position, the overlap of actin and myosin reduces the number of sites available for the cross-bridge formation. Active insufficiency of a muscle occurs when the muscle is incapable of shortening to the extent required to produce a full range of motion (ROM) at all joints crossed simultaneously.[2,54,71,72] For example, the finger flexors cannot produce a closed fist when the wrist is fully flexed, as they can when it is in neutral position.
- If the muscle is in a lengthened position compared with its optimum length, the actin filaments are pulled away from the myosin heads such that they cannot create as many cross-bridges.[46] Passive insufficiency of the muscle occurs when the two-joint muscle cannot stretch to the extent required for full ROM in the opposite direction at all joints crossed.[2,54,71,72] For example, when an individual attempts to make a closed fist with the wrist fully flexed, the active shortening of the finger and wrist flexors results in passive lengthening of the finger extensors. In this example, the length of the finger extensors is insufficient to allow full ROM at both the wrist and the fingers.[73]

The force and speed of a muscle contraction depend on the requirements of the activity, which in turn, are dependent on the ability of the central nervous system to control the recruitment of motor units.[2] The motor units of slow-twitch fibers have lower thresholds and are easier to activate than those of the fast-twitch motor units. Consequently, the slow-twitch fibers are recruited first, even when the resulting limb movement is rapid.[74]

As the force requirement, speed requirement, or duration of activity increases, motor units with higher thresholds are recruited. Type IIa units are recruited before type IIb.[75]

CLINICAL PEARL

The term temporal summation refers to the summation of individual contractile units. The summation can increase the muscular force by increasing the muscle activation frequency.[76]

Although each muscle contains the contractile machinery to produce the forces for movement, it is the tendon that transmits these forces to the bones to achieve movement or stability of the body in space.[9] The angle of insertion the tendon makes with a bone determines the line of pull, whereas the tension generated by a muscle is a function of its angle of insertion. A muscle generates the greatest amount of torque when its line of pull is oriented at a 90-degree angle to the bone, and it is attached anatomically as far from the joint center as possible.[2]

Just as there are optimal speeds of length change and optimal muscle lengths, there are optimal insertion angles for each of the muscles. The angle of insertion of a muscle, and, therefore, its line of pull, can change during dynamic movements.[46]

The angle *of* pennation is the angle created between the fiber direction and the line of pull. When the fibers of a muscle lie parallel to the long axis of the muscle, there is no angle of pennation. The number of fibers within a fixed volume of a muscle increases with the angle of pennation.[46] Although pennation can enhance the maximum tension, the range of shortening of the muscle is reduced. Muscle fibers can contract to about 60% of their resting length. Since the muscle fibers in pennate muscles are shorter than the no-pennate equivalent, the amount of contraction is similarly reduced. Muscles that need to have large changes in length without the need for very high tension, such as the sartorius muscle, do not have pennate muscle fibers.[46] In contrast, pennate muscle fibers are found in those muscles in which the emphasis is on a high capacity for tension generation rather than ROM (e.g., gluteus maximus).

CLINICAL PEARL

Skeletal muscle blood flow increases 20-fold during muscle contractions.[77] The muscle blood flow increases in proportion to the metabolic demands of the tissue, a relationship reflected by positive correlations between muscle blood flow and exercise. As body temperature elevates, the speeds of nerve and muscle functions increase, resulting in a higher value of maximum isometric tension and a higher maximum velocity of shortening possible with fewer motor units at any given load.[78] Muscle function is most efficient at 38.5°C (101°F).[79]

During physical exercise, energy turnover in skeletal muscle may increase by 400 times compared with muscle at rest and muscle oxygen consumption may increase by more than 100 times.[80] The hydrolysis of ATP to ADP and inorganic phosphate (P_i) provides the power for muscular activity. Despite the large fluctuations in energy demand just mentioned, muscle ATP remains practically constant and demonstrates a remarkable precision of the system in adjusting the rate of the ATP-generating processes to the demand.[81] There are three energy systems that contribute to the resynthesis of ATP via ADP rephosphorylation. These energy systems are as follows:

- Phosphagen system. The phosphagen, or ATP-PCr, system is an anaerobic process—it can proceed without oxygen (O_2). The skeletal muscle cell stores the phosphocreatine (PCr) and ADP, of which PCr is the chemical fuel source. At the onset of muscular contraction, PCr represents the most immediate reserve for the rephosphorylation of ATP. The phosphagen system provides ATP primarily for short-term, high-intensity activities (i.e., sprinting), and is the major source of energy during the first 30 seconds of intense exercise, but it is also active at the start of all exercises, regardless of intensity.[82] Once a muscle returns to rest, the supply of ATP-PCr is replenished. While the maximum power of this system is great, one disadvantage of the phosphagen system is that because of its significant contribution to the energy yield at the onset of near-maximal exercise, the concentration of PCr can be reduced to less than 40% of resting levels within 10 seconds of the start of intense

exercise, which translates into a small maximum capacity of the system.[83]

- **Glycolytic system.** The glycolytic system is an anaerobic process that involves the breakdown of carbohydrates—either glycogen stored in the muscle or glucose delivered through the blood—into pyruvate to produce ATP in a process called glycolysis. Pyruvate is then transformed into lactic acid as a byproduct of the anaerobic glycolysis. Because this system relies on a series of nine different chemical reactions, it is slower to become fully active. However, glycogenolysis has a greater capacity to provide energy than does PCr, and therefore it supplements PCr during maximal exercise and continues to rephosphorylate ADP during maximal exercise after PCr reserves have become essentially depleted.[82] The process of glycolysis can be in one of the two ways, termed *f*ast glycolysis and slow glycolysis, depending on the energy demands within the cell. If energy must be supplied at a high rate, fast glycolysis is used primarily. If the energy demand is not so high, slow glycolysis is activated. The main disadvantage of the fast glycolysis system is that during very high-intensity exercise, hydrogen ions dissociate from the glycogenolytic end product of lactic acid.[81] The accumulation of lactic acid in the contracting muscle is recognized in sports and resistance training circles. An increase in hydrogen ion concentration is believed to inhibit glycolytic reactions and directly interfere with muscle excitation–contraction and coupling, which can potentially impair contractile force during an exercise.[82] This inhibition occurs once the muscle pH drops below a certain level, prompting the appearance of phosphofructokinase (PFK), resulting in local energy production ceasing until replenished by oxygen stores.

CLINICAL PEARL

Lactic acid is the major energy source for providing the muscle with ATP during exercise bouts that last 1–3 minutes (e.g., running 400–800 m).

- **Oxidative system.** As its name suggests, the oxidative system requires O_2 and is consequently termed the "aerobic" system. The fuel sources for this system are glycogen, fats, and proteins. This system is the primary source of ATP at rest and during low-intensity activities. The ATP is resynthesized in the mitochondria of the muscle cell such that the ability to metabolize oxygen and other substrates is related to the number and concentration of the mitochondria and cells. It is worth noting that at no time during either rest or exercise does any single energy system provide the complete supply of energy. While being unable to produce ATP at an equivalent rate to that produced by PCr breakdown and glycogenolysis, the oxidative system is capable of sustaining low-intensity exercise for several hours.[82] However, because of increased complexity, the time between the onset of exercise and when this system is operating at its full potential is around 45 seconds.[84]

The relative contribution of these energy systems to ATP resynthesis has been shown to depend upon the intensity and duration of exercise, with the primary system used being based on the duration of the event:[85]

- 0–10 seconds: ATP–PCr. These bursts of activity develop muscle strength and stronger tendons and ligaments, with the ATP being supplied by the phosphagen system.
- 10–30 seconds: ATP–PCr plus anaerobic glycolysis.
- 30 seconds to 2 minutes: anaerobic glycolysis. These longer bursts of activity, if repeated after 4 minutes of rest or mild exercise, enhance anaerobic power with the ATP being supplied by the phosphagen and anaerobic glycolytic system.
- 2–3 minutes: anaerobic glycolysis plus oxidative system.
- > 3 minutes and rest: oxidative system. These periods of activity using less than maximum intensity may develop aerobic power and endurance capabilities, and the phosphogen, anaerobic glycotic, and anaerobic systems supply the ATP.

Respiratory Muscles

Although the respiratory muscles share some mechanical similarities with skeletal muscles, they are distinct from skeletal muscles in several aspects as follows:[86,87]

- Whereas skeletal muscles of the limbs overcome inertial loads, the respiratory muscles overcome primarily elastic and resistive loads.
- The respiratory muscles are under both voluntary and involuntary control.
- The respiratory muscles are similar to the heart muscles, in that they have to contract rhythmically and generate the required forces for ventilation throughout the entire lifespan of the individual. The respiratory muscles, however, do not contain pacemaker cells and are under the control of mechanical and chemical stimuli, requiring neural input from higher centers to initiate and coordinate contraction.
- The resting length of the respiratory muscles is a relationship between the inward recoil forces of the lung and the outward recoil forces of the chest wall. Changes in the balance of recoil forces will result in changes in the resting length of the respiratory muscles. Thus, simple and everyday life occurrences such as changes in posture may alter the operational length and the contractile strength of the respiratory muscles.[88] If uncompensated, these length changes can lead to decreases in the output of the muscles, and hence, a reduction in the ability to generate lung volume changes.[88] The skeletal muscles of the limbs, on the other hand, are not constrained to operate at a particular resting length.

CLINICAL PEARL

The primary respiratory muscles of the body include the diaphragm; the internal, external, and transverse intercostals; the levator costae; and the serratus posterior inferior and superior.

JOINTS

Arthrology is the study of the classification, structure, and function of articulations (joints or arthroses). A joint represents the junction between two or more bones. Joints are regions where bones are capped and surrounded by CTs that hold the bones together and determine the type and degree of movement between them.[89] An understanding of the anatomy and biomechanics of the various joints is required to be able to assess and treat a patient thoroughly. When classified according to movement potential, joints may be classified into two broad categories synarthrosis (nonsynovial) or diarthrosis (synovial).

Synarthrosis

T e type of tissue uniting the bone surfaces determines the major types of synarthroses:[89]

- Fibrous joints, which are joined by dense fibrous CT. T ree types exist:
  - Suture (e.g., suture of the skull).
  - Gomphosis (e.g., tooth and mandible or maxilla articulation).
  - Syndesmosis (e.g., tibiofibular or radioulnar joints). T ese joints usually allow a small amount of motion.
- Cartilaginous joints originally referred to as amphiarthrosis joints, are stable joints that allow for minimal or little movement. T ese joints exist in humans in one of two ways: synchondrosis (e.g., manubriosternal joints) and symphysis (e.g., symphysis pubis). A synchondrosis is a joint in which the material used to connect the two components is hyaline cartilage.[90] In a symphysis joint, the two bony components are covered with a thin lamina of hyaline cartilage and directly joined by fibrocartilage in the form of disks or pads.[90]

Diarthrosis

T is joint unites long bones and permits free bone movement and greater mobility. A fibroelastic joint capsule, which characterizes these joints, is filled with a lubricating substance called synovial *fl*uid. Consequently, these joints are often referred to as synovial joints.

Examples include, but are not limited to, the hip, knee and shoulder, and elbow joints. Synovial joints are further classified based on complexity:

- Simple (uniaxial): a single pair of articular surfaces one male, or convex, surface and one female, or concave, surface. Examples include hinge joint and trochoid (pivot) joints.
- Compound (biaxial): a single joint capsule that contains more than a single pair of mating articulating surfaces. T e two types of biaxial joint in the body include the condyloid and saddle.
- Complex (triaxial or multiaxial): contain an intra-articular inclusion within the joint class such as a meniscus or disk that increases the number of joint surfaces. T e two types of joint in this category are plane joints and ball-and-socket joints.

Synovial joints have five distinguishing characteristics: a joint cavity that is enclosed by the joint capsule, hyaline articular cartilage that covers the surfaces of the enclosed contiguous bones, synovial fluid that forms a film over the joint surfaces, synovial membrane that lines the inner surface of the capsule, and a joint capsule that is composed of two layers.[90] All synovial joints of the body are provided with an array of corpuscular (mechanoreceptors) and noncorpuscular (nociceptors) receptor endings embedded in articular, muscular, and cutaneous structures with varying characteristic behaviors and distributions depending on the articular tissue (see Chapter 3). One intra-articular structure worth mentioning is the articular disk or meniscus. A meniscus, which consists of a dense ECM, is not covered by a synovial membrane and occurs between articular surfaces where congruity is low. T e cells of the meniscus are referred to as fibrochondrocytes because they appear to be a mixture of fibroblasts and chondrocytes.[91] A meniscal disk may extend across a synovial joint, dividing it structurally and functionally into two synovial cavities. Complete disks occur in the sternoclavicular and distal radioulnar joints, while that in the temporomandibular joint may be complete or incomplete.[13] Peripherally disks are connected to fibrous capsules, usually by vascularized connective tissue, so that they become invaded by vessels and afferent and motor nerves.[13] Mechanoreceptors within the menisci function as transducers, converting the physical stimulus of tension and compression into a specific electrical nerve impulse (see Chapter 3).[92]

Synovial joints can be broadly classified according to structure or analogy (Fig. 1-3) into the following categories[93]:

- Spheroid. As the name suggests, a spheroid joint is a freely moving joint in which a sphere on the head of one bone fits into a rounded cavity in the other bone. Spheroid (ball-and-socket) joints allow motions in three planes (Fig. 1-3) (see later). Examples of a spheroid joint surface include the heads of the femur and humerus.
- Trochoid. T e trochoid, or pivot, joint is characterized by a pivot-like process turning within a ring, or a ring on a pivot, the ring being formed partly of bone, partly of ligament (Fig. 1-3). Trochoid joints permit only rotation. Examples of a trochoid joint include the humeroradial joint and the atlantoaxial joint.
- Condyloid (ovoid). T is joint is characterized by an ovoid articular surface, or condyle (Fig. 1-3). One bone may articulate with another by one surface or by two, but never more than two. If two distinct surfaces are present, the joint is called condylar, or bicondylar. T e elliptical cavity of the joint is designed in such a manner as to permit the motions of flexion, extension, adduction, abduction, and circumduction, but no axial rotation. T e wrist joint is an example of this form of articulation.
- Ginglymoid. A ginglymoid joint is a hinge joint (Fig. 1-3). It is characterized by a spool-like surface and a concave surface. An example of a ginglymoid joint is the humeroulnar joint.
- Ellipsoid. Ellipsoid joints are similar to spheroid joints in that they allow the same type of movement albeit to a lesser magnitude. T e ellipsoid joint allows movement in two planes (flexion, extension; abduction, adduction)

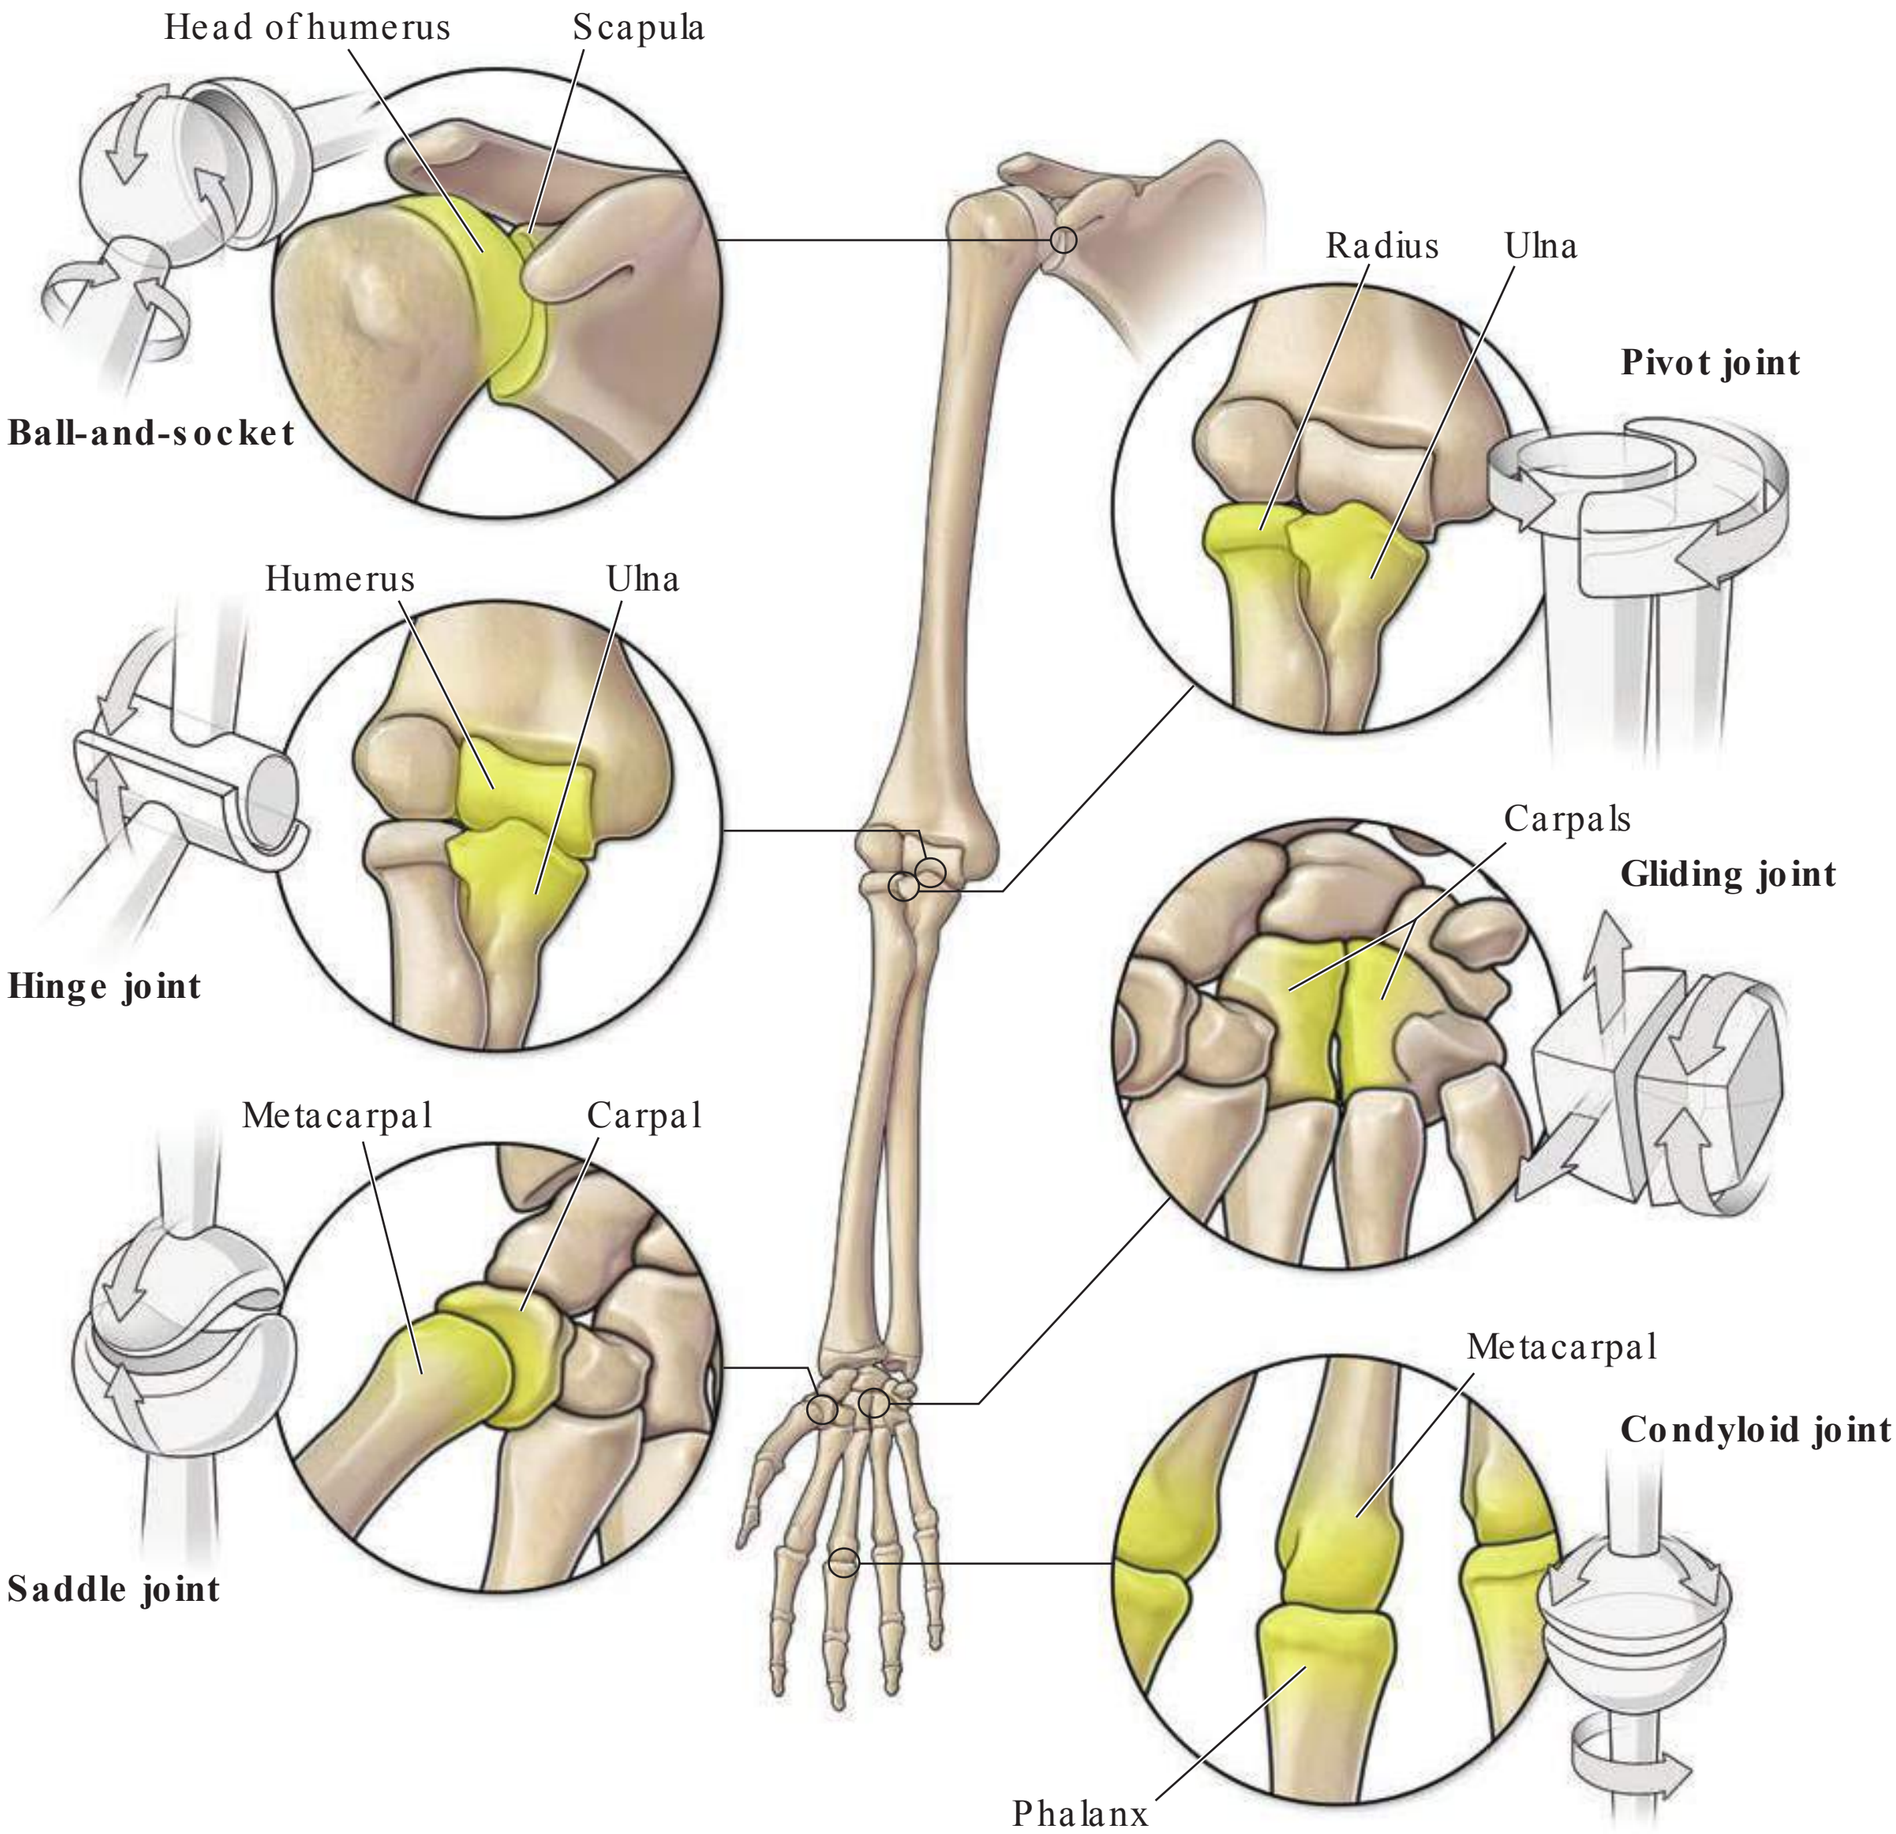

FIGURE 1-3 Types of diarthrosis or synovial joints.

and is biaxial. Examples of this joint can be found at the radiocarpal articulation at the wrist and the metacarpophalangeal articulation with the phalanges.

- Planar. As its name suggests, a planar joint is characterized by flat surfaces that slide over each other. Movement at this joint does not occur about an axis and is termed nonaxial. Examples of a planar joint include the intermetatarsal joints and some intercarpal joints.
- Saddle (sellar). Saddle joints are characterized by a convex surface in one cross-sectional plane and a concave surface in the plane perpendicular to it (Fig. 1-3). Examples of a saddle joint include the interphalangeal joints, the carpometacarpal joint of the thumb, the humeroulnar joint, and the calcaneocuboid joints.

In reality, no joint surface is planar or resembles a true geometric form; that is they resemble either the outer or inner surface of a piece of eggshell.[94]

Synovial Fluid

Articular cartilage is subject to a great variation of loading conditions, so joint lubrication through the synovial fluid is necessary to minimize frictional resistance between the weight-bearing surfaces. Fortunately, synovial joints are blessed with a very superior lubricating system, which permits a remarkably frictionless interaction at the joint surfaces. A cartilaginous lubricated interface has a coef cient of friction* of 0.002.[95] By way of comparison, ice on ice has a higher coef cient of friction (0.03).[95] T e composition of synovial fluid is nearly the same as blood plasma, but with a decreased total protein content and a higher concentration of hyaluronan.[96]

*Coef cient of friction is a ratio of the force needed to make a body glide across a surface compared with the weight or force holding the two surfaces in contact.

CLINICAL PEARL

Hyaluronan is a critical constituent component of normal synovial fluid and an important contributor to joint homeostasis.[97] Hyaluronan imparts anti-inflammatory and anti-nociceptive properties to normal synovial fluid and contributes to joint lubrication. It also is responsible for the viscoelastic properties of synovial fluid,[96] and contributes to the lubrication of articular cartilage surfaces.

Indeed, synovial fluid is essentially a dialysate of plasma to which hyaluronan has been added.[98] Hyaluronan is a GAG that is continually synthesized and released into the synovial fluid by specialized synoviocytes.[98,99] The mechanical properties of synovial fluid permit it to act as both a cushion and a lubricant to the joint. Diseases such as osteoarthritis, affect the thixotropic properties (thixotropy is the property of various gels becoming fluid when disturbed, as by shaking) of synovial fluid, resulting in reduced lubrication and subsequent wear of the articular cartilage and joint surfaces.[100,101] It is well established that damaged articular cartilage in adults has a very limited potential for healing (see Chapter 2) because it possesses neither a blood supply nor lymphatic drainage.[102]

Bursae

Closely associated with some synovial joints are flattened, saclike structures called bursae that are lined with a synovial membrane and filled with synovial fluid. The bursa produces small amounts of fluid, allowing for smooth and almost frictionless motion between contiguous muscles, tendons, bones, ligaments, and skin.[103–105] A tendon sheath is a modified bursa. A bursa can be a source of pain if it becomes inflamed or infected.

KINESIOLOGY

When describing movements, it is necessary to have a starting position as the reference position. This starting position is referred to as the anatomic reference position. The anatomic reference position for the human body is described as the erect standing position with the feet just slightly separated and the arms hanging by the side, the elbows straight, and the palms of the hand facing forward (Fig. 1-4).

Directional Terms

Directional terms are used to describe the relationship of body parts or the location of an external object with respect to the body.[106] The following are commonly used directional terms:

- Superior or cranial. Closer to the head.
- Inferior or caudal. Closer to the feet.
- Anterior or ventral. Toward the front of the body.
- Posterior or dorsal. Toward the back of the body.
- Medial. Toward the midline of the body.
- Lateral. Away from the midline of the body.

FIGURE 1-4 The anatomical position.

- Proximal. Closer to the trunk.
- Distal. Away from the trunk.
- Superficial. Toward the surface of the body.
- Deep. Away from the surface of the body in the direction of the inside of the body.

MOVEMENTS OF THE BODY SEGMENTS

In general, there are two types of motions: translation, which occurs in either a straight or curved line, and rotation, which involves a circular motion around a pivot point. Movements of the body segments occur in three dimensions along imaginary planes and around various axes of the body.

Planes of the Body

There are three traditional planes of the body corresponding to the three dimensions of space: sagittal, frontal, and transverse (Fig. 1-5).

- Sagittal. The sagittal plane, also known as the anterior–posterior or median plane, divides the body vertically into left and right halves of equal size.
- Frontal. The frontal plane, also known as the lateral or coronal plane, divides the body equally into front and back halves.
- Transverse. The transverse plane, also known as the horizontal plane, divides the body equally into top and bottom halves.

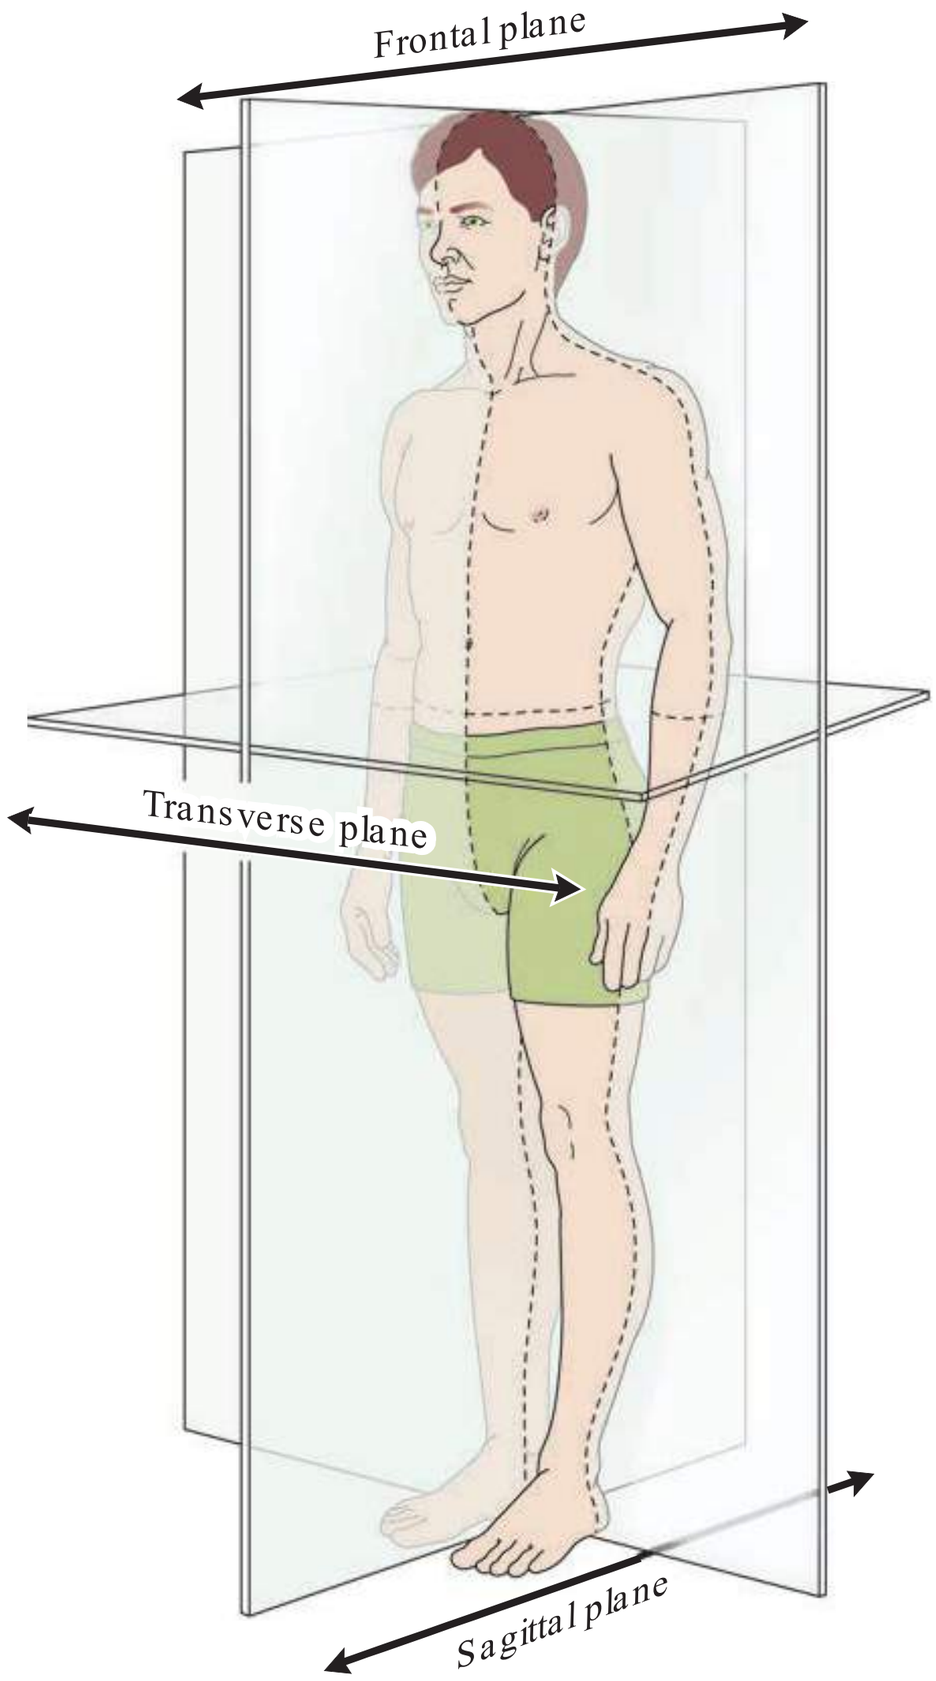

FIGURE 1-5 Planes of the body.

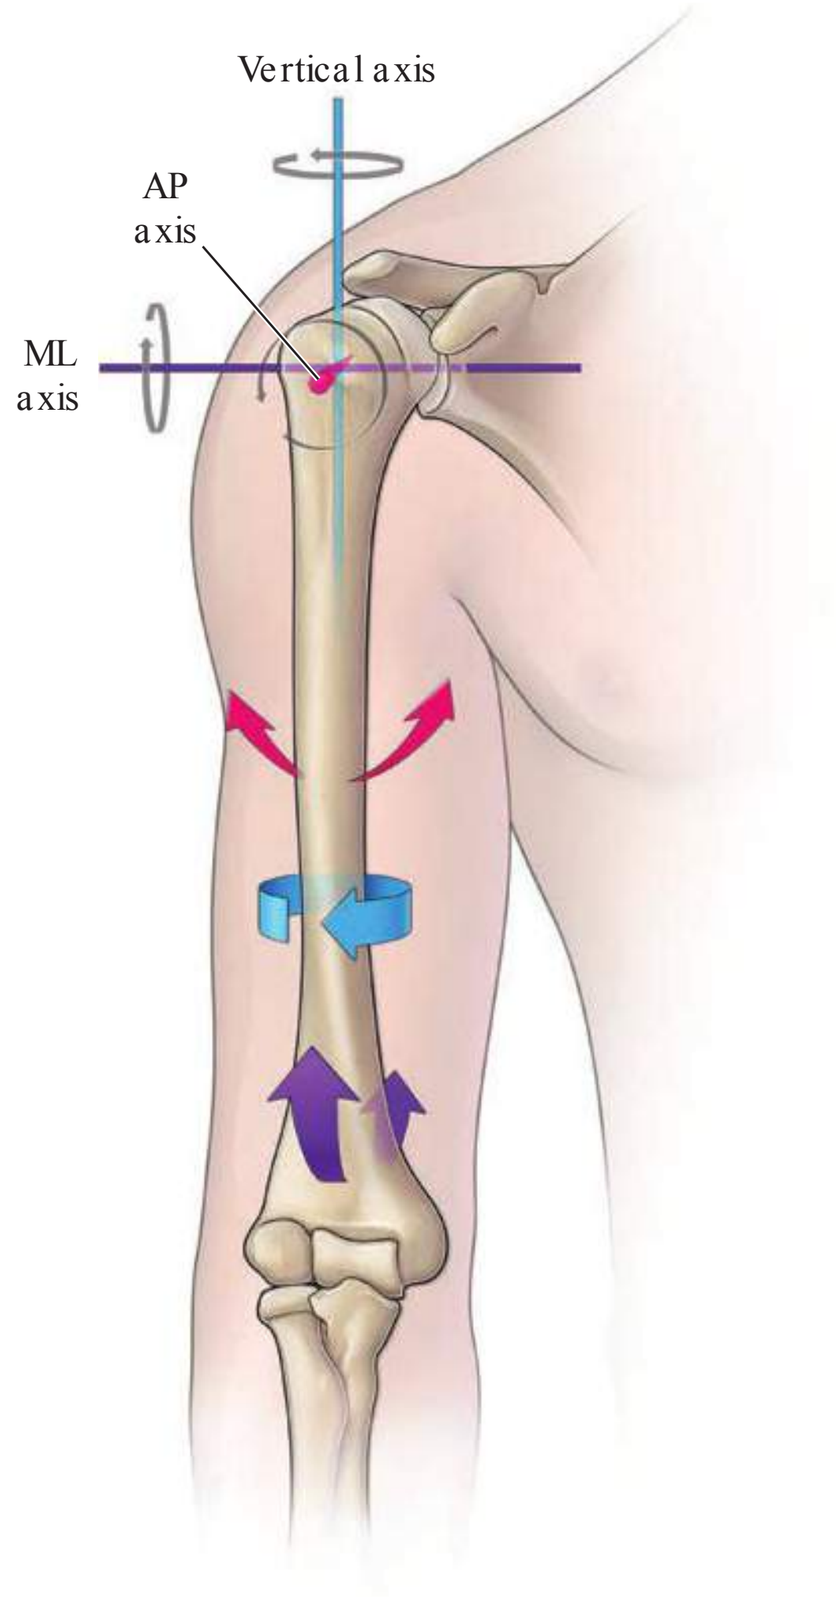

FIGURE 1-6 Axes of the body.

Because each of these planes bisects the body, it follows that each plane must pass through the center of gravity (COG) or center of mass (COM).* Where a gravity field can be considered to be uniform, the COG and COM are the same (see later). If the movement described occurs in a plane that passes through the center of gravity, that movement is deemed to have occurred in a cardinal plane. An arc *of* motion represents the total number of degrees traced between the two extreme positions of movement in a specific plane of motion.[107] If a joint has more than one plane of motion, each type of motion is referred to as a unit *of* motion. For example, the wrist has two units of motion: flexion–extension (anterior–posterior plane) and ulnar–radial deviation (lateral plane).[107]

Few movements involved with functional activities occur in the cardinal planes. Instead, most movements occur in an infinite number of vertical and horizontal planes parallel to the cardinal planes (see the discussion that follows).

Axes of the Body

Three reference axes are used to describe human motion (Fig. 1-6). The axis around which the movement takes place is always perpendicular to the plane in which it occurs.

- **Mediolateral.** The mediolateral (ML) or coronal, axis, is perpendicular to the sagittal plane.
- **Vertical.** The vertical or longitudinal axis is perpendicular to the frontal plane.
- **Anteroposterior (AP).** The AP axis is perpendicular to the transverse plane.

Most movements occur in planes and around axes that are somewhere in between the traditional planes and axes. Thus, nominal identification of every plane and axis of movement is impractical. The structure of the joint determines the possible axes of motion that are available. The axis of rotation remains stationary only if the convex member of a joint is a perfect sphere and articulates with a perfect reciprocally shaped

*The COG, or COM, may be defined as the point at which the three planes of the body intersect each other. The line of gravity is defined as the vertical line at which the two vertical planes intersect each other and is always vertically downward toward the center of the earth.

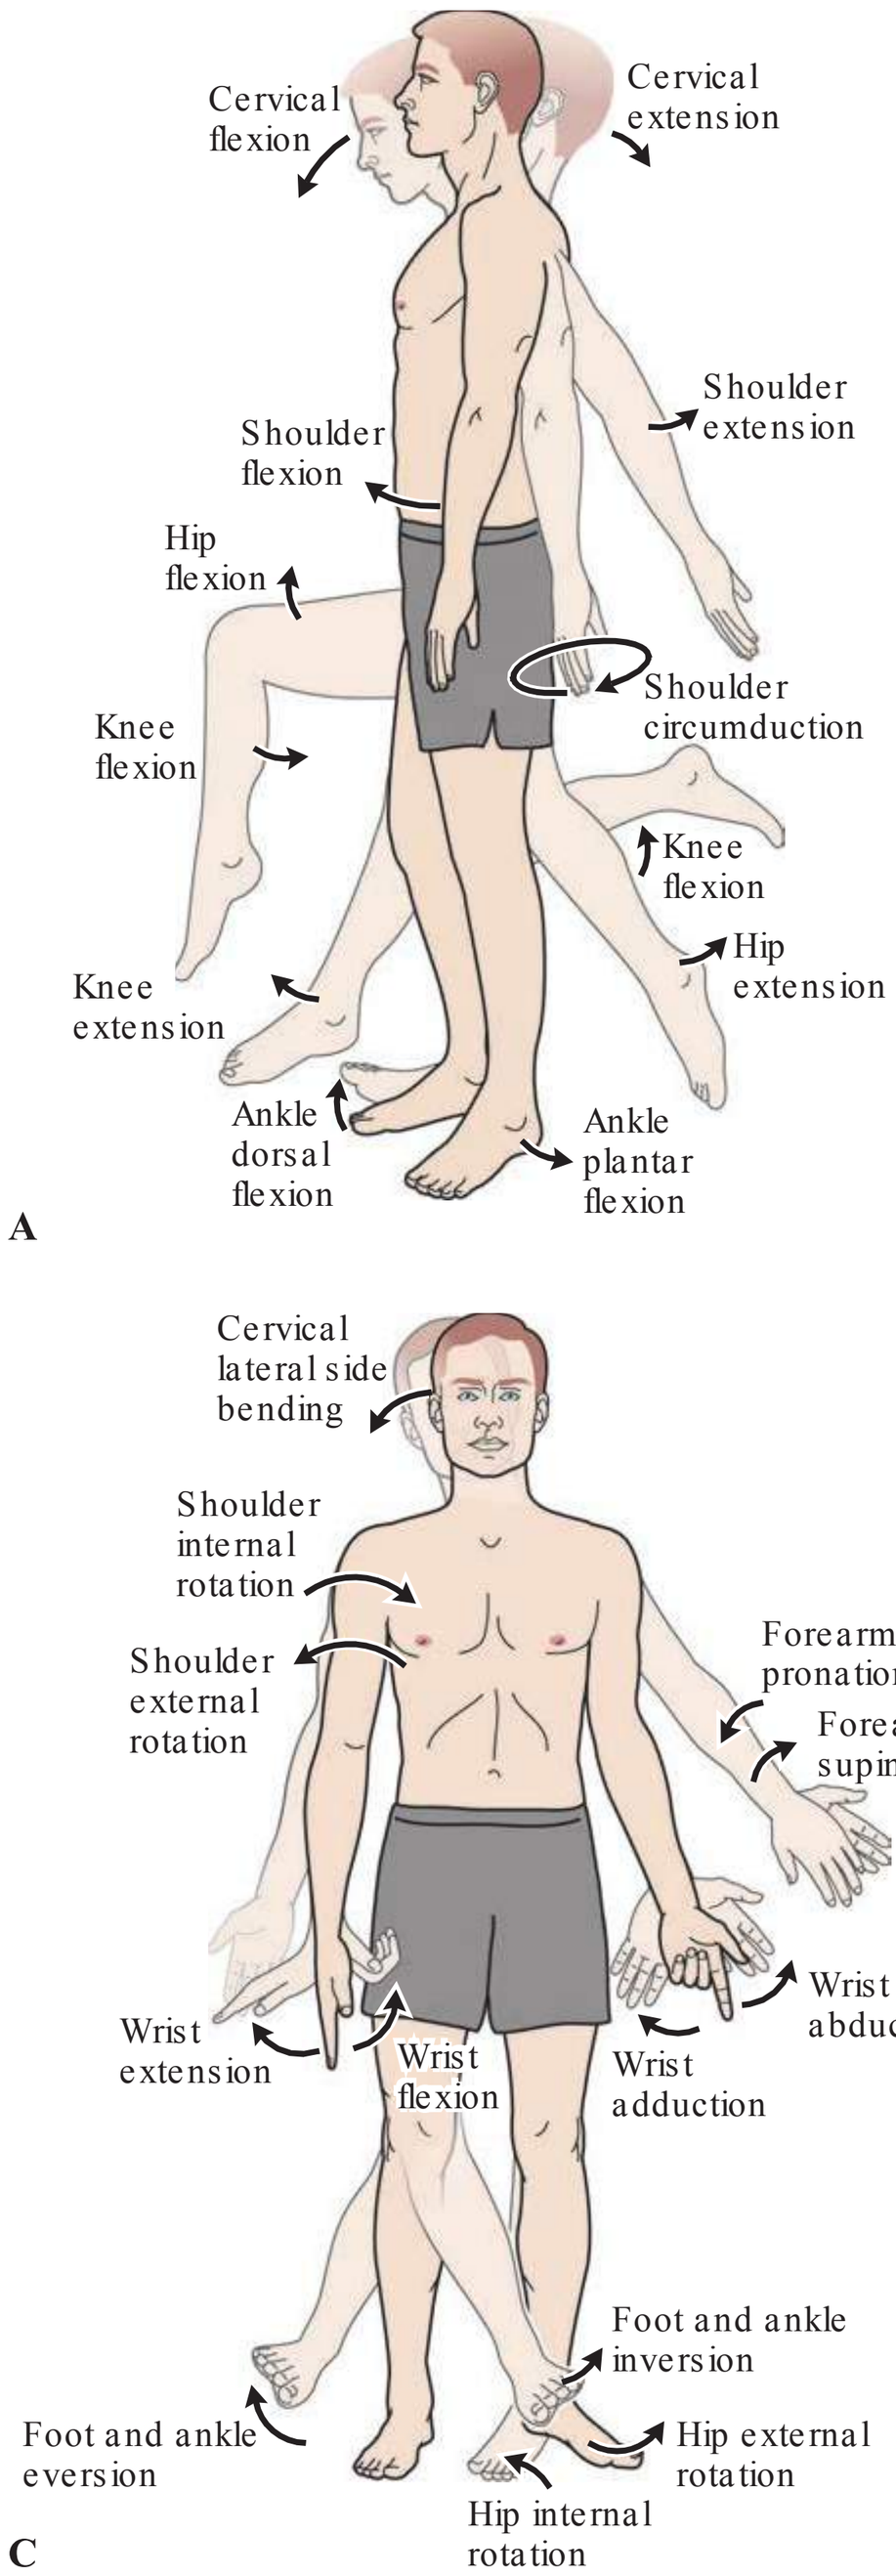

FIGURE 1-7 Movements of the body.

concave member. T e planes and axes for the more common planar movements (Fig. 1-7) are as follows:

- Flexion, extension, hyperextension, dorsiflexion, and plantar flexion occur in the sagittal plane around an ML axis. Exceptions to this include carpometacarpal flexion and extension of the thumb.
- Abduction and adduction, side flexion of the trunk, elevation and depression of the shoulder girdle, radial and ulnar deviation of the wrist, and eversion and inversion of the foot occur in the frontal plane around an AP axis.
- Rotation of the head, neck, and trunk; internal rotation and external rotation of the arm or leg; horizontal

adduction and abduction of the arm or thigh; and pronation and supination of the forearm usually occur in the transverse plane around the vertical axis. Rotary motions involve the curved movement of a segment around a fixed axis, or center *of* rotation (COR). When a curved movement occurs around an axis that is not fixed, but instead shifts in space as the object moves, the axis around which the segment appears to move is referred to as the instantaneous axis *of* rotation or instantaneous COR (see Moment Arm).

- Arm circling and trunk circling are examples of circumduction. Circumduction involves an orderly sequence of circular movements that occur in the sagittal, frontal, and intermediate oblique planes, so that the segment as a whole incorporates a combination of flexion, extension, abduction, and adduction. Circumduction movements can occur at biaxial and triaxial joints. Examples of these joints include the tibiofemoral, radiohumeral, hip, glenohumeral, and the spinal joints.

Both the configuration of a joint and the line of pull of the muscle acting at a joint determine the motion that occurs at a joint:

- A muscle whose line of pull is lateral to the joint is a potential abductor.
- A muscle whose line of pull is medial to the joint is a potential adductor.
- A muscle whose line of pull is anterior to a joint has the potential to extend or flex the joint. At the knee, an anterior line of pull may cause the knee to extend, whereas, at the elbow joint, an anterior line of pull may cause flexion of the elbow.
- A muscle whose line of pull is posterior to the joint has the potential to extend or flex a joint (refer to preceding example).

Center of Gravity

Every object or segment can be considered to have a single COG, or COM—the point at which all the mass of the object or segment appears to be concentrated. In a symmetrical object, the COG is always located in the geometric center of the object. However, in an asymmetrical object such as the human body, the COG becomes the point at which the line of gravity balances the object. The line of gravity can best be visualized as a string with the weight on the end (a plumbline), with a string attached to the COG of an object.[108] If the human body is considered as a rigid object, the COG of the body lies approximately anterior to the second sacral vertebra (S2). Since the human body is not rigid, an individual's COG continues to change with movement with the amount of change in the location depending on how disproportionately the segments are rearranged.[108] During static standing, the body's line of gravity is between the individual's feet (base of support). The BOS includes the part of the body in contact with the supporting surface and the intervening area.[109] If an individual bends forward at the waist, the line of gravity moves outside of the BOS. The size of the BOS and its relation to the COG are important factors in the maintenance of balance and, thus, the stability of an object. The COG must be maintained over the BOS if an equilibrium is to be maintained. If the BOS of an object is large, the line of gravity is less likely to be displaced outside the BOS, which makes the object more stable.[108]

Degrees of Freedom

The number of independent modes of motion at a joint is referred to as the available degrees *of* freedom (DOF). A joint can have up to 3 degrees of angular freedom, corresponding to the three dimensions of space.[110] If a joint can swing in one direction or can only spin, it is said to have 1 DOF.[111–114] The proximal interphalangeal joint is an example of a joint with 1 DOF. If a joint can spin and swing in one way only, or it can swing in two completely distinct ways, but not spin, it is said to have 2 DOF.[111–114] The tibiofemoral joint, temporomandibular joint, proximal and distal radioulnar joints, subtalar joint, and talocalcaneal joint are examples of joints with 2 DOF. If the bone can spin and also swing in two distinct directions, then it is said to have 3 DOF.[111–114] Ball-and-socket joints, such as the shoulder and hip, have 3 DOF.

CLINICAL PEARL

Joint motion that occurs only in one plane is designated as 1 DOF; in two planes, 2 DOF; and in three planes, 3 DOF.

Because of the arrangement of the articulating surfaces—the surrounding ligaments and joint capsules—most motions around a joint do not occur in straight planes or along straight lines. Instead, the bones at any joint move through space in curved paths. This is can best be illustrated using Codman's paradox.

1. Stand with your arms by your side, palms facing inward, thumbs extended. Notice that the thumb is pointing forward.
2. Flex one arm to 90 degrees at the shoulder so that the thumb is pointing up.
3. From this position, horizontally extend your arm so that the thumb remains pointing up, but your arm is in a position of 90 degrees of glenohumeral abduction.
4. From this position, without rotating your arm, return the arm to your side and note that your thumb is now pointing away from your thigh.

Referring to the start position, and using the thumb as the reference, the arm has undergone an external rotation of 90 degrees. But where and when did the rotation take place? Undoubtedly, it occurred during the three separate, straight-plane motions or swings that etched a triangle in space. What you have just witnessed is an example of a conjunct rotation—a rotation that occurs as a result of joint surface shapes—and the effect of inert tissues rather than contractile tissues. Conjunct rotations can only occur in joints that can rotate internally or externally. Although not always apparent, most joints can so rotate. Consider the motions of elbow flexion and extension. While fully flexing and extending your elbow a few times, watch the pisiform bone and

forearm. If you watch carefully, you should notice that the pisiform and the forearm move in a direction of supination during flexion, and pronation during extension of the elbow. T e pronation and supination motions are examples of conjunct rotations.

Most habitual movements, or those movements that occur most frequently at a joint involve a conjunct rotation. However, the conjunct rotations are not always under volitional control. In fact, the conjunct rotation is only under volitional control in joints with 3 DOF (e.g., glenohumeral and hip joints). In joints with fewer than 3 DOF (hinge joints, such as the tibiofemoral and ulnohumeral joints), the conjunct rotation occurs as part of the movement but is not under voluntary control. T e implications for this become important when attempting to restore motion at these joints: the mobilizing techniques must take into consideration both the relative shapes of the articulating surfaces as well as the conjunct rotation that is associated with a particular motion (see Chapter 10).

JOINT KINEMATICS

Kinematics is the study of motion and describes how something is moving without stating the cause. Kinetics is the term used to explain why an object moves the way it does due to the forces acting on that object (see Chapter 2). In studying joint kinematics, two major types of motion are involved: (1) osteokinematic and (2) arthrokinematic.

Osteokinematic Motion

T e normal ROM of a joint is sometimes called the physiologic or anatomic ROM. Physiologic movements of the bones termed osteokinematics, are movements that can be performed voluntarily, for example, flexion of the shoulder. Osteokinematic motion occurs when any object forms the radius of an imaginary circle about a fixed point. T e axis of rotation for osteokinematic motions is oriented perpendicular to the plane in which the rotation occurs.[106] T e distance traveled by the motion may be a small arc or a complete circle and is measured as an angle, in degrees. All human body segment motions involve osteokinematic motions. Examples of osteokinematic motion include abduction or adduction of the arm, flexion of the hip or knee, and side bending of the trunk. A number of factors determine the amount of available physiologic joint motion, including

- the integrity of the joint surfaces and the amount of joint motion;
- the mobility and pliability of the soft tissues that surround a joint;
- the degree of soft-tissue approximation that occurs;
- the amount of scarring that is present[115]—interstitial scarring or fibrosis can occur in and around the joint capsules, within the muscles, and within the ligaments as a result of previous trauma;
- age—joint motion tends to decrease with increasing age;
- gender—in general, females have more joint motion than males.

ROM is considered to be pathological when motion at a joint either exceeds or fails to reach the normal physiologic limits of motion (see Chapter 2).[90]

Moment Arm

To understand the concept of a moment arm, an understanding of the anatomy and movement (kinematics) of the joint of interest is necessary. Although muscles produce linear forces, motions at joints are all rotary. For example, some joints can be considered to rotate about a fixed point. A good example of such a joint is the elbow. At the elbow joint, where the humerus and ulna articulate, the resulting rotation occurs primarily about a fixed point, referred to as the COR. In the case of the elbow joint, this COR is relatively constant throughout the joint ROM. However, in other joints (e.g., the knee) the COR moves through space as the knee joint flexes and extends because the articulating surfaces are not perfect circles. In the case of the knee, it is not appropriate to discuss a single COR—rather we must speak of a COR corresponding to a particular joint angle, or, using the terminology of joint kinematics, we must speak of the instantaneous center of rotation (ICR), that is, the COR at any "instant" in time or space. T us, the moment arm is defined as the perpendicular distance from the line of force application to the axis of rotation.

Arthrokinematic Motion

T e term arthrokinematics is used to describe the motions of the bone surfaces within the joint. T ese movements cannot be performed voluntarily and can only occur when resistance to active motion is applied, or when the patient's muscles are completely relaxed. Both the physiologic (osteokinematic) and joint play (arthrokinematic) motions occur simultaneously during movement and are directly proportional to each other, with a small increment of arthrokinematic motion resulting in a larger increment of osteokinematic motion. Normal arthrokinematic motions must occur for a full-range of physiologic motion to occur. Mennell[116,117] introduced the concept that full, painless, active ROM is not possible without these motions and that a restriction of arthrokinematic motion results in a decrease in osteokinematic motion. At each synovial articulation, the articulating surface of each bone moves in relation to the shape of the other articulating surface. A normal joint has an available range of active, or physiologic, motion, which is limited by a physiologic barrier as tension develops within the surrounding tissues, such as the joint capsule, ligaments, and CT. Beyond the available passive ROM, the anatomic barrier is found. T is barrier cannot be exceeded without disruption to the integrity of the joint. Accessory or component motions, which are also not under voluntary control occur during active motion. T ese include examples such as rotation of the ulna during forearm pronation and supination. At the physiologic barrier, there is an additional amount of passive ROM. T is small motion,

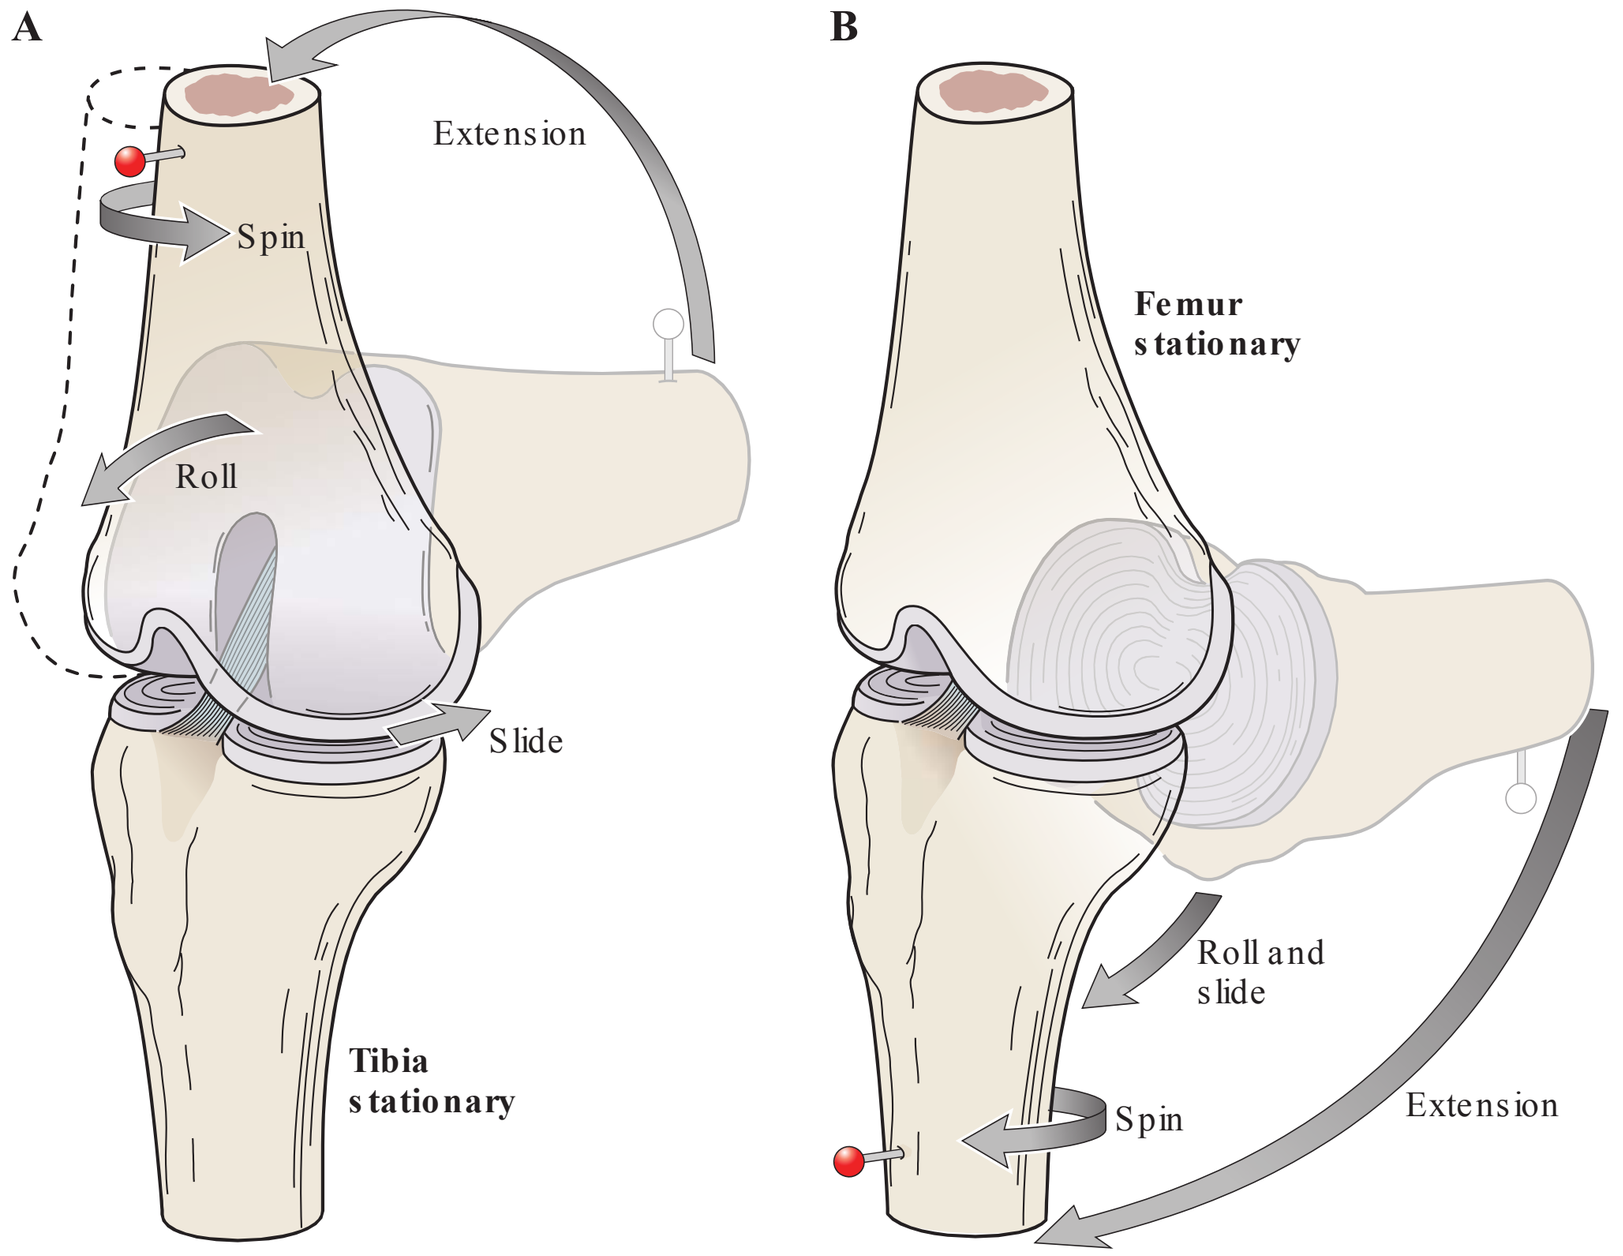

FIGURE 1-8 Arthrokinematics of motion.

which is available at the joint surfaces, is referred to as joint-play motion. T e type and amount of motion occurring at the joint surfaces is influenced by the shape of their respective joint surfaces. T ree fundamental types of joint-play motions exist based on the different types of joint surfaces (Fig. 1-8):[118]

- Roll. A roll occurs when the points of contact on each incongruent joint surface are constantly changing so that new point on one surface meets a new point on the opposite surface (see Fig. 1-8). T is type of movement is analogous to a tire on a car as the car rolls forward. In a normal functioning joint, pure rolling does not occur alone but instead occurs in combination with joint sliding and spinning. T e term rock is often used to describe small rolling motions. Rolling is always in the same direction as the swinging bone motion irrespective of whether the surface is convex or concave (Fig. 1-8). If the rolling occurs alone, it causes compression of the surfaces on the side to which the bone is swinging and separation on the other side.
- Slide. A slide is a pure translation if the two surfaces are congruently flat or curved. It occurs if only one point on the moving surface makes contact with new points on the opposing surface (see Fig. 1-8). T is type of movement is analogous to a car tire skidding when the brakes are applied suddenly on a wet road. T is type of motion also is referred to as translatory motion. Although the roll of a joint always occurs in the same direction as the swing of a bone, the direction of the slide is determined by the shape of the articulating surface (Fig. 1-9). T is rule is

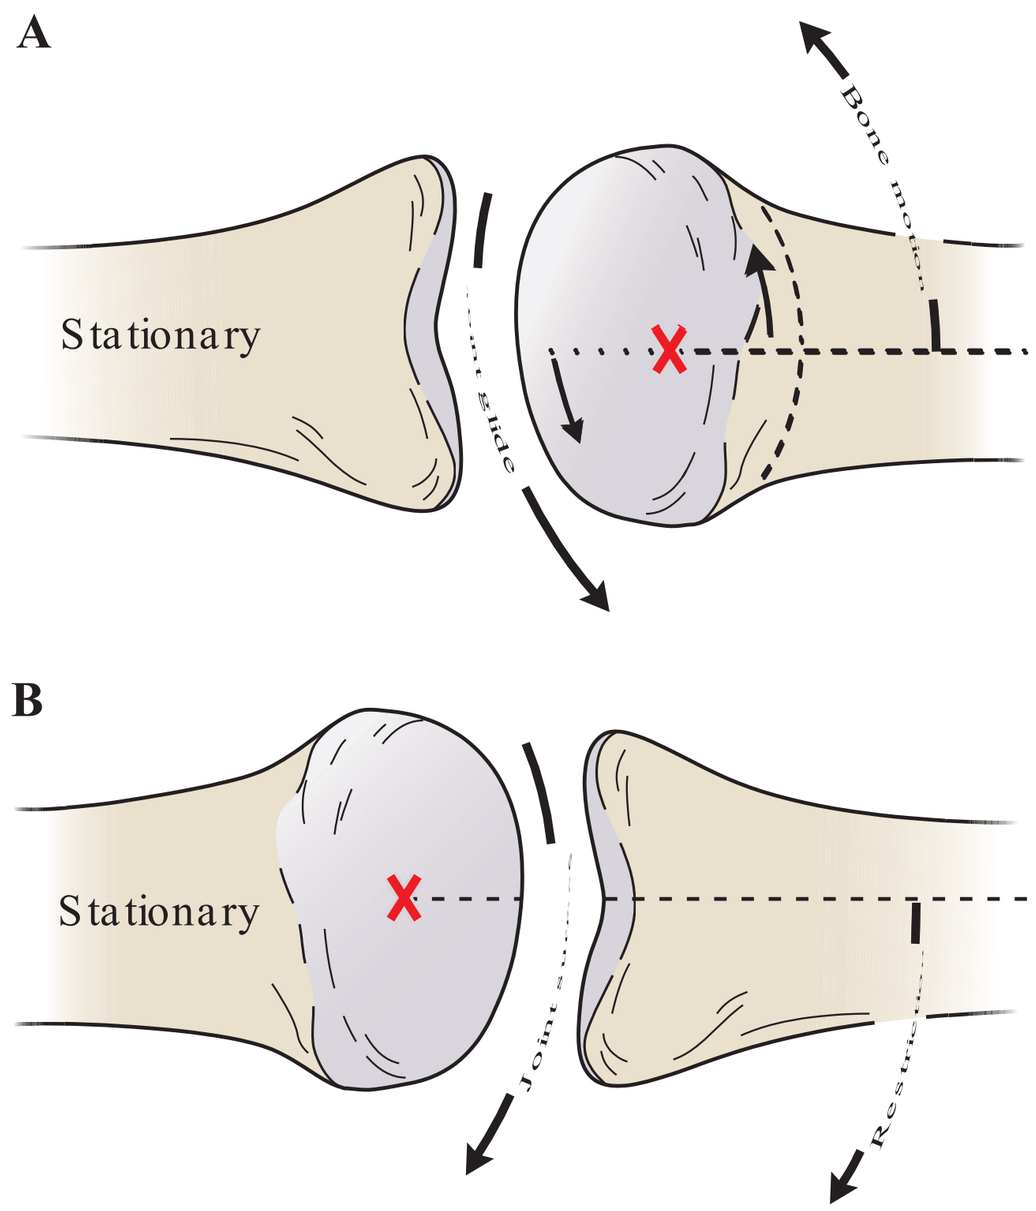

FIGURE 1-9 Gliding motions according to joint surfaces.

often referred to as the concave–convex rule: If the joint surface is convex relative to the other surface, the slide occurs in the opposite direction to the osteokinematic motion (see Fig. 1-9). If, on the other hand, the joint surface is concave, the slide occurs in the same direction as the osteokinematic motion (see Fig. 1-9). T e clinical significance of the concave–convex rule is described in Chapter 10.

- Spin. A spin is defined as any movement in which the bone moves, but the mechanical axis remains stationary. A spin involves a rotation of one surface on an opposing surface around a vertical axis (see Fig. 1-8). T is type of motion is analogous to the pirouette performed by a ballet dancer. Spinning rarely occurs alone in joints but instead occurs in combination with rolling and sliding. Spin motions in the body include internal and external rotation of the glenohumeral joint when the humerus is abducted to 90 degrees; and at the radial head during forearm pronation and supination.

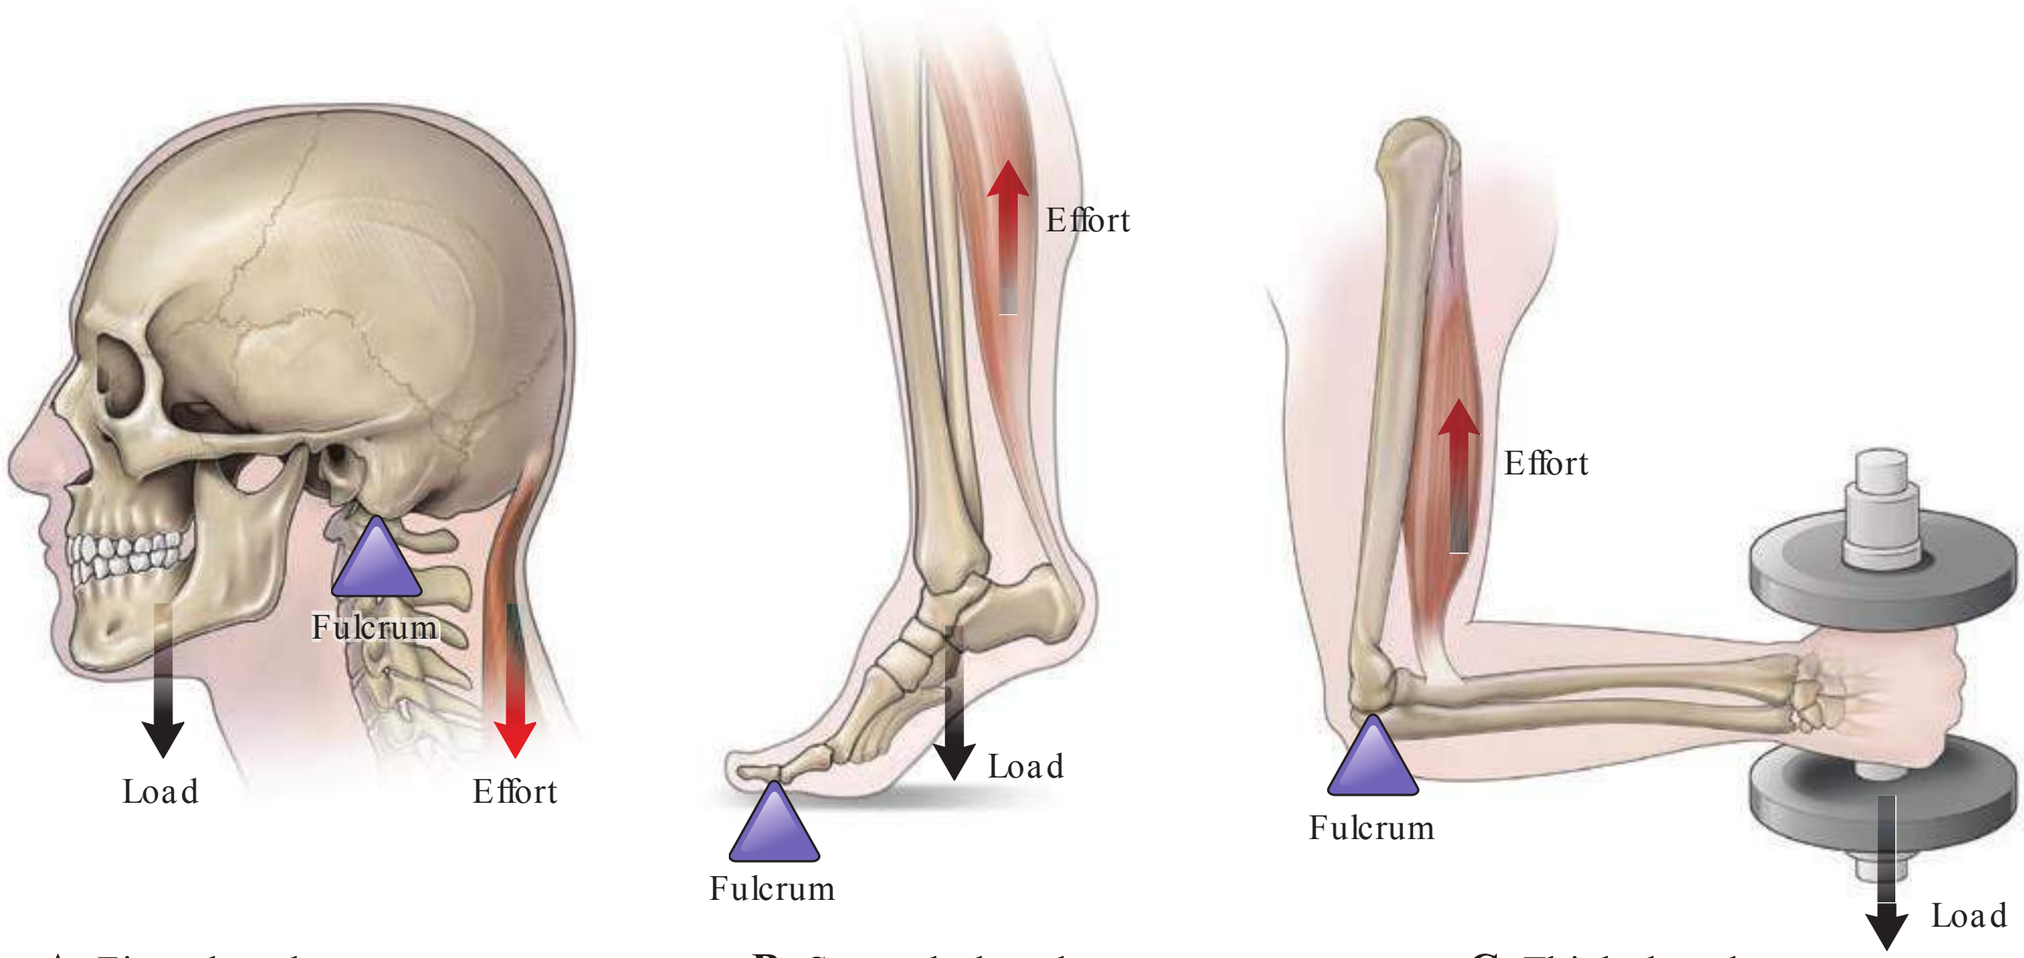
As osteokinematic and arthrokinematic motions are directly proportional to each other, such that one cannot occur completely without the other, it follows that if a joint is not functioning correctly, one or both of these motions may be at fault. When examining a patient with movement impairment, it is critical that the clinician determine whether the osteokinematic motion or the arthrokinematic motion is restricted so that the intervention can be made as specific as possible. T is is particularly important when trying to regain motion using traditional stretching methods which employ osteokinematic motions, as these methods magnify the force at the joint and cause compression of the joint surfaces in the direction of the rolling bone. In contrast, using an arthrokinematic technique to increase the joint play allows the force to be applied close to the joint surface and in the direction that replicates the sliding component of the joint mechanics.

CLINICAL PEARL

Two other accessory motions are used by clinicians in various manual techniques, compression and distraction:

- Compression. This occurs when there is a decrease in the joint space between bony partners and although it occurs naturally throughout the body whenever a joint is weight bearing, it can be applied manually to help move synovial fuid and maintain cartilage health.
- Distraction. This involves an increase in the joint space between bony partners. The terms traction and distraction are not synonymous, as the former involves a force applied to the long axis of a bone, which does not always result in the joint space increasing between the bony partners. For example, if traction is applied to the shaft of the femur, it results in a glide occurring at the hip joint surface, whereas if a distraction force is applied at right angles to the acetabulum, distraction at the hip joint occurs.

In the extremities, osteokinematic motion is controlled by the amount of flexibility of the surrounding soft tissues of the joint, where flexibility is defined as the amount of internal resistance to motion. In contrast, the arthrokinematic motion is controlled by the integrity of the joint surfaces and the supporting tissues of the joint. T is characteristic can be noted clinically in a chronic rupture of the anterior cruciate ligament of the knee. Upon examination of that knee, the arthrokinematic motion (joint slide or glide) is found to be increased, illustrated by a positive Lachman test, but the ROM of the knee, its osteokinematic motion, is not affected (see Chapter 20).



In contrast, in the spine, the osteokinematic motion is controlled by both the flexibility of the surrounding soft tissues and by the integrity of the joint surfaces and the supporting tissues of the joint. T is characteristic can be noted clinically when examining the craniovertebral joint, where a restriction in the arthrokinematic motion (joint slide or glide) can be caused by either a joint restriction or an adaptively shortened sub-occipital muscle (see Chapter 23).

T e examination of these motions and their clinical implications are described in Chapters 4 and 10.

Levers

A lever is a rigid object that is used to either multiply the mechanical force (effort) or resistance force (load) applied to it around an axis. T e effort force attempts to cause movement of the load. For simplicity sake, levers are usually described using a straight bar that is the lever, and the fulcrum, which is the point on which the bar is resting, and around which the lever rotates. T at part of the lever between the fulcrum and the load is referred to as the load arm. T ree types of levers are commonly cited:

- First class: occurs when two forces are applied on either side of the axis, and the fulcrum lies between the effort and the load (Fig. 1-10), like a seesaw. Examples in the human body include the contraction of the triceps at the elbow joint, or tipping of the head forward and backward.
- Second class: occurs when the load (resistance) is applied between the fulcrum and the point where the effort is exerted (Fig. 1-10). T e magnifying effects of the effort require less force to move the resistance. Examples of second-class levers in everyday life include the nutcracker, and the wheelbarrow—with the wheel acting as the fulcrum. Examples of second-class levers in the human body include weight-bearing plantarflexion (rising up on the toes) (Fig. 1-10). Another would be an isolated contraction of the brachioradialis to flex the elbow, which could only occur if the other elbow flexors are paralyzed.
- T ird class: occurs when the load is located at the end of the lever (Fig. 1-10), and the effort lies between the fulcrum and the load, like a drawbridge or a crane. T e effort is exerted between the load and the fulcrum. T e effort expended is greater than the load, but the load is moved a greater distance. Most movable joints in the human body function as third-class levers—flexion at the elbow.

A First-class lever **B** Second-class lever **C** Third-class lever

FIGURE 1-10 Classes of levers.

When a machine puts out more force than is put in, the machine is said to have a mechanical advantage (MA). The MA of the musculoskeletal lever is defined as the ratio of the internal moment arm to the external moment arm. Depending on the location of the axis of rotation, the first-class lever can have an MA equal to, less than, or greater than 1.[110] Second-class levers always have an MA greater than 1. Third-class levers always have an MA less than 1. The majority of muscles throughout the musculoskeletal system function with an MA of much less than 1. Therefore, the muscles and underlying joints must "pay the price" by generating and dispersing relative large forces, respectively, even for seemingly low-load activities.[110]

KINEMATIC CHAINS

When a body moves, it does so by its kinematics, which in the human body take place through arthrokinematic and osteokinematic movements. The expression kinematic chain is used in rehabilitation to describe the function or activity of an extremity or trunk in terms of a series of linked chains (see Chapter 12). A kinematic chain refers to a series of articulated, segmented links, such as the connected pelvis, thigh, leg, and foot of the lower extremity.[110] According to kinematic chain theory, each of the joint segments of the body involved in a particular movement constitutes a link in the kinematic chain. Because each motion of a joint is often a function of other joint motions, the efficiency of an activity can be dependent on how well these chain-links work together.[119]

CLINICAL PEARL

The number of links within a particular kinematic chain varies, depending on the activity. In general, longer kinematic chains are involved with more strenuous activities.

Two types of kinematic chain systems are recognized: closed kinematic chain (CKC) systems and the open kinematic chain (OKC) systems (Table 1-5).[120]

Closed Kinematic Chain

A variety of definitions for a CKC activity have been proposed:

1. Palmitier et al.[121] define an activity as closed if both ends of the kinetic chain are connected to an immovable framework, thus preventing translation of either the proximal, or distal joint center, and creating a situation whereby movement at one joint produces a predictable movement at all other joints.
2. Gray[122] considers a closed-chain activity to involve fixation of the distal segment so that joint motion takes place in multiple planes, and the limb is supporting the weight.
3. Dillman et al.[123] describe the characteristics of closed-chain activities to include relatively small joint movements, low joint accelerations, greater joint compressive forces, greater joint congruity, decreased shear, stimulation of joint proprioception, and enhanced dynamic stabilization through muscle coactivation.[124]
4. Kibler[124] defines a closed-chain activity as a sequential combination of joint motions that have the following characteristics:
   a. The distal segment of the kinetic chain meets considerable resistance.
   b. The movement of the individual joints, and translation of their instant centers of rotation occurs in a predictable manner that is secondary to the distribution of forces from each end of the chain.

Examples of closed kinematic chain exercises (CKCEs) involving the lower extremities include the squat and the leg

TABLE 1-5	Differential Features of OKC and CKC Exercises		
Exercise Mode	**Characteristics**	**Advantages**	**Disadvantages**
Open kinematic chain	1. Single muscle group 2. Single axis and plane 3. Emphasizes concentric contraction 4. Nonweight bearing	1. Isolated recruitment 2. Simple movement pattern 3. Minimal joint compression	1. Limited function 2. Limited eccentrics 3. Less proprioception and joint stability with increased joint shear forces
Closed kinematic	1. Multiple muscle groups 2. Multiple axes and planes 3. Balance of concentric and eccentric contractions 4. Weight-bearing exercise	1. Functional recruitment 2. Functional movement patterns 3. Functional contractions 4. Increased proprioception and joint stability	1. Difficult to isolate 2. More complex 3. Loss of control of target joint 4. Compressive forces on articular surfaces

Data from Greenfield BH, Tovin BJ. The application of open and closed kinematic chain exercises in rehabilitation of the lower extremity. J Back Musculoskel Rehabil. 1992;2:38–51.

press. T e activities of walking, running, jumping, climbing, and rising from the floor all incorporate closed kinetic chain components. An example of a CKCE for the upper extremities is the push-up, or when using the arms to push down on the armrests to rise out of a chair.

CLINICAL PEARL

In most activities of daily living, the activation sequence of the links involves a closed chain whereby the activity is initiated from a firm base of support and transferred to a more mobile distal segment.

Open Kinematic Chain

It is accepted that the difference between OKC and CKC activities is determined by the movement of the end segment. T e traditional definition for an open-chain activity included all activities that involved the end segment of an extremity moving freely through space, resulting in isolated movement of a joint.

Examples of an open-chain activity include lifting a drinking glass and kicking a soccer ball. Open kinematic chain exercises (OKCEs) involving the lower extremity include the seated knee extension and prone knee flexion. Upper extremity examples of OKCE include the biceps curl and the military press.

Many activities, such as swimming and cycling, traditionally viewed as OKC activities, include a load on the end segment; yet the end segment is not "fixed" and restricted from movement. T is ambiguity of definitions for CKC and OKC activities has allowed some activities to be classified in opposing categories.[123] T us, there has been a growing need for clarification of OKC and CKC terminology, especially when related to functional activities.

T e works of Dillman et al.[123] and then Lephart and Henry[125] have attempted to address the confusion. Dillman et al.[123] proposed three classifications of activity to help clarify the gray area between the CKC and the OKC activity. T ese classifications were based on the boundary condition, either movable or fixed, and the presence or absence of a load on the end segment. An activity with a fixed boundary and no load does not exist, resulting in three classifications:

1. Movable no load. T ese activities involve a movable end with no load and closely resemble the extreme of an open-chain activity. An example of this type of activity is hitting a ball with a tennis racket.
2. Movable external load. T ese activities involve a movable end with an external load and include a combination of open- and closed-chain actions because they are characterized by cocontractions of the muscles around the joints. An example of this type of activity is the overhead shoulder (military) press.
3. Fixed external load. T ese activities involve a fixed end with an external load, and closely resemble the extreme of a closed-chain activity. An example of this type of activity is the push-up.

Lephart and Henry suggested that a further definition could be made by analyzing the following characteristics of an activity:

- T e direction of force.
- T e magnitude of the load.
- Muscle action.
- Joint motion.
- Neuromuscular function.

Under Lephart and Henry's classification, activities could be subdivided into four groups:

1. Activities that involve a fixed boundary with an external and axial load. An example of this type of activity is the use of a slide board.
2. Activities that involve a movable boundary with an external and axial load. An example of this type of activity is the bench press.
3. Activities that involve a movable boundary with an external and rotary load. An example of this type of activity is a

resisted proprioceptive neuromuscular facilitation (PNF) motion pattern (see Chapter 10).

4. Activities that involve a movable boundary with no load. An example of this type of activity is position training.

Although both the Dillman and Lephart and Henry models appear to be describing the same concept, the Lephart and Henry model is distinct in that it incorporates diagonal or rotary components to the movements. These diagonal and rotary movements feature in the vast majority of functional activities.

CLOSE-PACKED AND OPEN-PACKED POSITIONS OF THE JOINT

Joint movements usually are accompanied by a relative compression (approximation) or distraction (separation) of the opposing joint surfaces. These relative compressions or distractions affect the level of congruity of the opposing surfaces. The position of maximum congruity of the opposing joint surfaces is termed the close-packed position of the joint. The position of least congruity is termed the open-packed position. Thus, movements toward the close-packed position of a joint involve an element of compression, whereas movements out of this position involve an element of distraction.

Close-Packed Position

The close-packed position of a joint is the joint position that results in:

- The maximal tautness of the major ligaments.
- Maximal surface congruity.
- Minimal joint volume.
- Maximal stability of the joint.

Once the close-packed position is achieved, no further motion in that direction is possible. This is the often-cited reason most fractures and dislocations occur when an external force is applied to a joint that is in its close-packed position. Also, many of the traumatic injuries of the upper extremities result from falling on a shoulder, elbow or wrist, which are in their close-packed position. This type of injury, a *f*all on an outstretched hand is often referred to as a FOOSH injury. The close-packed positions for the various joints are depicted in Table 1-6.

Open-Packed Position

In essence, any position of the joint, other than the close-packed position, could be considered as an open-packed position. The open-packed position, also referred to as the loose-packed position of a joint, is the joint position that results in:

- Slackening of the major ligaments of the joint.
- Minimal surface congruity.
- Minimal joint surface contact.
- Maximal joint volume.
- Minimal stability of the joint.

The open-packed position permits maximal distraction of the joint surfaces. Because the open-packed position causes the brunt of any external force to be borne by the joint capsule or surrounding ligaments, most capsular or ligamentous sprains occur when a joint is in its open-packed position. The open-packed positions for the various joints are depicted in Table 1-7.

TABLE 1-6 Close-Packed Position of the Joints

Joint	Position
Zygapophyseal (spine)	Extension
Temporomandibular	Teeth clenched
Glenohumeral	Abduction and external rotation
Acromioclavicular	Arm abducted to 90 degrees
Sternoclavicular	Maximum shoulder elevation
Ulnohumeral	Extension
Radiohumeral	Elbow flexed 90 degrees; forearm supinated 5 degrees
Proximal radioulnar	5 degrees of supination
Distal radioulnar	5 degrees of supination
Radiocarpal (wrist)	Extension with radial deviation
Metacarpophalangeal	Full flexion
Carpometacarpal	Full opposition
Interphalangeal	Full extension
Hip	Full extension, internal rotation, and abduction
Tibiofemoral	Full extension and external rotation of tibia
Talocrural (ankle)	Maximum dorsiflexion
Subtalar	Supination
Midtarsal	Supination
Tarsometatarsal	Supination
Metatarsophalangeal	Full extension
Interphalangeal	Full extension

CLINICAL PEARL

The open-packed position is commonly used during joint mobilization techniques (see Chapter 10).

TABLE 1-7 Open-Packed (Resting) Position of the Joints

Joint	Position
Zygapophyseal (spine)	Midway between flexion and extension
Temporomandibular	Mouth slightly open (freeway space)
Glenohumeral	55 degrees of abduction; 30 degrees of horizontal adduction
Acromioclavicular	Arm resting by side
Sternoclavicular	Arm resting by side
Ulnohumeral	70 degrees of flexion; 10 degrees of supination
Radiohumeral	Full extension; full supination
Proximal radioulnar	70 degrees of flexion; 35 degrees of supination
Distal radioulnar	10 degrees of supination
Radiocarpal (wrist)	Neutral with slight ulnar deviation
Carpometacarpal	Midway between abduction–adduction and flexion–extension
Metacarpophalangeal	Slight flexion
Interphalangeal	Slight flexion
Hip	10–30 degrees of flexion; 10–30 degrees of abduction; and 0–5 degrees of external rotation
Tibiofemoral	25 degrees of flexion
Talocrural (ankle)	10 degrees of plantar flexion; midway between maximum inversion and eversion
Subtalar	Midway between extremes of range of movement
Midtarsal	Midway between extremes of range of movement
Tarsometatarsal	Midway between extremes of range of movement
Metatarsophalangeal	Neutral
Interphalangeal	Slight flexion

CHAPTER 2

Tissue Behavior, Injury, Healing, and Treatment

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the various types of stress that are applied to the body.
2. Describe the various physiological processes by which the body adapts to stress.
3. Define the various common mechanisms of injury.
4. Describe the etiology and pathophysiology of musculoskeletal injuries associated with various types of body tissue.
5. Outline the pathophysiology of the healing process and the various stages of healing of the various connective tissues.
6. Describe the factors that can impede the healing process.
7. Outline the more common surgical procedures available for musculoskeletal injuries.
8. Outline the principles behind postsurgical rehabilitation.
9. Describe the detrimental effects of immobilization.

OVERVIEW

Tissues in the body are designed to function while undergoing the stresses of everyday living. Body weight, friction, and air or water resistance are all types of stresses that commonly act on the body. The ability of the tissues to respond to stress is due to the differing viscoelastic properties of the tissue, with each tissue responding to stress in an individual manner based on design. Maintaining the health of the various tissues is a delicate balance because insufficient, excessive, or repetitive stresses can prove deleterious. Fortunately, most tissues have an inherent ability to self-heal—a process that is an intricate phenomenon.

THE RESPONSE OF TISSUE TO STRESS

Kinetics is the term applied to define the forces acting on the body. Posture and movement are both governed by the body's ability to control these forces. The same forces that move and stabilize the body also have the potential to deform and injure the body.[1] A wide range of external and internal forces are either generated or resisted by the human body during daily activities. Examples of these external forces include ground reaction force, gravity, and applied force through contact. Examples of internal forces include structural tension, joint compression, and joint shear forces (Fig. 2-1). Under the right circumstances, the body can respond and adapt to these stresses. The terms stress and strain have specific mechanical meanings. Stress, or load, is defined in units of force per area, and is used to describe the type of force applied. Stress is independent of the amount of material, but is directly related to the magnitude of force and inversely related to the unit area.[2] Strain is defined as the change in length of a material due to an imposed load, divided by the original length.[2] The two basic types of strain are a linear strain, which causes a change in the length of a structure, and shear strain, which causes a change in the angular relationships within a structure. It is the concentration of proteoglycans in solution (see Chapter 1) that is responsible for influencing the mechanical properties of the tissue, including compressive stiffness, sheer stiffness, osmotic pressure, and the regulation of hydration.[3]

CLINICAL PEARL

Strain is the amount of elongation divided by the length of the structure.

Stress is the force in a structure divided by the cross-sectional area.

The inherent ability of a tissue to tolerate load can be observed experimentally in graphic form. When any stress is plotted on a graph against the resulting strain for a given material, the shape of the resulting load–deformation curve depends on the kind of material involved. The load–deformation curve, or stress–strain curve, of a structure (Fig. 2-2) depicts the relationship between the amount of force applied to a structure and the

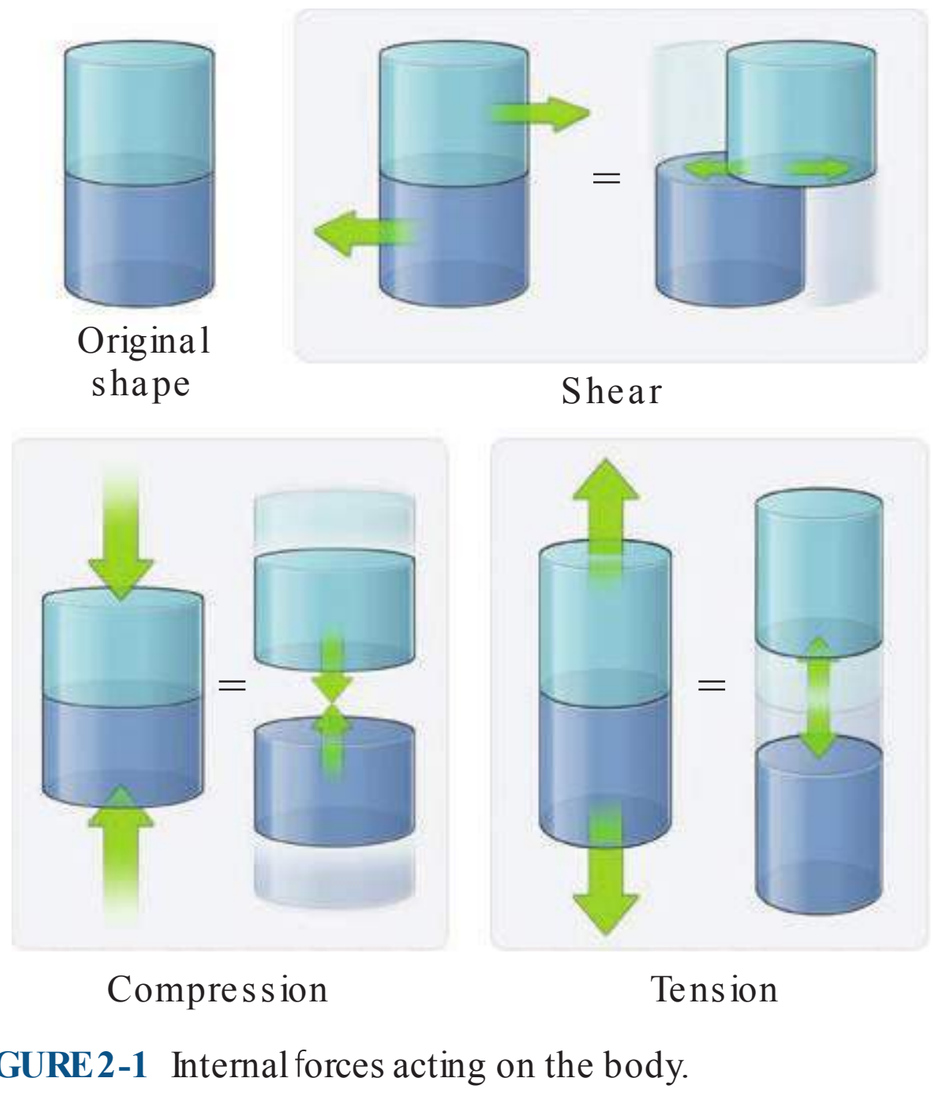

FIGURE 2-1 Internal forces acting on the body.

structure's response in terms of deformation or acceleration. The horizontal axis (deformation or strain) represents the ratio of the tissue's deformed length to its original length. The vertical axis of the graph (load or stress) denotes the internal resistance generated as a tissue resists its deformation, divided by its cross-sectional area. The load–deformation curve can be divided into four regions, each region representing a biomechanical property of the tissue (Fig. 2-2):

- Toe region. Collagen fibers have a wavy, or folded, appearance at rest or on slack. When a force that lengthens the collagen fibers is initially applied to connective tissue, this slack range is affected first, and the fibers unfold as the slack is taken up (see Crimp later). The toe region is an artifact caused by this take-up of slack, alignment, and/or seating of the test specimen. The length of the toe region depends on the type of material and the waviness of the collagen pattern.
- Elastic region. Within the elastic deformation region, the structure imitates a spring—the geometric deformation in the structure increases linearly with increasing load, and after the load is released the structure returns to its original shape. The slope of the elastic region of the load–deformation curve from one point in the curve to another, which corresponds to the physiological range of a structure, is called the modulus of elasticity or Young's modulus, and represents the extrinsic stiffness or rigidity of the structure—the stiffer the tissue, the steeper the slope. A key characteristic of passive tendon loading is its stiffness—the force in the tendon divided by the amount of lengthening of the tendon.[4] Young's modulus is a numerical description of the relationship between the amount of stress a tissue undergoes and the deformation that results—stress divided by the strain. The ratio of stress to strain in an elastic material is a measure of its stiffness. Young's modulus is independent of specimen size and is, therefore, a measure of the intrinsic stiffness of the material. The greater the Young's modulus for a material, the better it can withstand greater forces. Mathematically, the value for stiffness is found by dividing the load by the deformation at any point in the selected range. All normal tissues within the musculoskeletal system exhibit some degree of stiffness. Larger structures will have greater rigidity than smaller structures of similar composition. Stiffness is not necessarily a negative characteristic—tendons transmit force more effectively and efficiently when they are stiffer.[4]
- Plastic region. The end of the elastic deformation range, and the beginning of the plastic deformation range, represents the point where an increasing level of stress on

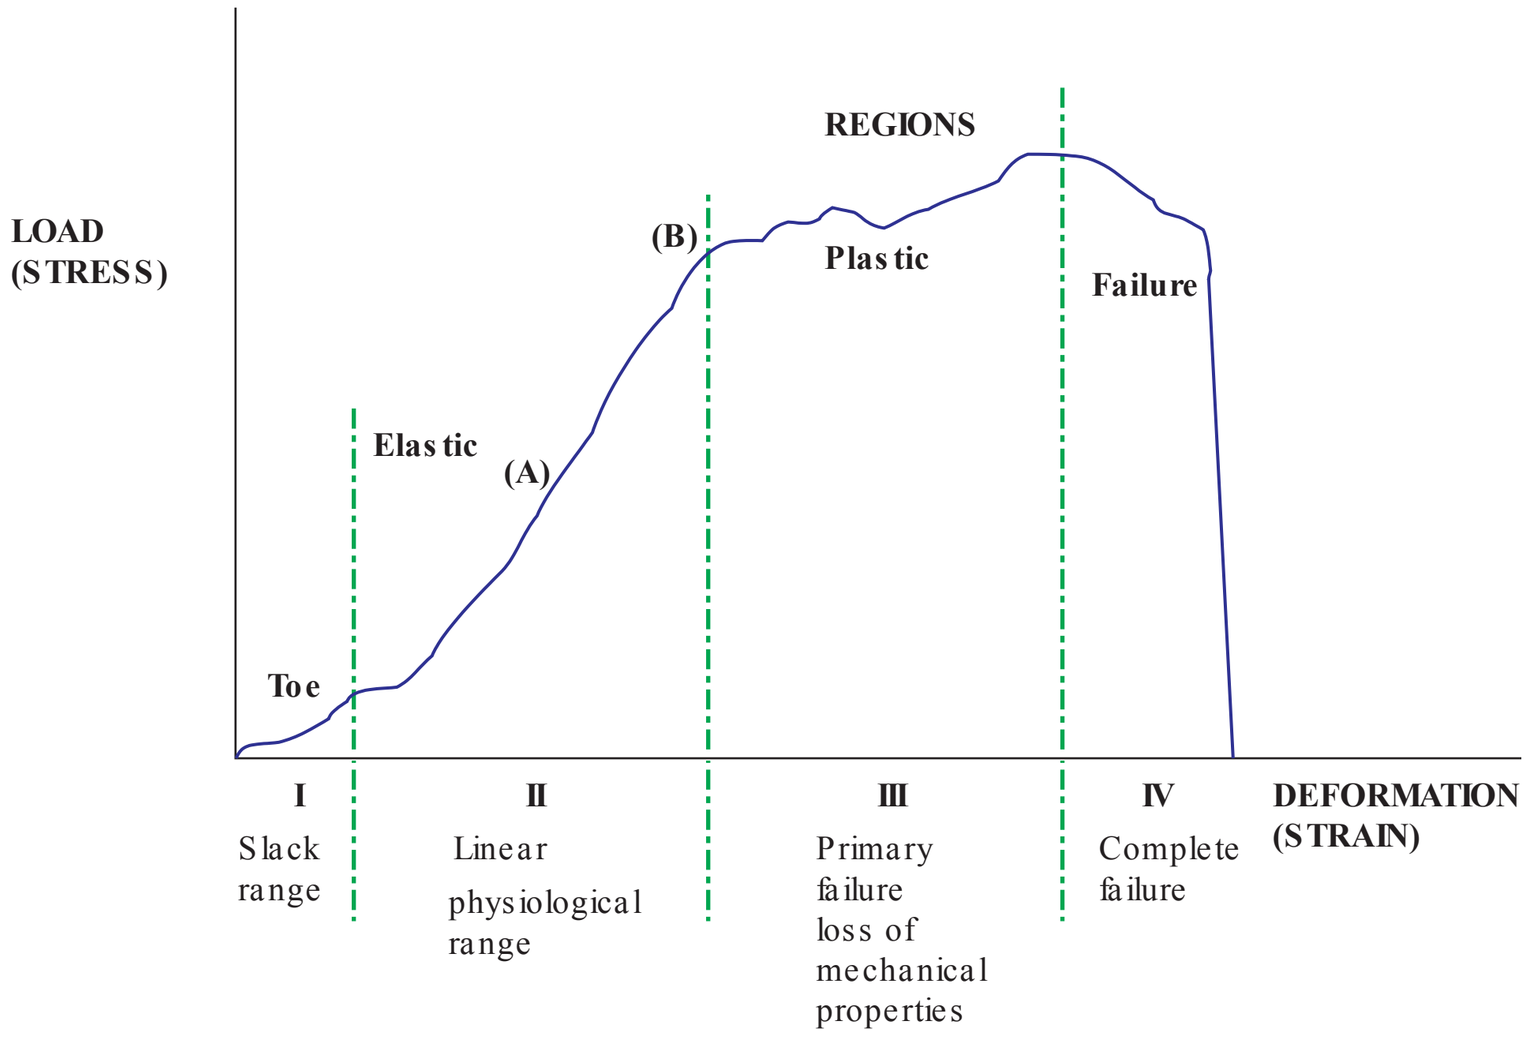

FIGURE 2-2 The stress–strain curve.

the tissue results in progressive failure and microscopic tearing of the collagen fibers. Further increases in strain result in microscopic damage and permanent deformation. The permanent change results from the breaking of bonds and their subsequent inability to contribute to the recovery of the tissue. Unlike the elastic region, removal of the load in this region will not result in a return of the tissue to its original length.

- Failure region. Deformations exceeding the ultimate failure point (Fig. 2-2) produce mechanical failure of the structure, which in the human body may be represented by the fracturing of bone or the rupturing of a soft tissue.

CLINICAL PEARL

Stiffness = force/deformation. The gradient in the linear portion of the load-deformation graph immediately after the toe region of the load–displacement curve represents the stiffness value. The load–deformation curve does not indicate the variable of time.

Elastic modulus = stress/strain. The larger the Young's modulus for a material, the greater stress needed for a given strain.

Biological tissues are anisotropic, which means they can demonstrate differing mechanical behavior as a function of test direction. The properties of extensibility and elasticity are common to many biologic tissues. Extensibility is the ability to be stretched, and elasticity is the ability to return to normal length after lengthening or shortening.[5]

CLINICAL PEARL

Unloading a tendon significantly influences the mechanical properties. For example, one study that looked at the effects of 4 weeks of unilateral lower limb suspension followed by 6 weeks of rehabilitation found that there was a 17% decrease in the elastic modulus (lower stiffness) after suspension, and the restoration of normal stiffness after rehabilitation.[6]

Some protective mechanisms exist in connective tissue to help respond to stress and strain, including crimp, viscoelasticity, creep and stress relaxation, plastic deformation, and stress response.

CLINICAL PEARL

Protective tissue mechanisms include:

- Crimp
- Viscoelasticity
- Creep and stress relaxation
- Plastic deformation
- Stress response

Crimp

The crimp of collagen is one of the major factors behind the viscoelastic properties of connective tissue. Crimp, a collagen tissue's first line of response to stress, is different for each type of connective tissue, providing each with different viscoelastic properties. Collagen fibers are oriented obliquely when relaxed. However, when a load is applied, the fibers line up in the direction of the applied force as they uncrimp. Crimping is seen primarily in ligaments, tendons, and joint capsules, and occurs in the toe phase of the stress–strain curve (Fig. 2-2).

CLINICAL PEARL

If a load is applied to the connective tissue and then removed immediately, the material recoils to its original size. If, however, the load is allowed to remain, the material continues to stretch. After a period of a sustained stretch, the stretching tends to reach a steady-state value. Realignment of the collagen fibers in the direction of the stress occurs, and water and proteoglycans are displaced from the fibers.

Viscoelasticity

Viscoelasticity is the time-dependent mechanical property of a material to stretch or compress over time, and to return to its original shape when a force is removed. The mechanical qualities of a tissue can be separated into categories based on whether the tissue acts primarily as a solid, fluid, or a mixture of the two. Solids are described according to their elasticity, strength, hardness, and stiffness. Bone, ligaments, tendons, and skeletal muscle are all examples of elastic solids. Biological tissues that demonstrate attributes of both solids and fluids are viscoelastic. The viscoelastic properties of a structure determine its response to loading. For example, a ligament demonstrates more viscous behavior at lower loads whereas, at higher loads, elastic behaviors dominate.[7]

Creep and Stress Relaxation

Creep and stress relaxation are two characteristics of viscoelastic materials that are used to document their behavior quantitatively.[5]

Creep is the gradual rearrangement of collagen fibers, proteoglycans, and water that occurs because of a constantly applied force after the initial lengthening caused by crimp has ceased. Creep is a time-dependent and transient biomechanical phenomenon. Short duration stresses (<15 minutes) do not have sufficient time to produce this displacement; however, longer times can produce it. Once creep occurs, the tissue has difficulty returning to its initial length (see below).

Stress relaxation is a phenomenon in which stress or force in a deformed structure decreases with time while the deformation is held constant.[5] Unlike creep, stress relaxation responds with a high initial stress that decreases over time until equilibrium is reached and the stress equals zero, hence the label "relaxation." As a result, no change in length is produced.

Thus, stress to connective tissues can result in no change, a semipermanent change, or a permanent change to the microstructure of the collagenous tissue. The semipermanent or permanent changes may result in either microfailure.

Plastic Deformation

Plastic deformation of connective tissue occurs when a tissue remains deformed and does not recover its prestress length. Once all of the possible realignment has occurred, any further loading breaks the restraining bonds, resulting in microfailure. On average, collagen fibers can sustain a 3% increase in elongation (strain) before microscopic damage occurs.[8] Following a brief stretch, providing the chemical bonds remain intact, the collagen and proteoglycans gradually recover their original alignment. The recovery process occurs at a slower rate and often to a lesser extent. The loss of energy that occurs between the lengthening force and the recovery activity is referred to as hysteresis. The more chemical bonds that are broken with applied stress, the greater the hysteresis. If the stretch is of sufficient force and duration, and a sufficient number of chemical bonds are broken, the tissue is unable to return to its original length until the bonds are re-formed. Instead, it returns to a new length and a new level of strain resistance. Increased tissue excursion is now needed before tension develops in the structure. In essence, this has the effect of decreasing the stabilizing capabilities of the connective tissue.

Stress Response

Exercises may be used to change the physical properties of both muscles/tendons and ligaments, as both have demonstrated adaptability to external loads with an increase in strength:weight ratios.[9–11] The improved strength results from an increase in the proteoglycan content and collagen cross-links.[9–11]

CLINICAL PEARL

Three biomechanical attributes of connective tissue can have clinical significance:

- Structural behavior
- Material behavior
- Viscoelastic behavior

TISSUE INJURY

Soft tissue injuries of all types are extremely common in the general population. Studies have shown that there is a linear relationship between soft tissue injuries and aging, with fewer than 10% of individuals younger than 34 years being affected, in contrast to 32–49% of those older than 75 years being affected.[12] Whether a stress proves to be beneficial or detrimental to a tissue is very much dependent on the physiologic capacity of the tissue to accept load. This is capacity is dependent on some factors, among them:

- The health of the tissue. Healthy tissues can resist changes in their shape. Any tissue weakened by disease or trauma may not be able to resist adequately the application of force.
- Age. Increasing age reduces the capacity of the tissues to cope with stress loading.
- Proteoglycan and collagen content of the tissue. Both increasing age and exposure to trauma can result in unfavorable alterations in the proteoglycan and collagen content of a tissue.
- The ability of the tissue to undergo adaptive change. All musculoskeletal tissue can adapt to change. This is capacity to change is determined primarily by the viscoelastic property of the tissue.
- The speed at which the adaptive change occurs. This is is dependent on the type and severity of the insult to the tissue. Insults of low force and longer duration may provide the tissue an opportunity to adapt. In contrast, insults of a higher force and shorter duration are less likely to provide the tissue time to adapt. The distinction between sudden and repetitive stress is important. An acute stress (loading) occurs when a single force is large enough to cause injury on biological tissues; the causative force is termed macrotrauma. A repetitive stress (loading) occurs when a single force itself is insufficient to cause injury on biological tissues. However, when repeated or chronic stress over a period causes an injury, the injury is called a chronic injury, and the causative mechanism is termed microtrauma. Etiologic factors for microtraumatic injuries are of two basic types: intrinsic or extrinsic. Intrinsic factors are physical characteristics that predispose an individual to microtrauma injuries and include muscle imbalances, leg length discrepancies, and anatomical anomalies.[13] Extrinsic factors, which are the most common cause of microtrauma injuries, are related to the external conditions under which the activity is performed. These include training errors, type of terrain, environmental temperature, and incorrect use of equipment.[13]

INJURY CLASSIFICATION

Injuries to the soft tissues can be classified as primary or secondary.

- Primary, or macrotraumatic, injuries can be self-inflicted, caused by another individual or entity, or caused by the environment.[14–17] These injuries include fractures, subluxations, and dislocations, which are outside the scope of practice for a physical therapist, and sprains, and strains, which make up the majority of conditions seen in the physical therapy clinic. For the purposes of the intervention, primary injuries are classified into acute, subacute, or chronic.
  - Acute. This is type of injury is usually caused by macrotrauma and indicates the early phase of injury and healing, which typically lasts approximately 4–6 days unless the insult is perpetuated.
  - Subacute. This is phase occurs after the acute phase and typically lasts from 10 to 17 days after the acute phase has ended but may last weeks in those tissues with limited circulation, such as tendons.[18]

- Chronic. T is type of injury can have several definitions. On the one hand it may indicate the final stage of healing that occurs 26–34 days after injury but can last 6 months to 1 year depending on the tissue involved and the amount of tissue damage. On occasion, a persistent inflammatory state results in an accumulation of repetitive scar adhesions, degenerative changes, and other harmful effects referred to as subclinical adaptations (see Chapter 8).

CLINICAL PEARL

An acute-on-chronic injury involves a re-injury of the tissue—an acute exacerbation of a chronic injury.

- Secondary or microtraumatic injuries are essentially the inflammatory response that occurs with the primary injury.[19] Microtraumatic injuries include tendinopathy, tenosynovitis, and bursitis.

TISSUE HEALING

Fortunately, the majority of tissue injuries heal without complication in a predictable series of events (Fig. 2-3). T e most important factor regulating the regional time line of healing is sufficient blood flow.[20] Many factors can determine the outcome of the tissue injury, including those listed

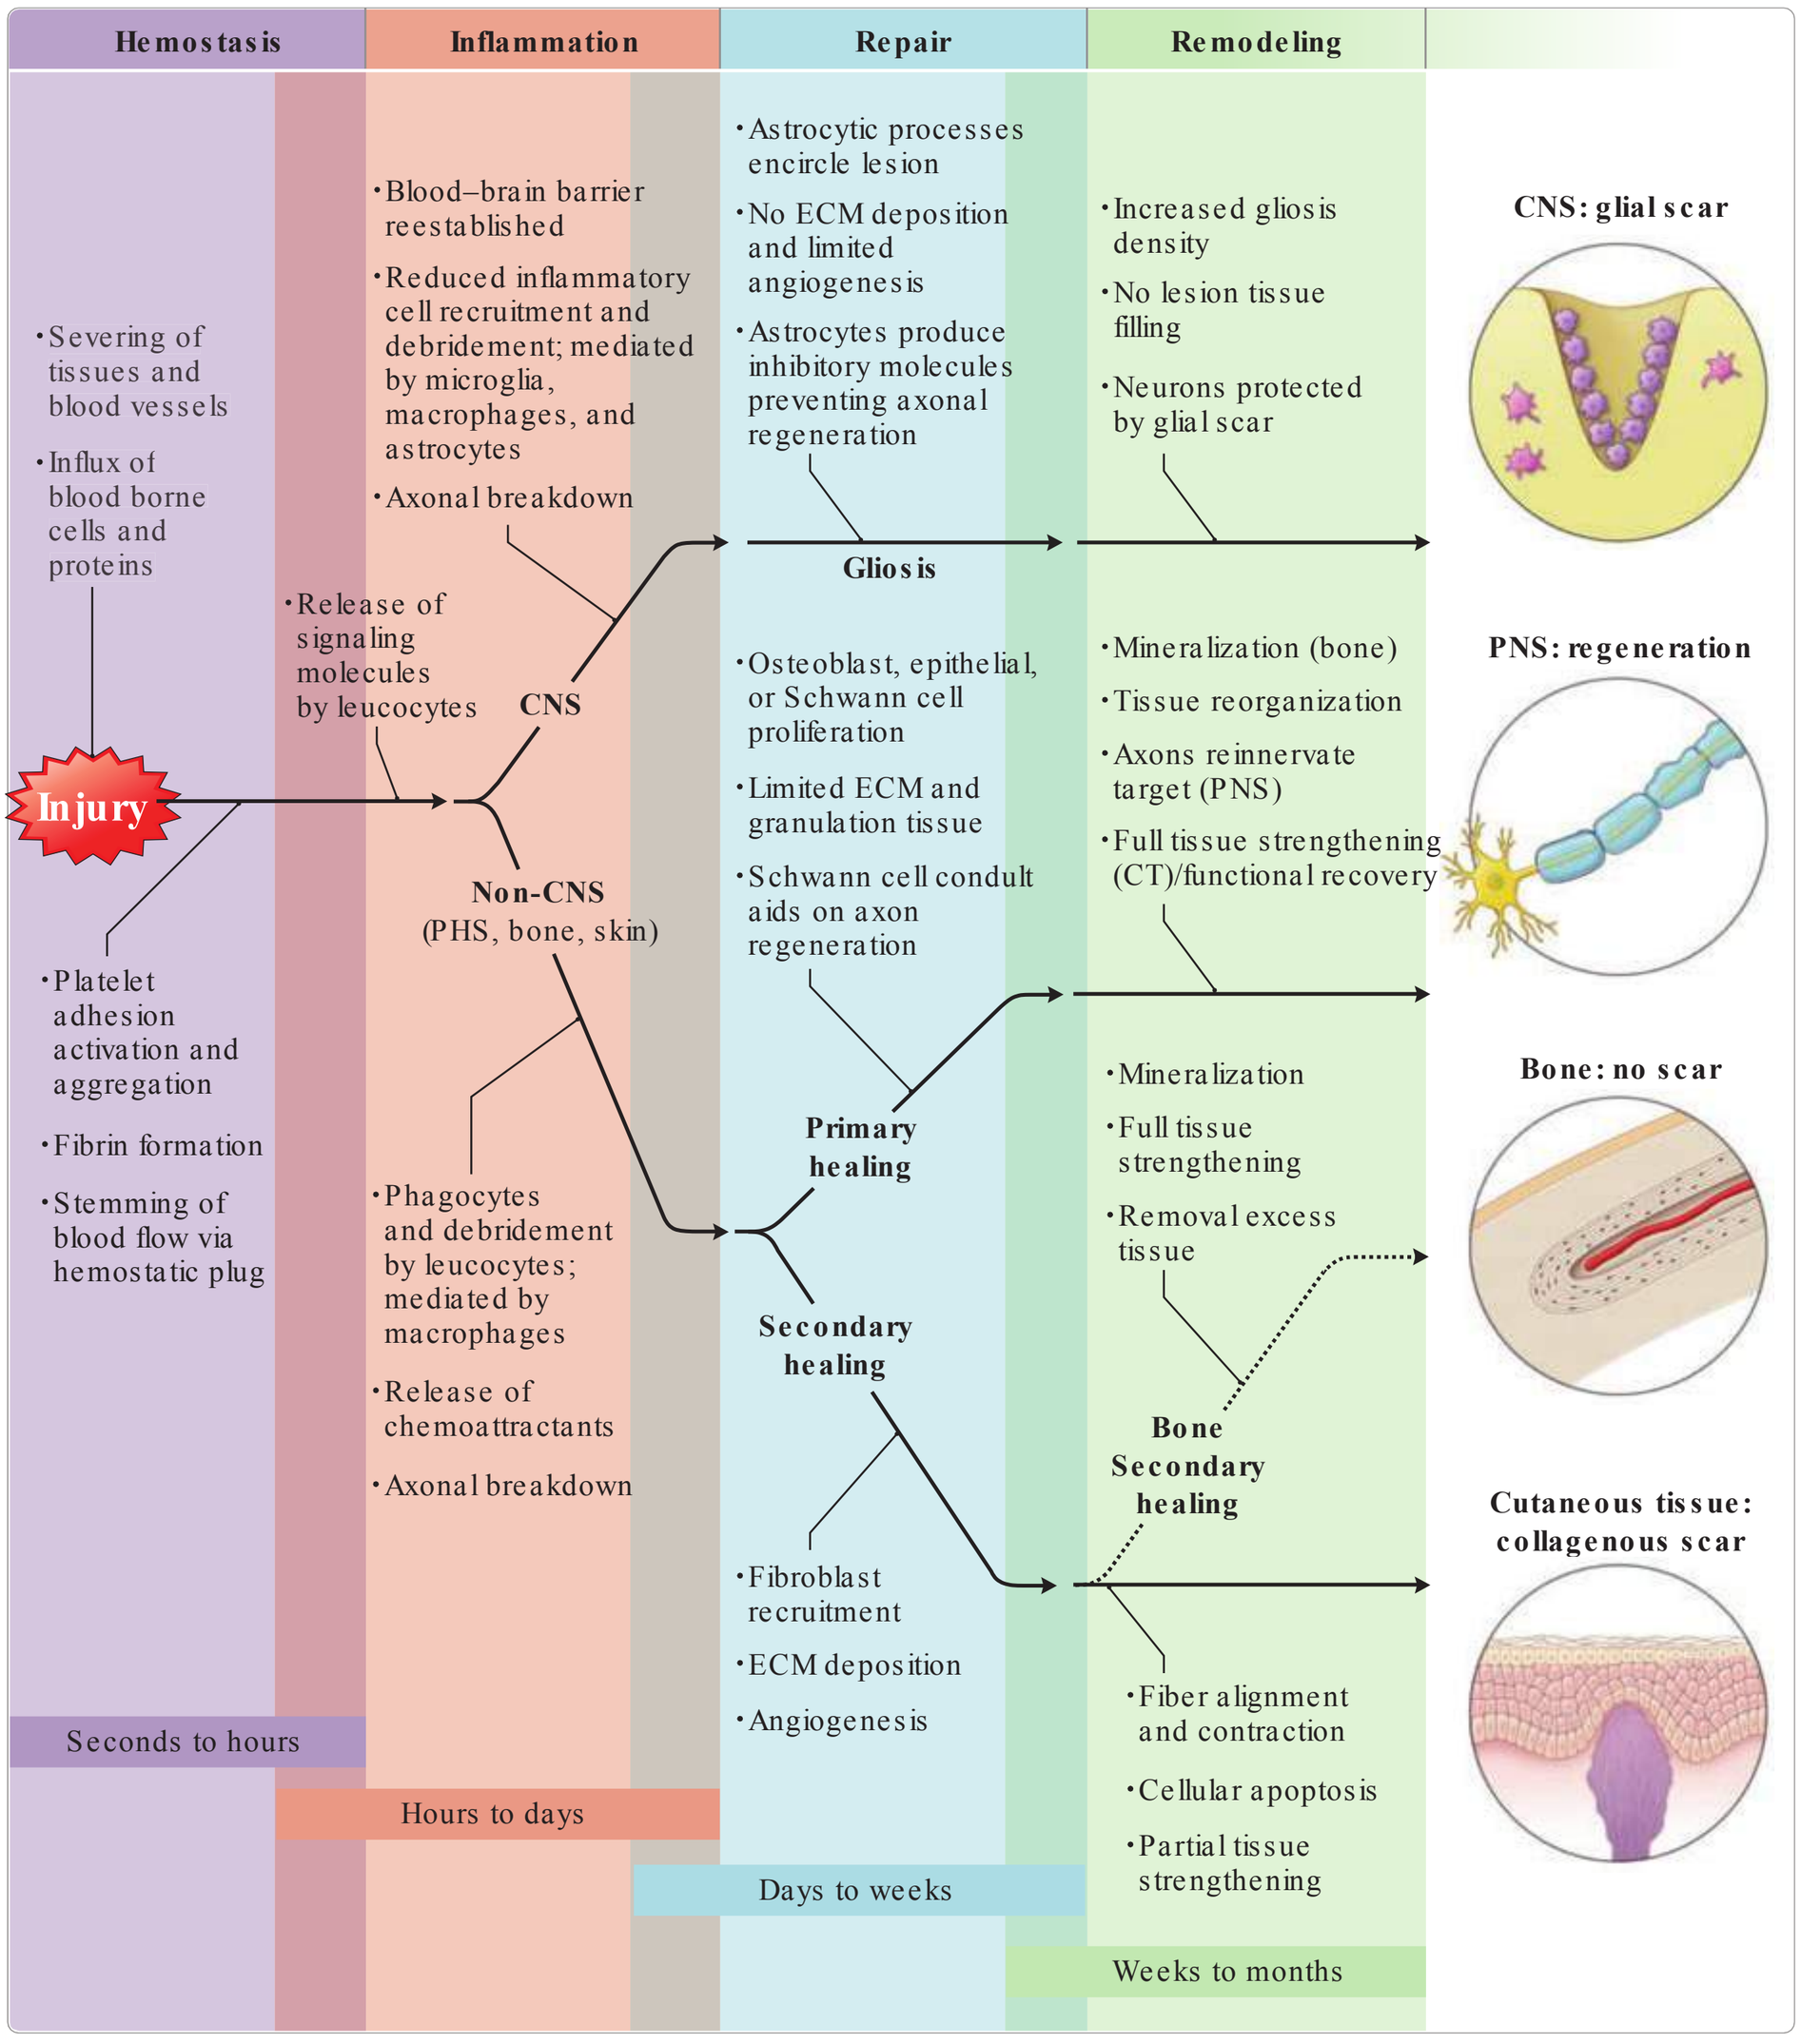

FIGURE 2-3 Stages of healing.

TABLE 2-1 Factors Impacting Healing

Intrinsic (Local)	Systemic	Extrinsic
Extent of injury. Microtears involve only minor damage, whereas macrotears involve significantly greater destruction	Age. The ability to heal injuries decreases with age	Drugs. Nonsteroidal anti-inflammatory drugs and corticosteroids decrease inflammation and swelling, resulting in decreased pain
Edema. Swelling can cause increased pressure that can impede nutrition to the injured part, inhibit neuromuscular control, and retard the healing process	Obesity. Oxygen pressure in the tissues is lower in obese patients.	Absorbent dressings. The degree of humidity greatly affects the process of epithelialization—the epithelium regenerates twice as quickly in a moist environment
Hemorrhage. Bleeding produces the same negative effects on healing as does the accumulation of edema	Malnutrition. Wound healing places a higher than usual demand on a patient's energy resources. In every stage of wound healing, protein is needed. In addition, adequate nutritional intake and body stores of all vitamins are essential.	Temperature and oxygen tension. Hypothermia has a negative effect on healing. Oxygen tension relates to the neovascularization of the wound.
Poor vascular supply. Wounds heal poorly and at a slower rate when the blood supply is inadequate	Hormone levels. Hormones affect the composition and structure of a variety of tissues.	
Separation of tissue. A wound that has smooth edges and good apposition will tend to heal by primary intention with minimal scarring.	Infection. Infection can delay healing	Physical modalities. These can be used to promote an ef cient healing environment for an injury when used individually, or in combination with other modalities or exercise
Muscle spasm. Spasm causes traction on the already torn tissue, preventing approximation.	General health. Comorbidity can play a significant role in the overall healing process. For example, diabetes can impede tissue healing	Exercise. Exercise can help in the remodeling process of all connective tissues. Wolff's law states that tissue remodeling and the response to therapeutic exercise are determined by the specific adaptation of the tissue to the imposed level of demand.
Atrophy. Consider a secondary impairment to injury and subsequent disuse		
Degree of scarring. Scarring that occurs normally, but hypertrophic scarring produces keloids when the rate of collagen production exceeds the rate of collagen breakdown		

in Table 2-1. Also, complications such as infection, compromised circulation, and neuropathy hurt the healing process and can cause great physical and psychological stress to the involved patient and his or her family.

Stages of Tissue Healing

T e general stages of soft tissue healing are described here, whereas the healing of specific structures is described later under the relevant headings. After microtrauma, macrotrauma, or disease, the body attempts to heal itself through a predictable series of overlapping events that include coagulation and inflammation (acute), which begins shortly after the initial injury; a migratory and proliferative process (subacute), which begins within days and includes the major processes of healing; and a remodeling process (chronic), which may last for up to a year depending on the tissue type, and is responsible for scar tissue formation and the development of new tissue.[14,20–24]

Whereas simplification of the complex events of healing into separate categories may facilitate understanding of the phenomenon, in reality these events occur as an amalgamation of different reactions, both spatially and temporally.[25]

T e various therapeutic approaches that can be used during each of these stages of healing are described in Chapter 8.

Coagulation and Inf ammatory Stage

An injury to the soft tissue triggers a process that represents the body's immediate reaction to trauma, which includes a series of repair and defensive events.[20,26] Following an injury to the tissues, the cellular and plasma components of blood and lymph enter the wound. Capillary blood flow is disrupted, causing hypoxia to the area. T is initial period of vasoconstriction, which lasts 5–10 minutes, prompts a period of vasodilation, and the extravasation of blood constituents.[20] Extravasated blood contains platelets, which secrete substances that form a clot to prevent bleeding and infection, clean dead tissue, and nourish white cells. T ese substances include macrophages and fibroblasts.[27] T e coagulation and platelet release results in the excretion of platelet-derived

growth factor (PDGF),[28] platelet factor 4,[29] transforming growth factor-alpha (TGF-α),[30] and transforming growth factor-beta (TGF-β).[31] The main functions of a cell-rich tissue exudate are to provide cells capable of producing the components and biological mediators necessary for the directed reconstruction of damaged tissue, while diluting microbial toxins and removing contaminants present in the wound.[25]

Inflammation is mediated by chemotactic substances, including anaphylatoxins that attract neutrophils and monocytes.

- Neutrophils. Neutrophils are white blood cells (WBCs) of the polymorphonuclear (PMN) leukocyte subgroup (the others being eosinophils, and basophils) that are filled with granules of toxic chemicals (phagocytes) that enable them to bind to microorganisms, internalize them, and kill them.
- Monocytes. Monocytes are WBCs of the mononuclear leukocyte subgroup (the other being lymphocytes). The monocytes migrate into tissues and develop into macrophages, providing immunological defenses against many infectious organisms. Macrophages serve to orchestrate a "long-term" response to injured cells subsequent to the acute response.[32]

The WBCs of the inflammatory stage serve to clean the wound debris of foreign substances, increase vascular permeability, and promote fibroblast activity.[32] Other cell participants include local immune accessory cells, such as endothelial cells, mast cells, and tissue fibroblasts. The PMN leukocytes, through their characteristic "respiratory burst" activity, produce superoxide anion radical, which is well known to be critical for defense against bacteria and other pathogens.[33] Superoxide is rapidly converted to a membrane permeable form, hydrogen peroxide (H_2O_2), by superoxide dismutase activity or even spontaneously.[32] The release of H_2O_2 may promote the formation of other oxidants that are more stable (have a longer half-life), including hypochlorous acid, chloramines, and aldehydes.[32] The phagocytic cells that initiate the innate immune response produce a set of proinflammatory cytokines (e.g., TNF-α, IL-1, and IL-6) in the form of a cascade that amplifies the local inflammatory response, influences the adaptive immune response, and serves to signal the central nervous system (CNS) of an inflammatory response (Fig. 2-3). The extent and severity of this inflammatory response depend on the size and the type of the injury, the tissue involved, and the vascularity of that tissue.[17,23,34–36]

Local vasodilation is promoted by biologically active products of the complement and kinin cascades[25]:

- The complement cascade involves 20 or more proteins that circulate throughout the blood in an inactive form.[25] After tissue injury, activation of the complement cascade produces a variety of proteins with activities essential to healing.
- The kinin cascade handles the transformation of the inactive enzyme kallikrein, which is present in both blood and tissue, to its active form, bradykinin. Bradykinin also contributes to the production of tissue exudate through the promotion of vasodilation and increased vessel-wall permeability.[37]

Because of the variety of vascular and other physiological responses occurring, this stage of healing is characterized by swelling, redness, heat, and impairment or loss of function. The edema is due to an increase in the permeability of the venules, plasma proteins, and leukocytes, which leak into the site of injury, resulting in edema.[38,39] New stroma, often called granulation tissue, begins to invade the wound space approximately 4 days after the injury.[38,39] The complete removal of the wound debris marks the end of the inflammatory process.

Clinically, this stage is characterized by pain at rest or with active motion, or when specific stress is applied to the injured structure. The pain, if severe enough, can result in muscle guarding and a loss of function. This is often referred to as the protection phase based on the focus of the intervention. The goals of the intervention during this phase are therefore to minimize pain and edema, control inflammation, restore full, passive range of motion, prevent atrophy, maintain soft tissue joint integrity, and to enhance function (see Chapter 8).

Two key types of inflammation are recognized: the normal acute inflammatory response and an abnormal, chronic, or persistent inflammatory response. Common causes for a persistent chronic inflammatory response include infectious agents, persistent viruses, hypertrophic scarring, poor blood supply, edema, repetitive mechanical trauma, excessive tension at the wound site, and hypersensitivity reactions.[40,41] The monocyte-predominant infiltration, angiogenesis, and fibrous changes are the most characteristic morphologic features of chronic inflammation. This is perpetuation of inflammation involves the binding of neutrophilic myeloperoxidase to the macrophage mannose receptor.[42]

Migratory and Proliferative Stage

The second stage of soft tissue healing, characterized by migration and proliferation, usually occurs from the time of the initial injury and overlaps the inflammation phase. Characteristic changes include capillary growth and granulation tissue formation, fibroblast proliferation with collagen synthesis, and increased macrophage and mast cell activities. This is stage handles the development of wound tensile strength.

After the wound base is free of necrotic tissue, the body begins to work to repair and close the wound (Fig. 2-3). The connective tissue in healing wounds is composed primarily of collagen, types I and III[43] cells, vessels, and a matrix that contains glycoproteins and proteoglycans. Proliferation of collagen results from the actions of the fibroblasts that have been attracted to the area and stimulated to multiply by growth factors, such as PDGF, TGF-β, fibroblast growth factor (FGF), epidermal growth factor, and insulin-like growth factor-1, and tissue factors such as fibronectin.[25] This is proliferation produces first fibrinogen and then fibrin, which eventually becomes organized into a honeycomb matrix and walls off the injured site.[44]

The wound matrix functions as glue to hold the wound edges together, giving it some mechanical protection while also preventing the spread of infection. However, the wound matrix has a low tensile strength and is vulnerable to breakdown until the provisional extracellular matrix (ECM) is replaced with a collagenous matrix. The collagenous matrix facilitates angiogenesis by providing time and protection to

new and friable vessels. Angiogenesis occurs in response to the hypoxic state created by tissue damage as well as to factors released from cells during injury.[25]

T e process of neovascularization during this phase provides a granular appearance to the wound as a result of the formation of loops of capillaries and migration of macrophages, fibroblasts, and endothelial cells into the wound matrix. Once an abundant collagen matrix has been deposited in the wound, the fibroblasts stop producing collagen, and the fibroblast-rich granulation tissue is replaced by a relatively acellular scar, marking the end of this stage.

Upon progressing to this stage, the active effusion and local erythema of the inflammation stage are no longer present clinically. However, residual effusion may still be present at this time and resist resorption.[45,46] From a clinical perspective, this phase is often referred to as the controlled motion phase. T e treatment goals for this phase are to protect the forming collagen, direct its orientation to be parallel to the lines of force it must withstand, and prevent cross-linking and scar contracture (see Chapter 8).

Remodeling Stage

An optimal wound environment lessens the duration of the inflammatory and proliferative phases and protects fragile tissue from breakdown during early remodeling. T e remodeling phase involves a conversion of the initial healing tissue to scar tissue. T is lengthy phase of contraction, tissue remodeling, and increasing tensile strength in the wound can last for up to 1 year. Fibroblasts handle the synthesis, deposition, and remodeling of the ECM. Following the deposition of granulation tissue, some fibroblasts are transformed into myofibroblasts, which congregate at the wound margins and start pulling the edges inward, reducing the size of the wound. Increases in collagen types I and III and other aspects of the remodeling process are responsible for wound contraction and visible scar formation. Epithelial cells migrate from the wound edges and continue to migrate until similar cells from the opposite side are met. T is contracted tissue, or scar tissue, is functionally inferior to original tissue and is a barrier to diffused oxygen and nutrients.[47] Eventually, the new epidermis becomes toughened by the production of the protein keratin. T e visible scar changes color from red or purple that blanches with slight pressure, to nonblanchable white as the scar matures.

Imbalances in collagen synthesis and degradation during this phase of healing may result in hypertrophic scarring or keloid formation with superficial wounds. If the healing tissues are kept immobile, the fibrous repair is weak, and there are no forces influencing the collagen—if left untreated, the scar formed is less than 20% of its original size.[48] Contraction of the scar results from cross-linking of the collagen fibers and bundles, and adhesions between the immature collagen and surrounding tissues, producing hypomobility. In areas where the skin is loose and mobile, this creates the minimal effect. However, in areas such as the dorsum of the hand where there is no extra skin, wound contracture can have a significant effect on function. Consequently, controlled stresses must always be applied to new scar tissue to help prevent it from shortening.[20,36] Scarring that occurs parallel to the line of force of a structure is less vulnerable to reinjury than a scar that is perpendicular to those lines of force.[49]

CLINICAL PEARL

Despite the presence of an intact epithelium at 3–4 weeks after the injury, the tensile strength of the wound has been measured at approximately 25% of its normal value. Several months later, only 70–80% of the strength may be restored.[50] This would appear to demonstrate that the remodeling process may last many months or even years, making it extremely important to continue applying controlled stresses to the tissue long after healing appears to have occurred.[50]

Normally, the remodeling phase is characterized by a progression to pain-free function and activity. For this reason, this healing phase is often referred to as the return to function phase (see Chapter 8). T e therapeutic goals for this phase are outlined in Chapter 8. Clinically, the chronic inflammatory response is characterized by the signs and symptoms of acute inflammation (redness, heat, edema, and pain), but at a much less pronounced level. In the ideal world, the injured patient makes a smooth transition through the various stages of healing, and the sharp and burning acute pain is replaced by a duller ache, which then subsides to a point where no pain is felt. However, a persistent chronic inflammatory response results in the continued release of inflammatory products and a local proliferation of mononuclear cells. T e macrophages remain in the inflamed tissue if the acute inflammation does not resolve, and begin to attract large numbers of fibroblasts, which invade and produce increased quantities of collagen.[13] T is failure during the healing phase continuum can result in chronic pathologic changes in the tissue. Often, the increased collagen production results in decreased extensibility of a joint or soft tissue structure. Characteristics of this chronic inflammation include a physiologic response that is resistant to both physical and pharmacologic intervention, resulting in a failure to remodel adequately, an imperfect repair, and a persistence of symptoms.[40,51] Also, fibrosis can occur in synovial structures, and in extraarticular tissues, including tendons and ligaments; in bursa; or in muscle.

MUSCLE BEHAVIOR, INJURY, HEALING, AND TREATMENT

As outlined in Chapter 1, skeletal muscles primarily function to transmit forces mechanically via their respective tendons to provide movement.

Behavior

T ere are approximately 430 skeletal muscles in the body, each of which can be considered anatomically as a separate organ. Of these 430 muscles, about 75 pairs provide the majority of body movements and postures.[52] Like any collagenous tissue, the musculotendinous unit exhibits viscoelastic properties (stress relaxation, creep, hysteresis, etc.) allowing

it to respond to load and deformation appropriately, with the rate of deformation being directly proportional to the applied force when considering the viscous property. Three important factors can influence muscle performance:[53]

- Age. With aging, the cross-sectional area of muscle decreases decline and the number of muscle fibers are reduced by about 39% by age 80.[54] Type I muscle fibers are not affected much by aging, but type II fibers demonstrate a reduction in cross-sectional area of 26% from age 20 to 80, most likely a result of denervation.[55] These changes seem to be secondary to the declining demand of the muscle and lack of physical activity, and thus can be minimized or even reversed with adequate training (see "Muscle and Aging" section).[54]
- Temperature. Collagenous tissues have an inverse temperature-elastic modulus relationship, especially at higher temperatures, which means that temperature elevation results in increased elasticity and decreased stiffness.[56] This would suggest that warming a muscle may confer a protective effect against muscle strain injury as warmer muscles must undergo greater deformation before failure. However, somewhat contradictory, a warm muscle may be prone to injury because it undergoes greater deformation to attain a given load.
- Immobilization or disuse. The effect of rigid immobilization on muscle has been well detailed (see "Detrimental Effects of Immobilization" section later). However the results of restricted motion, in which joint and associated muscles are not allowed to move through the complete range, have not been well studied. Biomechanically, muscle immobilized in a shortened position develops less force and stretches to a shorter length before becoming susceptible to injury than does a nonimmobilized muscle. A muscle immobilized in a lengthened position responds differently; greater force and a greater change in length are required to cause a tear than in nonimmobilized muscle.

Injury

Muscle injury can result from excessive strain, excessive tension, contusions, lacerations, thermal stress, and myotoxic agents, such as some local anesthetics, excessive use of corticosteroids, and snake and bee venoms.[57] The majority of muscle injuries (>90%) are caused either by excessive strain of the muscle or by contusion.[58] Muscle strains may be graded by severity (Table 2-2). Muscle injuries are the most common injury in sports, with an incidence varying from 10% to 55% of all injuries sustained in sports events.[59,60] A number of factors contribute to muscle strain injury, including:[53]

- inadequate flexibility
- inadequate strength or endurance
- dyssynergistic muscle contraction
- insufficient warm-up
- inadequate rehabilitation from the previous injury

A distraction strain occurs in muscle to which an excessive pulling force is applied, resulting in overstretching.[58] A contusion may occur if a muscle is injured by a heavy compressive force, such as a direct blow. At the site of the direct blow, a hematoma may develop. Two types of hematoma can be identified:[61]

1. Intramuscular. This type of hematoma is associated with a muscle strain or bruise. The size of the hematoma is limited by the muscle fascia. Clinical findings may include pain and loss of function.
2. Intermuscular. This type of hematoma develops if the muscle fascia is ruptured, and the extravasated blood spreads into the interfascial and interstitial spaces. The pain is usually less severe with this type.

TABLE 2-2 Classification of Muscle Injury

Type	Related Factors
Exercise-induced muscle injury (delayed muscle soreness)	Increased activity Unaccustomed activity Excessive eccentric work Viral infections Muscle cell damage
Strains	
First degree (mild): minimal structural damage; minimal hemorrhage; early resolution	Onset at 24–48 hours after exercise Sudden overstretch Sudden contraction
Second degree (moderate): partial tear; large spectrum of injury; significant early functional loss	Decelerating limb Insufficient warm-up Lack of flexibility
Third degree (severe): complete tear; may require aspiration; may require surgery	Increasing severity of strain associated with greater muscle fiber death, more hemorrhage, and more eventual scarring Steroid use or abuse Previous muscle injury Collagen disease
Contusions Mild, moderate, severe Intramuscular vs. intermuscular	Direct blow, associated with increasing muscle trauma and tearing of fiber proportionate to severity

Data from Reid DC. Sports Injury Assessment and Rehabilitation. New York, NY: Churchill Livingstone; 1992.

Healing

Skeletal muscle has considerable regenerative capabilities, and the process of skeletal muscle regeneration after injury is a well-studied cascade of events.[62–64] The essential process of muscle regeneration is similar, irrespective of the cause of injury, but the outcome and time course of regeneration vary according to the type, severity, and extent of the injury.[62,65,66] Broadly speaking, there are three phases in the healing process of an injured muscle: the destruction phase, the repair phase, and the remodeling phase.[61]

Destruction Phase

The pathology of skeletal muscle damage varies, depending on the initiating cause. Muscle damage can occur during the prolonged immobility of hospitalization and from external sources such as mechanical injury.[67] One of the potential consequences of muscle injury is atrophy. The amount of muscle atrophy that occurs depends on the usage prior to bed rest and the function of the muscle.[67] Antigravity muscles (such as the quadriceps) tend to have greater potential for atrophy than antagonist muscles (such as the hamstrings). Research has shown that a single bout of exercise protects against muscle damage, with the effects lasting between 6 weeks[68] and 9 months.[69]

Muscle resistance to damage may result from an eccentric exercise-induced morphologic change in the number of sarcomeres connected in series.[70] This finding appears to support initiating a reconditioning program with gradual progression from lower intensity activities with minimal eccentric actions to protect against muscle damage.[67,71] If a muscle is severely injured, the muscle fibers and their connective tissue sheaths are totally disrupted, and a gap appears between the ends of the ruptured muscle fibers after the muscle fibers retract.[64] This phase is characterized by the necrosis of muscle tissue, degeneration, and an infiltration by PMN leukocytes as hematoma and edema form at the site of injury.

Repair Phase

The repair phase usually involves the following steps:

- Hematoma *f*ormation. The gap between the ruptured ends of the fibers is at first filled by a hematoma. During the first day, the hematoma is invaded by inflammatory cells, including phagocytes, which begin disposal of the blood clot.[64]
- Matrix *f*ormation. Blood-derived fibronectin and fibrin cross-link to form a primary matrix, which acts as a scaffold and anchorage site for the invading fibroblasts.[63,64] The matrix gives the initial strength for wound tissue to withstand the forces applied to it.[72] Fibroblasts begin to synthesize proteins of the ECM.
- Collagen *f*ormation. The production of type I collagen by fibroblasts increases the tensile strength of the injured muscle. An excessive proliferation of fibroblasts can rapidly lead to an excessive formation of dense scar tissue, which creates a mechanical barrier that restricts or considerably delays complete regeneration of the muscle fibers across the gap.[61,64]

During the first week of healing, the injury site is the weakest point of the muscle–tendon unit. This phase also includes regeneration of the striated muscle, production of a connective-tissue scar, and capillary ingrowth. The regeneration of the myofibers begins with the activation of satellite cells, located between the basal lamina and the plasma membrane of each myofiber.[73]

Satellite cells, myoblastic precursor cells, proliferate to reconstitute the injured area.[66] During muscle regeneration, it is presumed that trophic substances released by the injured muscle activate the satellite cells.[74] Unlike the multinucleated myofibers, these mononuclear cells maintain mitotic potential and respond to cellular signals by entering the cell cycle to provide the substrate for muscle regeneration and growth.[73]

The satellite cells proliferate and differentiate into multinucleated myotubes and eventually into myofibers, which mature and increase in length and diameter to span the muscle injury. Many of these myoblasts can fuse with existing necrosed myofibers and may prevent the muscle fibers from completely degenerating.[73]

The final stage in the regenerative process involves the integration of the neural elements and the formation of a functional neuromuscular junction.[75,76] Provided that the continuity of the muscle fiber is not disrupted, and the innervation, vascular supply, and ECM are left intact, muscle will regenerate without loss of normal tissue architecture and function.[77]

Remodeling Phase

In this phase, the regenerated muscle matures and contracts with the reorganization of the scar tissue. There is often complete restoration of the functional capacity of the injured muscle. The tensile strength of the healing muscle tissue increases over time. However, whereas normal intramuscular collagenous tissue has a greater proportion of type I collagen than type III collagen, initially after injury, type III collagen demonstrates a significant increase over type I collagen in the area of repair. Over time, the proportion of type I to type III collagen returns to normal. Controlled mobility and stress are key considerations in the post-acute period to allow scar formation, muscle regeneration, correct orientation of new muscle fibers, and the normalization of the tensile properties of muscle.

Treatment

The intervention depends on the stage of healing (see Chapter 8). The following principles should guide the clinician when rehabilitating a muscle injury:[53]

- Prevention is easier than treatment. Patient education is important to inform the patient about the expected duration and extent of symptoms, and any precautions or contraindications to prevent reinjury or disruption of the healing process.
- Controlled mobility and activity are best.
- Medications and modalities can be important adjuncts to care.
- It is important to develop strong, flexible tissue using pain as the guiding factor.

The typical exercise progression involves PROM, then AAROM, then AROM, and then submaximal isometrics, initially in a protective range before progressing throughout the range. Once the patient can tolerate submaximal isometrics, a progression to maximal isometrics is made at multi-angles and then throughout the range, before progressing to progressive resistive exercises.

Muscle and Aging

With age, there is a reduction in the ability to produce and sustain the muscular power. This is age-related phenomenon,

termed senescence sarcopenia, can result in a 20–25% loss of skeletal muscle mass (see Chapter 30).[78]

CLINICAL PEARL

Sarcopenia (sarco = muscle, penia = lack of) is not a disease, but rather refers specifically to the universal, involuntary decline in lean body mass that can occur with age, primarily as a result of the loss of skeletal muscle volume.

Sarcopenia has important consequences. The loss of lean body mass reduces function, and loss of approximately 40% of lean body mass is fatal.[79,80] Sarcopenia is distinct from wasting—involuntary weight loss resulting from inadequate intake, which is seen in starvation, advanced cancer, or acquired immunodeficiency syndrome.

While a variety of studies have investigated the underlying mechanisms and treatments of age-related muscle loss, very few epidemiologic studies have looked at the prevalence, incidence, pathogenesis, and consequences of sarcopenia in elderly populations. It is likely that the determinants of sarcopenia are multifactorial and include genetic factors, environmental factors, and age-related changes in muscle tissue.[81]

The effects of aging on muscle morphology have been studied. Aging causes a decrease in muscle volume,[82] with type II fiber apparently being more affected by gradual atrophy.[83] Specifically, there is a disproportionate atrophy of type IIa muscle fibers with aging. These losses of muscular strength and muscle mass can have important health consequences because they can predispose the elderly to disability, an increased risk of falls and hip fractures, and a decrease in bone mineral density.

CLINICAL PEARL

When older people maintain muscular activity, the losses in strength with age are reduced substantially. Age-related muscle fiber atrophy and weakness may be completely reversed in some individuals with resistance training (see Chapter 30).

TENDON BEHAVIOR, INJURY, HEALING, AND TREATMENT

As outlined in Chapter 1, tendons primarily function to transmit force between muscle and bone.[84]

Behavior

The organization of the tendon determines its mechanical behavior. As tendons have more parallel collagen fibers than ligaments, and less realignment occurs during initial loading, the toe region of the load–deformation curve is smaller in tendons than in ligaments.[85] The compliance of tendons varies. Tendons of the digital flexors and extensors are very stiff, and their length changes very little when muscle forces are applied through them. In contrast, the tendons of some muscles, particularly those involved in locomotion and ballistic performance, are more elastic. For example, the Achilles tendon is stretched during the late stance phase in gait as the triceps surae is stretched as the ankle dorsiflexes. Near the beginning of the plantar flexion contraction, the muscle activation ceases and energy stored in the stretched tendon helps to initiate plantar flexion. The resting tendon has a slightly crimped or wave-like appearance. As force is applied to the tendon, a straightening of the crimp results in the toe region in the load–deformation curve (Fig. 2-2), where little force is required to change tendon length.[84] Total tendon strains (percentage deformity) of 1–2% result in the straightening of the crimp pattern of unloaded tendon collagen. Strains of 2–6% are well tolerated by most healthy tendons. However, with a strain higher than 6%, incomplete tears start to occur within the tendon, and complete structural failure typically occurs in the range of 8–10%.[86] As the load increases beyond the toe region, the collagen fibrils stretch, creating the linear region of the load–deformation curve (Fig. 2-2).[84] Most tendons likely function in the toe and early linear regions under physiological loading conditions.[87]

CLINICAL PEARL

As the amount of crimp in a tendon decreases with age, the toe region becomes smaller.

Tendon tissue homeostasis is based on the ability of the tendon cells to sense and respond to mechanical load through mechanotransduction.[88] As with all CT, tendons have a positive adaptive response to repeated physiologic mechanical loading, which results in biologic and mechanical changes. A tendon can resist tensile stress in the directional of its fibers orientation because of the collagen structure, and it can resist some compressive stress because of its proteoglycan content. The total amount of load the tendon can resist and the amount it stretches during loading depend on its cross-sectional area, composition, and length. However, tendons can adapt structurally or materially to changes in the mechanical environment as a result of load conditions.[87] The exact level of mechanical and biological stimulation required to maintain normal tendon homeostasis is not currently known, but is widely believed that an abnormal level of stimulation (under load or overload) may play a role in the pathogenesis of tendinopathy.[88] Strain injuries are common at the musculotendinous junction (MTJ), the weakest point in the muscle tendon unit.[89]

CLINICAL PEARL

The MTJ is the location of most common muscle strains caused by tensile forces in a normal muscle–tendon unit.[90,91] In particular, a predilection for a tear near the MTJ has been reported in the biceps and triceps brachii, rotator cuff muscles, flexor pollicis longus, fibularis (peroneus) longus, medial head of the gastrocnemius, rectus femoris, adductor longus, iliopsoas, pectoralis major, semimembranosus, and the entire hamstring group.[57,59,92]

Injury

Tendinopathy is a clinical syndrome, often but not always implying overuse of a tendon, characterized by a combination of pain, diffuse or localized swelling, and impaired performance.[93] Recently, it has been recommended that the term tendinopathy replace the traditional term tendinitis for describing tendon pathology.[94] Tendinitis, which is seen to a much lesser extent (<3%), is associated with the classical signs of inflammation usually observed during the early reparative phase.[95] However, confusing the issue is the fact that the noninflammatory etiology of tendinopathy has lately been questioned, as inflammation may play a role in the initial phase of the disease.[96] T is may be because the tendon insertion and bursa surrounding the tendon are common sites of classical inflammation as a response to repetitive stress, because of their greater density of blood vessels and nerves,[97] whereas the tendon proper is mostly aneural and avascular and does not, under normal conditions, exhibit classical inflammatory responses.[98,99] Tendon overuse injuries have been reported to account for 30–50% of injuries in sports and 30% of all general practitioner consultations for musculoskeletal injuries.[100] Tendons that transmit large loads under eccentric and elastic conditions, such as the Achilles and patellar tendons, are more subject to injury.[101] T us, in the lower extremity, chronic tendon overuse accounts for 30% of all running-related injuries, typically involving the patellar or Achilles tendons.[102] In the upper extremities, the supraspinatus, and extensor carpi radialis brevis tendons appear to be the most vulnerable.

T e etiology of tendinopathy is still unclear; however, histological evidence consistently demonstrates an absence of prostaglandin-mediated inflammation.[103] T e common pathological conditions associated with tendinopathy are tendinosis and peritendinitis[97]:

- Tendinosis. *T*endinosis is an intratendinous degenerative lesion without an inflammatory component (the suffix "-osis" is indicative of a degenerative process rather than an inflammatory disorder).[104] T is condition is characterized by the histopathological findings of collagen disorganization and fiber separation, increase in mucoid ground substance, hypercellularity, and nerve and vessel ingrowth but mostly without signs of intratendinous inflammation (tendinitis).[99]
- Peritendinitis. T is condition is an acute or chronic inflammation of the thin membrane, paratenon, surrounding the tendon, often induced by repetitive exercise and characterized by local swelling and infiltration of inflammatory cells.[95]

Specimens taken from torn tendons show disorientation of collagen fibers, thinning of the fibers, myxoid degeneration, chondroid metaplasia, calcification, and vascular infiltration.[105]

Although sports activity is the most common source of tendinopathy, it can be work related, drug related (e.g., cortisone, cyclosporine, statins, and quinolone antibiotics), or due to a metabolic disorder such as disturbed glucose metabolism and atherosclerosis.[97] Most tendon trauma tends to occur from loading (sudden overload or repetitive), or rapid unloading. T is mechanical loading is anabolic by upregulating collagen gene expression and increasing synthesis of collagen proteins, which peaks around 24 hours after exercise and remains elevated for up to 70–80 hours.[97] Simultaneously, there is a degradation of collagen proteins, although the timing of this catabolic peak occurs earlier than the anabolic peak, resulting in a net loss of collagen around the first 24–36 hours after training, followed by a net gain in collagen.[99] T is would tend to indicate that a certain restitution time interval in between exercise bouts is critical for the tissue to adapt and to avoid a net catabolic situation.

Mechanical overload does not seem to be the only factor to explain a tendon injury and may even be merely a permissive factor, allowing the tendon problem to become symptomatic.[106]

CLINICAL PEARL

Tendons become weaker, stiffer, and less yielding as a result of the vascular, cellular, and collagen-related alterations that occur with aging.[85]

While it is easy to understand why a sudden overload could damage a tendon, it is more difficult to understand why the application of normal loads, repeated frequently, can cause tendon damage. Repetitive loading can occur as a result of external factors, such as anatomic predisposition resulting from inflexibility, weakness, or malposition, excessive compression, and friction.[107–109]

CLINICAL PEARL

Rapid force application or release is more likely to cause tendon damage than the same load applied gradually.[110]

Muscle physiology experiments have shown the force increases as the velocity of active muscle lengthening (eccentric) increases while the opposite is true during concentric (shortening) muscle activations (see Chapter 1). Indeed, the tendon is exposed to larger loads during eccentric loading, especially if the movement occurs rapidly.[111,112] Almost all concentric contractions are preceded by a lengthening (eccentric) while the muscle is active. T is activation pattern stretches the elastic elements in the muscle–tendon unit and contributes to movement *if* the muscle is allowed to shorten immediately after being lengthened.[87]

CLINICAL PEARL

Estimates of the Bureau of Labor Statistics[113] indicate that chronic tendon injuries account for 48% of reported occupational illnesses, whereas overuse injuries in sports account for 30–50% of all sports injuries.[114]

Terminology regarding tendon pathology has been somewhat confusing. Tendon injuries are typically classified as either acute or chronic.

- Acute injuries. Acute injuries include those in which the time and method of injury are known.[87] Acute

injuries include tendon rupture and partial tendon tears. Tendinopathy can be graded according to severity:

- Grade I: Pain only after activity; does not interfere with performance; often generalized tenderness; disappears before the next exercise session.
- Grade II: Minimal pain with activity; does not interfere with intensity or distance; usually localized tenderness.
- Grade III: Pain interferes with activity; usually disappears between sessions; definite local tenderness.
- Grade IV: Pain does not disappear between activity sessions; seriously interferes with the intensity of training; significant local signs of pain, tenderness, crepitus, and swelling.
- Grade V: Pain interferes with sport and activities of daily living; symptoms often chronic or recurrent; signs of tissue changes and altered associated muscle function.

- Chronic injuries. Chronic tendon injuries are not typically associated with a known onset or with inflammation but involve repetitive loading that damages the tendon.

CLINICAL PEARL

The term tendinopathy has been used to describe any abnormal condition of the tendon.

A chronic tendon injury is characterized by the presence of dense populations of fibroblasts, vascular hyperplasia, and disorganized collagen.[115] T e disorganized collagen is termed angio*fi*broblastic hyperplasia.[116] It is thought that this disorganization results from a failure of the ECM to adapt to changes, resulting in disordered healing with the absence of inflammatory cells. Degenerative tendinopathy occurs in approximately one-third of the population older than 35 years of age.[117] Although it is commonly presumed that pain results from an inflamed structure, it is not clear why tendinosis is painful, given the absence of acute inflammatory cells, nor is it known why the collagen fails to mature. Necropsy studies have shown that these degenerative changes also may be present in asymptomatic tendons.[118] T e degree of degeneration increases with age and may represent part of the normal aging process.[90] T e degeneration appears to be activity related, as well (see Chapter 30).[90]

T e typical clinical finding for tendinopathy is a strong but painful response to the resistance of the involved musculotendinous structure.

Healing

T ere are some factors that handle the poor healing potential of tendinous tissue, and these include:

- T e oxygen consumption by tendons (and ligaments) is 7.5 times lower than skeletal muscle, resulting in a lower metabolic rate.[119]
- T e blood vessels do not extend beyond the proximal third of the tendon.
- Healing can create adhesion formation and even though remodeling occurs, the biochemical and mechanical properties are never the same as normal tendon tissue.

If an acute tendon injury disrupts vascular tissues within the tendon, it results in a well-studied healing process involving three overlapping phases[120]:

- Inflammatory response: T is occurs as a hematoma forms within erythrocytes and activated platelets. T is is followed by the infiltration of inflammatory cells, including neutrophils, monocytes, and macrophages that migrate to the injury site to remove debris. Shortly after, chemotactic signals induce fibroblasts to start synthesizing collagen.[104] Following injury, the initial inflammatory stage triggers an increase in glycosaminoglycans (GAG) synthesis within days, rapidly followed by synthesis of types I and III collagen, such that the healing wound can be subjected to low levels of force within a matter of days.[87,121–124]
- Repair: T is phase involves the deposition of collagen and tendon matrix components.
- Remodeling: During this phase the collagen becomes more structured and organized, although the injured site never achieves the original histologic or mechanical features of a healthy uninjured tendon.

Unlike most soft tissue healing, healing tendons pose a particular problem as they require both extensibility and flexibility at the site of attachment.[19,122–124] A judicious application of force is necessary to encourage collagen synthesis and collagen fiber cross-linking, which in turn facilitates the new collagen fibrils to align in the direction of force application (see Chapter 8).[87]

Treatment

While the treatment for tendinopathy appears relatively straightforward, tendinopathies are difficult to grade in terms of guiding treatment or prognosis. Since inflammatory infiltrates are largely absent in tendinopathy, it is recognized that anti-inflammatory strategies are ineffective for this condition. T is shift in understanding of pathophysiology has prompted the use of interventions such as eccentric exercises to be considered as a viable option for rehabilitation.[125] For example, the eccentric heel drop exercise is commonly used in clinical practice for Achilles tendinopathy although the mechanical properties are not clear. Table 2-3 outlines some guidelines for treatment.

Some biomechanical factors are important to consider during the treatment of tendinopathies, which include:[4]

- Tendon mechanical properties in healthy individuals may respond to exercise by increasing stiffness if a specific threshold is exceeded.
- Tendon mechanical properties are affected by a variety of common conditions (e.g., bed rest, tendinopathy, and rupture), usually by decreasing stiffness.
- Exercises that targets tendon stiffness likely will need to hit a specific threshold, and possibly frequency, to be effective.

TABLE 2-3 Eccentric-Based Treatment for Chronic Tendinopathy

Principles and Method	Description
1. Warm-up	A generalized exercise such as cycling or like jogging that does not cause local pain or discomfort local heating modality, such as hot pack ultrasound
2. Stretching to improve flexibility	A minimum of two 30-second static stretches of the involved musculotendinous unit and its antagonist(s)
3. Completion of the specific eccentric exercise	Three sets of 10 repetitions, with a brief rest or stretch between each set. Symptoms should be felt after 20 repetitions (i.e., between 20 and 30 repetitions) at a level similar to that felt during activities. -If pain is felt before the 20th repetition, either the speed of movement is reduced, or the load is decreased -If no pain is experienced by 30 repetitions, the speed or load is increased. The intensity of subsequent treatments is based on the patient's response to the previous treatment
4. Repeat flexibility exercises	See step 2
5. Apply ice	Ice is applied for 10–15 minutes to the painful to palpation area

Data from Curwin SL. Tendon pathology and injuries: Pathophysiology, healing, and treatment considerations. In: Magee D, Zachazewski JE, Quillen WS, eds. Scientific Foundations and Principles of Practice in Musculoskeletal Rehabilitation. St. Louis, MO: WB Saunders; 2007:47–78.

Treatment of tendinosis involves a multifaceted approach, which includes:[87]

- The identification and removal of all negative internal and/or external forces/factors.
- The establishment of a stable baseline for treatment.
- The determination of the tensile load starting point
- A progression of the loading program according to the patient's symptoms. Eccentric training produces around 20% more load on the tendon compared with concentric training.[126] Studies have shown that exercise, particularly eccentric-based exercise (Table 2-3), has positive effects on the mechanical and structural properties of tendons:
  - Nakamura et al.[127] demonstrated that eccentric exercises contributed to stable angiogenesis in early tendon injury whereas concentric exercises did not. Daily eccentric exercises were clinically beneficial and not harmful to tendon microcirculation.
  - Knobloch et al.[128] showed in a controlled study that in tendinosis lesions, an eccentric loading program resulted in a significant decrease in the paratenon vascularity and pain while not changing the oxygen saturation of the paratenon tissues.
  - Shalabi et al.[129] demonstrated decreased tendon volume, decreased magnetic resonance imaging (MRI) signal in the tendinosis lesions, and improved clinical pain scores in patients with Achilles tendinosis who were treated with eccentric training regimens.
  - Dimitrios et al.[130] reported that eccentric training and static stretching exercises combined were superior to eccentric training alone to reduce pain and improve function in patients with patellar tendinopathy.
  - Conversely, immobilization adversely affects the biomechanical properties of a tendon, resulting in decreased tensile strength, increased stiffness, and a reduction in total weight.[85]
- The control of pain.
- Addressing the entire kinetic chain.

Also, other modes of conservative treatment can be incorporated including:[104]

- Extracorporeal shockwave therapy (ESWT). Chen et al.[131] demonstrated that ESWT promoted tendon healing in a collagenase-induced tendinopathy of a rat tendon. Rompe et al.[132] showed in a randomized controlled trial that eccentric exercise, combined with ESWT, was more effective than eccentric exercise alone. In contrast, Zwerver et al.[133] found that when ESWT was used as a solitary treatment during the competitive season, it demonstrated no benefit over placebo treatment in the management of actively competing jumping athletes with patellar tendinopathy who had symptoms for less than 12 months.[134]
- Nonsteroidal anti-inflammatory agents (NSAIDs) and corticosteroids. Although steroids have been commonly used in the treatment of tendinosis, their benefit appears to be limited to short-term improvement in pain (i.e., < 6 weeks), as there is no evidence to suggest long-term improvement.[135] The is lack of efficacy is likely explained by the absence of inflammation as a significant factor in tendinosis pathology.
- Sclerosing treatments. Several studies have demonstrated that sclerosing treatment aids in the neovascularization of tendinosis lesions.[136,137]
- Platelet-rich plasma (PRP). PRP appears to be a promising intervention for tendinosis lesions.[138,139]
- Nitric oxide. Nitric oxide is an important cell signal molecule and appears to be involved in numerous tissue types, responses to mechanical loading, modulating tendon healing, and collagen synthesis.[140]
- Matrix metalloproteinase inhibitors. This is a recent intervention for tendinosis. Matrix metalloproteinase inhibitors aim to decrease the catabolic enzymatic activity in tendinosis lesions.[141]

If the patient fails to improve, the clinician must consider the following possibilities:[87]

- Incorrect loading magnitude or progression
- Incorrect diagnosis
- Noncompliance
- An unrecognized external factor

LIGAMENT BEHAVIOR, INJURY, HEALING, AND TREATMENT

As outlined in Chapter 1, ligaments function to bind bones together at or near the margins of bony articulation.

Behavior

Because of their function as joint stabilizers, when a ligament is damaged, there is a loss of normal kinematic relationships between the connected bones, with the degree of loss based on severity. Structural changes occur in ligaments as a function of age. In middle-age, both ligaments and bone insertion sites begin to weaken, resulting in progressive losses in structural strength and, in the elderly, ligaments lose mass, stiffness, strength, and viscosity.[7] Hormone levels can also affect ligaments producing gender-specific alterations. For example, it has been reported that joint and ligament laxity can change during pregnancy due to the presence of the hormone relaxin, and during different phases of the menstrual cycle.[142,143] Finally, ligament complexes are extremely sensitive to load and load history, such that load deprivation causes a rapid deterioration in ligament biochemical and mechanical properties, which results in a net loss in ligament strength and stiffness.[144–146] Conversely, movement has been shown to maintain normal ligament behavior, although it is not clear how much movement is required to maintain baseline ligament behaviors.[147] Exercise appears to increase ligament strength and stiffness.

Injury

In any particular position of a joint, several ligaments around the joints are likely to be in a taut state. If an external load is then applied to that joint, those ligaments that are taut will absorb the greatest amount of energy. If the load is sufficient to deform a taut ligament past its elastic (recovery) limit, the ligament will fail, and other ligaments, or structures will simultaneously become recruited into tension.[7] Depending on the size of the load, a subsequent injury can also occur to other ligaments or structures. It is, therefore, unlikely for a truly isolated ligament injury ever to occur.[7] Point tenderness, joint effusion, and a history of trauma, are all characteristic of a ligamentous injury. Ligament injuries, referred to as sprains, may be graded by severity (Table 2-4). Stress tests applied perpendicular to the normal plane of joint motion can help distinguish between grade II and grade III ligament injuries. In grade III injuries, significant joint gapping occurs with the application of the stress test.[148] However, because of patient discomfort and guarding against possible pain, it is difficult to assess joint laxity by clinical examination alone. Currently, clinicians often use ancillary tests such as arthrometry or MRI when diagnosing and grading soft tissue injuries.

Healing

T e process of ligament healing follows the same course of repair as with other vascular tissues. However, intraarticular ligaments such as the anterior cruciate ligament (ACL) do not heal as well as extraarticular ligaments, because intraarticular ligaments have a limited blood supply and the synovial fluid may significantly hinder an inflammatory response.[85] T e healing of extraarticular ligaments, however, occurs in four overlapping phases.

TABLE 2-4 Ligament Injuries

Grade	Description	Signs and Symptoms	Implications
I (mild)	Some stretching or tearing of the ligamentous fibers	Mild pain Little or no swelling Some joint stiffness Minimal loss of structural integrity No abnormal motion Minimal bruising	Minimal functional loss Early return to training-some protection may be necessary
II (moderate)	Some tearing and separation of the ligamentous fibers	Moderate to severe pain Joint stiffness Significant structural weakening with abnormal motion Often associated hemarthrosis and effusion	Tendency for recurrence Need protection from risk of further injury May need modified immobilization May stretch out further with time
III (complete)	Total rupture of the ligament	Severe pain initially followed by little or no pain (total disruption of nerve fibers) Profuse swelling and bruising Loss of structural integrity with marked abnormal motion	Needs prolonged protection Surgery may be considered Often permanent functional instability

Phase I: Hemorrhagic

After disruption of the tissue, the gap is filled quickly with a blood clot (hematoma). PMN leukocytes and lymphocytes appear within several hours, triggered by cytokines released within the clot. The PMN leukocytes and lymphocytes respond to autocrine and paracrine signals to expand the inflammatory response and recruit other types of cells to the wound.[76]

Phase II: Inflammatory

Macrophages arrive within 24–48 hours and are the predominant cell type within several days. Macrophages perform phagocytosis of necrotic tissues and also secrete multiple types of growth factors that induce neovascularization and the formation of granulation tissue. By the third day after the injury, the wound contains macrophages, PMN leukocytes, lymphocytes, and multipotential mesenchymal cells, growth factors, and platelets. The growth factors are not only chemotactic for fibroblasts and other cells, but also stimulate fibroblast proliferation and the synthesis of collagen types I, III, and V, as well as noncollagenous proteins.[149,150]

Phase III: Proliferation

The last cell type to arrive within the wound is the fibroblast. Although debate continues, it currently is thought that fibroblasts are recruited from neighboring tissue and the systemic circulation.[151] These fibroblasts have abundant rough endoplasmic reticulum and begin producing collagen and other matrix proteins within 1 week of injury. By the second week after the disruption, the original blood clot becomes more organized because of cellular and matrix proliferation. Capillary buds begin to form. Although, the total collagen content is greater than in the normal ligament or tendon, the collagen concentration is lower, and the matrix remains disorganized.

Phase IV: Remodeling and Maturation

Phase IV is marked by a gradual decrease in the cellularity of the healed tissue. The matrix becomes denser and longitudinally oriented. Collagen turnover, water content, and the ratio of collagen types I to III begin to approach normal levels over several months.[152] An integrated sequence of biochemical and biomechanical signals are critical to ligament remodeling. These signals regulate the expression of structural and enzymatic proteins, including degradation enzymes such as collagenase, stromelysin, and plasminogen activator.[149] The healed tissue continues to mature but will never attain normal morphologic characteristics or mechanical properties. Ligament injuries can take as long as 3 years to heal to the point of regaining near-normal tensile strength,[153] although some tensile strength is regained by about the fifth week following injury, depending on the severity.[22,154–156] A ligament may have 50% of its normal tensile strength by 6 months after injury, and 80% after 1 year.[157–159]

Treatment

Immobilization and disuse dramatically compromise the structural material properties of ligaments, resulting in a significant decrease in the ability to resist strains and absorb energy.[85] Forces applied to the ligament during its recovery help it to develop strength in the direction that the force is applied.[157–161] Several studies have shown that actively exercised ligaments are stronger than immobilized ones. Thus, it is important to minimize periods of immobilization and to stress the injured ligaments progressively while exercising caution about the biomechanical considerations for specific ligaments.[162] The current concept is that very low cyclical loads on ligaments promote scar proliferation and material remodeling, thus making the scar stronger and stiffer structurally[163,164] and, possibly, materially.[7] In conjunction with exercise, it appears that the use of ice immediately after ligament injury decreases bleeding, swelling, and inflammation,[165] whereas heat, when used after the first 48 hours appears to increase blood flow (see Chapter 8). However, it is not known whether ice or heat have any effect on scar formation, or on the quality or quantity of ligament healing.

The surgical repair of torn ligament ends has been noted in the past to induce faster and stronger healing through a process that is likened to regeneration rather than scar formation.[7,166] However, although surgically repaired extraarticular ligaments heal with decreased scar formation and are stronger than unrepaired ligaments initially, this strength advantage might not be maintained as time progresses.[19]

Currently, some biological approaches are being used to improve ligament repair, including the use of growth factors and gene therapy:[7]

- Growth factors. Growth factors are molecules that modify cell proliferation or the secretion of proteins. Thus far, the uses of growth factors in ligament healing have demonstrated variable results.
- Gene therapy. Gene therapy refers to the modification of the genetic expression of cells. The introduction of marker and therapeutic genes into ligaments using vectors has demonstrated initial success with evidence of functional alterations.[167] Also, gene transfer has been used to manipulate the healing environment, opening the possibility of gene transfer to investigate ligament development.[167]

JOINT BEHAVIOR, INJURY, HEALING, AND TREATMENT

As described in Chapter 1, the amount of motion available at a joint is based on a number of factors, including the type of joint, the shape of the articulating surfaces, the health of the joint and the surrounding tissues, and the load-deformation history of the joint.

To discuss these concepts, it is important to have an understanding of the normal barriers that can be felt during movement. Three distinct areas or zones are recognized:[168]

- Neutral zone: the zone in which there is little or no internal resistance offered by the tissues to movement and the range in which the crimp of the tissue is being taken up. Increases in the size of the neutral zone result in the feeling or perception that the crimp is taken up later in the range of motion. Such increases can occur because of injury, and joint instability, joint degeneration, and muscle dysfunction (leading to loss of muscular control of the movement).[169]

In contrast, the size of the neutral zone may be decreased by osteophyte formation, surgical fusion, muscle spasm, muscle strengthening, or adaptive tissue shortening.

- Elastic zone: the zone in which the first barrier or restriction of movement occurs. T is zone occurs at the end of the neutral zone after the crimp has been taken up, and tension starts to build within the tissues. T e elastic zone extends from the crimp area through the physiological barrier (end of active movement) and toward the anatomic barrier (end of passive movement). T e elastic zone can be increased by injury to the joint structures, mobilization techniques, and muscle lengthening, and be decreased by osteophyte formation, surgical fusion or repair, muscle hypertrophy, or immobilization.
- Plastic zone: the zone in which deformation of the tissue is extended beyond the tissue's elastic recoil and the tissue begins to deform. If the deformation is sufficient, an injury can occur.

Behavior

T e working relationship of a door hinge and doorstop is a good analogy when describing joint motion behavior, in which the hinge represents the joint, and the doorstop represents the restriction imposed by the integrity of the joint and the surrounding tissues. Just as the doorstop prevents the door from swinging too far and damaging the wall, the integrity of the joint and its surrounding structures serve to prevent the joint moving past the normal range of motion and incurring injury.

T ree descriptors are used to describe normal and abnormal joint motion:

- Hypomobile. If the movement of a joint is less than that considered normal, or when compared with the same joint on the opposite extremity, it may be deemed hypomobile. Hypomobility can be secondary to any of the following:[170]
  - Joint fixation. T is can occur when the joint is stuck at the extreme of the range of motion secondary to a sudden macrotrauma, a prolonged or repeated microtrauma, or a microtrauma imposed on instability. Clinical findings associated with a joint fixation include limitation of gross motion or conjunct rotation toward the limitation. Also, the clinician notes that the end feel in the direction opposite the fixation is abnormal and has a rather firm capsular end feel (see Chapter 4).
  - Myofascial hypomobility. T is is caused by muscle shortening (scars, contracture, or adaptive tissue changes). Clinical findings for myofascial hypomobility include an elastic end feel and a constant-length phenomenon. T e constant-length phenomenon occurs when the amount of movement available at one joint is dependent upon the position in which another joint is held. For example, during a supine straight-leg raise, due to the anatomy (length) of the hamstrings, the amount of available hip flexion is decreased if the knee is maintained in a fully extended position as opposed to when the knee is allowed to flex.
  - Articular hypomobility. T is can be caused by intraarticular swelling or an intraarticular bleed. Clinical findings for an articular hypomobility include a spasm, or empty end feel, often accompanied with a capsular pattern (see Chapter 4). An arthrosis is a limitation of joint motion without inflammation.
  - Pericapsular hypomobility. T is is caused by capsular or ligamentous shortening, which creates a capsular pattern of restriction that does not demonstrate the constant-length phenomenon. Also a premature firm/hard capsular end feel exists if the joint is not inflamed, or possibly a spasm end feel if the joint is inflamed.
- Hypermobile. A joint that moves more than is considered normal, or when compared with the same joint on the opposite extremity, may be deemed hypermobile. Laxity, a function of the ligament and joint capsule resistance, is a term used to imply that an individual has an excessive joint range of motion but can control the movement of the joint in that extra range. Hypermobility may occur as a generalized phenomenon or be localized to just one direction of movement, as follows:
  - Generalized hypermobility. T e more generalized form of hypermobility, as its name suggests, refers to the manifestations of multiple joint hyperlaxity/hypermobility. T is type of hypermobility can be seen in acrobats, gymnasts, and those individuals who are "double jointed." Also, generalized hypermobility occurs with genetic diseases that include joint hypermobility as an associated finding, such as Ehlers–Danlos syndrome (see Chapter 5), osteogenesis imperfecta, and Marfan's syndrome.
  - Localized hypermobility. Localized hypermobility is likely to occur as a reaction to neighboring stiffness. For example, a compensatory hypermobility may occur at a joint when a neighboring joint or segment is injured and becomes hypomobile. T is decrease in movement of the neighboring joint is often the result of the body's initial response to trauma, which is a reflexive increase in the tone of the muscles in an attempt to stabilize the affected area. Over time, the prolonged increased tonus may result in a decreased blood supply and an increase in the buildup of lactic acid. Also, the nociceptor's response in the muscle or the joint capsule may result in an inhibition of the segmental muscles, which, in turn, may lead to uncoordinated movements and produce myofascial trigger points.

CLINICAL PEARL

A distinction must be made between laxity, hypermobility, and flexibility.

- Laxity: a normal finding unless associated with symptoms
- Hypermobility: a laxity associated with symptoms manifested by the patient's inability to control joint during movement, especially at end range.[171]
- Flexibility is a function of contractile tissue resistance primarily, but also as a function of ligament and joint capsule resistance (see Chapter 13). Two types are recognized:[171]
  - Static: related to the available range of motion in one or more joints
  - Dynamic: related to stiffness and ease of movement

- Unstable. In contrast to a hypermobile joint, an unstable joint is associated with a potential or real pathologic state as it involves a disruption of the osseous and ligamentous structures of that joint as the result of some applied external load. T e term instability, specifically related to the joint, has been the subject of much research.[172–187] Instability implies that an individual has increased joint range of motion and does not have the ability to stabilize the joint (loss of neuromuscular control). T is loss of control results in pain, weakness, and transitory deformity. Joint stability may be viewed as a factor of joint integrity, elastic energy, passive stiffness, and muscle activation.
  - Joint integrity. Joint integrity is enhanced in those ball-and-socket joints with deeper sockets, or steeper sides, as opposed to those that are planar and shallower. Joint integrity is also dependent on the attributes of the supporting structures around the joint, and the extent of any local joint disease. One such structure is the intraarticular disk, which is present in a number of joints, including the tibiofemoral joint (meniscus), the acromioclavicular joint, the temporomandibular joint, the sternoclavicular joint, and the distal radioulnar joint.
  - Muscle activation. Muscles and tendons (see Chapter 1) can provide static stabilization (isometric contraction) and dynamic stabilization (agonist concentric and antagonist eccentric contractions—see Chapter 12). Passive stability is provided when the contractile unit is on a stretch. Intrinsic muscle factors affecting stabilization include temporal summation, length–tension relationships, force–velocity relationships, and muscle architecture (see Chapter 1). Muscle activation can provide two forms of stabilization through the use of stabilizer and mobilizer muscles. T e stabilizer muscles contract first to provide a stable base from which the mobilizer muscles can function to position a joint for functional use. For example, in the spine, the stabilizer muscles are divided into two groups: local stabilizers and global stabilizers (see Chapter 28).[168] From a rehabilitation standpoint, before retraining the mobilizer muscles, the clinician must ensure that the stabilizer muscles are performing correctly. T is is the concept behind core stabilization or stabilization retraining progressions (see Chapters 12 and 14).
  - Passive sti*ff*ness. Passive stiffness is provided by the ligaments, capsules, skin, joints, bones, and other collagenous tissue. An injury to these passive structures that results in an inherent loss in the passive stiffness results in joint laxity.[188] Individual joints have a passive stiffness that increases toward the joint's end range. Dysfunction of the passive system is due most commonly to mechanical injury, overuse or repetitive stress, joint degeneration, or a disease process (e.g., rheumatoid arthritis).[168]
  - Muscle activation. T e central and peripheral nervous systems provide control through neural feedforward and feedback mechanisms from both active (muscle spindles, and Golgi tendon organs) and passive systems (joint afferents) all of which help determine position, load, and joint demands, while simultaneously controlling the contractile system to initiate conscious and unconscious movement (see Chapter 3).[168] Muscle activation increases stiffness, both within the muscle and within the joint(s) it crosses.[189] However, the synergist and antagonist muscles that cross the joint must be activated with the correct and appropriate activation in terms of magnitude or timing. A faulty motor control system may lead to inappropriate magnitudes of muscle force and stiffness, allowing a joint to buckle or undergo shear translation.[189]

Pathologic breakdown of the above factors may result in clinical instability. Instability is most obvious in movements that are executed too quickly or in cases where the loads placed on the joint are too great for the patient to control. For assessment purposes, instability can be divided into three types:

- Translational refers to a loss of control of the small, arthrokinematic joint movements that occur when the patient attempts to stabilize the joint during movement.
- Anatomical refers to excessive or gross physiological movement in the joint, which can lead to abnormal patterns of coupled and translational movements.[190]
- Functional occurs when the severity of the instability adversely affects a patient's function and can include both translational and anatomical instability. Functional instability may result in the following:[191–193]
  - Long-term nonacute pain or short-term episodic pain;
  - Early morning stiffness;
  - Inconsistent function and dysfunction (e.g., full range of motion but abnormal movement, which may include angulation, hinging, or deviation);
  - A feeling of apprehension or giving way.

Methods to enhance joint stability are provided in Chapter 12.

Injury

Using the door hinge and stop analogy again, it can be seen that both too much motion (resulting in damage to the wall) and too little motion (resulting in an inability to get through the door opening) can be disadvantageous. Similar consequences can be seen at a joint: a hypermobile joint may have insufficient stability to prevent damage occurring, whereas a hypomobile joint may provide insufficient motion at the joint for it to be functional. Hypermobile joints usually preserve their stability under normal conditions, remaining functional in weight bearing, and within certain limits of motion.

Pathologic barriers, which can occur anywhere in the range of motion, are restrictions to a movement that occur as a result of a pathologic process. T e causes of pathologic barriers include microtrauma or macrotrauma, muscle spasm, edema, pain, and adaptive shortening or lengthening of the tissue. T ree types of pathologic barriers are recognized:[168]

- Motion barrier. T is type of barrier is related to muscle hypertonus, muscle spasm, adaptive muscle shortening, intraarticular block, or muscle pain.

- Collagen barrier. This type of barrier results from a pathologic process affecting collagenous tissues, and usually results in adaptive shortening or pain, shifting the motion barrier to the left (earlier into the range of motion), resulting in a decrease in range of motion.
- Neurodynamic barrier. This type of barrier is the result of a pathologic process of neural tissues that must undergo lengthening and shortening in the course of range of motion and is manifested by the presence of neurological signs that commonly restrict movement—neural tension (see Chapter 11).

Healing

The healing of the joint surfaces is described in the next section (Articular Cartilage Behavior, Injury, Healing, and Treatment). In those cases where the joint restriction is caused by muscle hypertonus, muscle spasm, adaptive muscle shortening, intraarticular block, muscle pain, adaptive shortening of the local and surrounding soft tissues, neural tension, there are a number of manual techniques and prescribed exercises that can accelerate the return to function (see Chapters 10 and 11).

Treatment

It is essential to distinguish patients who have greater mobility in all their joints (generalized hypermobility) from those who for some other reason have one or a few joints that are more mobile than the rest (localized hypermobility). While intervention is unlikely to be either warranted or of benefit with generalized hypermobility, the intervention for a localized hypermobility should address any neighboring hypomobility.

ARTICULAR CARTILAGE BEHAVIOR, INJURY, HEALING, AND TREATMENT

Behavior

Articular cartilage is an avascular and aneural tissue composed of chondrocytes and ECM. Articular cartilage consists of two phases: a fluid phase and a solid phase. Water is the principal component of the fluid phase, contributing up to 80% of the wet weight of the tissue. The solid phase is characterized by the ECM, which is porous and permeable.[194] In adults, the articular cartilage matrix is separated from the subchondral vascular spaces by the subchondral plate. The thickness of the articular cartilage at various joints varies. For example, the articular cartilage of the knee is highly variable in nature, with an average depth of 2–4 mm.[195] Due to its avascularity, articular cartilage has low metabolic activity and poor regenerative capacity.[194] Nutrition of the articular cartilage occurs by diffusion from the synovial fluid. Chondrocytes, which account for 5% of the wet weight of articular cartilage, are responsible for the development, maintenance, and repair of the ECM (see Chapter 1). Without a direct supply of nutrients from blood vessels or lymphatics, chondrocytes depend primarily on an anaerobic metabolism. Chondrocytes in loaded joints experience hydrostatic compressive, tensile, and shear forces.

CLINICAL PEARL

Age determines the composition of the ECM, as well as the organization of chondrocytes and their response to external factors such as cytokines.[196] With increasing age, there are zonal changes in the distribution of chondrocytes, although the total number of chondrocytes remains essentially unchanged. However, with increasing age, there is a decrease in the hydration of the matrix, with a corresponding increase in compressive stiffness resulting in increased forces for the underlying subchondral bone.[197]

Provided the joint load forces are applied at an appropriate level, normal articular cartilage structure, and function will be maintained. Specifically, the intermittent hydrostatic pressure is believed to maintain healthy cartilage in contrast to shear stresses, prolonged static loading, or the absence of loading.[198] In contrast, immobilization results in degenerative changes that are similar to those seen in osteoarthritis (OA). The development of disease such as OA is associated with dramatic changes in cartilage metabolism. This occurs when there is a physiological imbalance of degradation and synthesis by chondrocytes.[199]

The biomechanical behaviors of articular cartilage are best understood when the tissue is used as a biphasic medium (fluid and solid).[197] The solid phase contains collagen and proteoglycans while the fluid phase is composed of water and ions. The solid phase has high frictional resistance to fluid flow, thus low permeability, which causes a high interstitial fluid pressurization in the fluid phase.[194] The relationship between proteoglycan aggregates and interstitial fluid provides compressive resistance to articular cartilage through negative electrostatic repulsion forces.[197] The initial and rapid application of articular contact forces during joint loading causes an immediate increase in interstitial fluid pressure, which causes the fluid to flow out of the ECM, generating a large frictional drag on the matrix.[200] This fluid pressure provides a significant component of total load support, thereby reducing the stress acting upon the solid collagen–proteoglycan matrix.[201] When the compressive load is removed, interstitial fluid flows back into the tissue. The low permeability of articular cartilage prevents fluid from being quickly squeezed out of the matrix, and the two opposing bones and surrounding cartilage confine the cartilage under the contact surface, which serves to restrict mechanical deformation.[197]

Articular cartilage is viscoelastic and exhibits time-dependent behavior when subjected to a constant local deformation.[56]

The meniscus, when present in a joint (it can be found in the knee, temporomandibular, wrist, acromioclavicular, and sternoclavicular joints), plays an integral role in the health and function of a joint. In layman terms, the meniscus is often referred to as cartilage, especially when referencing the knee (see Chapter 20). The meniscus typically acts to disperse joint loads and reduce friction during movement.

Injury

As articular cartilage is avascular, it is not capable of producing an inflammatory response, which is an important component of repair. Multiple factors are involved in cartilage breakdown, including:[198]

- An imbalance between ECM synthesis and degradation. OA involves a focal loss of articular cartilage with the variable reaction of the subchondral bone. Specifically, OA is a disease process resulting from the failure of chondrocytes to repair damaged articular cartilage in synovial joints.[202] In the early stages of chondrocyte injury, damage to the cellular membrane results in an influx of intracellular contents that causes a decrease in the metabolic capacity of the cell, disrupting proteoglycan production and concentration.[195] Increased synthesis of destructive tissue proteases such as matrix metalloproteinases increased chondrocyte apoptosis, and insufficient ECM generation, result in a cartilage matrix that is unable to withstand normal mechanical stresses.[203] T is leads to progressive cartilage loss, subchondral bone remodeling, osteophyte formation, and synovial inflammation.[204]
- Stress deprivation (immobilization, bed rest)
- Developmental etiologies leading to an abnormal force transmission (e.g., developmental hip dysplasia, coxa valgus, genu valgum)
- Joint surface incongruity and joint instability
- Disease (rheumatoid arthritis)

Injuries to the articular cartilage can be divided into three distinct types:

- Type 1 injuries (superficial) involve microscopic damage to the chondrocytes and ECM (cell injury).
- Type 2 injuries (partial thickness) involve microscopic disruption of the articular cartilage surface (chondral fractures or fissuring).[85] T is type of injury has traditionally had an extremely poor prognosis because the injury does not penetrate the subchondral bone and, therefore, does not provoke an inflammatory response.[85]
- Type 3 injuries (full thickness) involve disruption of the articular cartilage with penetration into the subchondral bone, which produces a significant inflammatory process.[85] T is inflammatory process, OA, is a significant health problem worldwide, affecting approximately 10% of men and 18% of women over 60 days of age.[205] OA typically affects weight-bearing joints and is a major cause of morbidity, disability, and pain.[206] T e onset of OA increases with age, and up to half of people over 50 years of age report symptomatic OA.[206]

CLINICAL PEARL

Previous joint injury, obesity, and occupational activity have all been associated with an increased risk of knee and hip OA. However, levels of physical activity and sports-specificity remain inconclusive as risk factors.[207]

T e clinical signs and symptoms of an articular injury include impaired mobility, impaired muscle performance, impaired balance, and activity limitations and participation restrictions. T e degree to which the patient is incapacitated depends on the extent of the articular damage, and any comorbidity that negatively impacts the clinical course, such as obesity and cardiovascular disease. Two of the more common articular disorders are OA and rheumatoid arthritis (RA) (see Chapter 5).

Meniscal Injuries. A meniscal injury can occur in any of the joints in which it presides, but it is the meniscal injury of the knee that is the most commonly encountered by the physical therapist. Meniscal tears at the knee can lead to disability, and their surgical treatment increases the long-term risk of knee OA fourfold (see Chapter 20).[208] T e ability of a meniscus to heal is based largely on its blood supply, which is a factor of the location of the injury. T e outer 25–30% of the menisci is known to be vascular.[209] Tears in the vascular region are repairable as well as tears extending into the avascular midsubstance if vascularity is stimulated.[209] T e various treatment options for meniscal injuries of the knee are described in Chapter 20. T e various treatment options for meniscal injuries of the temporomandibular joint are described in Chapter 26.

Healing

T e body's response to articular cartilage defects resulting from trauma upon impact loading depends on the lesion depth.[198] However, it is well known that the capacity of cartilage for repair is limited. T e healing of articular cartilage is described here. Injuries of the articular cartilage that do not penetrate the subchondral bone become necrotic and do not heal. T ese lesions usually progress to the degeneration of the articular surface.[210] Although a short-lived tissue response may occur, it fails to provide sufficient cells and matrix to repair even small defects.[211,212]

Injuries that penetrate the subchondral bone undergo repair as a result of access to the blood supply of the bone. T ese repairs usually are characterized as fibrous, fibrocartilaginous, or hyaline-like cartilaginous, depending on the species, the age, and the location and size of the injury.[213] However, these reparative tissues, even those that resemble hyaline cartilage histologically, differ from normal hyaline cartilage both biochemically and biomechanically. T us, by 6 months, fibrillation, fissuring, and extensive degenerative changes occur in the reparative tissues of approximately half of the full-thickness defects.[214,215] Similarly, the degenerated cartilage seen in osteoarthrosis does not usually undergo repair but instead progressively deteriorates.[210]

CLINICAL PEARL

Viscosupplementation, or intraarticular injections of hyaluronic acid, has been used to treat OA. The proposed mechanisms of action results in the physical properties of the hyaluronic acid, as well as the anti-inflammatory, anabolic, local analgesic, and chondroprotective effects.[85] Numerous studies have supported the effectiveness of other potential chondroprotective agents including chondroitin sulfate and glucosamine sulfate for the relief of symptoms of OA based on clinical trials and short-term follow-up.[85]

Treatment

The prevalent strategy for managing OA is to exhaust conservative measures to delay major reconstructive joint surgery, particularly in younger adults.[216] Pharmacological pain control remains the mainstay of treatment for symptomatic knee OA, specifically NSAIDs, opioid analgesics, and intraarticular corticosteroid injections.[216] At the knee, in patients with medial uni-compartmental OA, valgus unloader braces are used to reduce external varus moments and medial compartment load to improve pain and function.[216] Intraarticular viscosupplementation has become increasingly common for the treatment of symptomatic knee OA, but its efficacy remains controversial.[217,218] More recently, there has been increased focus on the potential role of mesenchymal stem cells in the management of OA.

Appropriate surgical management of OA is determined by specific patient's symptoms, clinical and radiographic findings, circumstances, and expectations.[216] For example, while a younger patient with an isolated uni-compartmental OA at the knee may benefit from a high tibial osteotomy or uni-compartmental knee arthroplasty, a patient with advanced, multiple compartmental OA is more likely to benefit from a total knee arthroplasty.

From a physical therapy perspective, the rehabilitation protocols differ by lesion location and by surgical technique (see Chapters 19 and 20), but the common goals of conservative treatment are to decrease joint pain and improve function through a combination of modalities, patient education, low-impact aerobic exercise, and range-of-motion and strengthening exercises.

BONE BEHAVIOR, INJURY, HEALING, AND TREATMENT

Behavior

From development to degradation, bone health is influenced by diet, hormone levels, and biomechanics.[219] Bone matrix comprises three elements: organic, mineral, and fluid. A bone of high mineral density may be less likely to endure a stress injury because it can better withstand repetitive applications of force. It is the mineral content that distinguishes bone from other connective tissues, and provides the bone with its characteristic stiffness while providing a mineral storage system. Collagen orientation in growing and mature bone has been linked to the mechanical behavior of individual layers of bone (lamellae), and the different types of bone. During normal activity, cortical bone sustains loads well within the linear region of the load–deformation curve (Fig. 2-2), so that the bone bends but does not sustain permanent deformation (elastic deformation). However, even when maintained within the linear region, if loads are sustained repetitively over a short period, changes in the bone may result (plastic deformation). For example, compressive forces shorten bone, and tensile forces elongate bone. Bone is strongest in compression and weakest in tension.

When loads are sustained that exceed the linear region, micro-architectural damage can occur. Trabecular, or cancellous bone, is anisotropic in nature, which means its mechanical behavior differs in different directions, or among various parts of the structure.

CLINICAL PEARL

Exercise-related increases in cortical thickness and bone mineral content suggest that exercise can be a potent stimulus for bone remodeling.[220]

Injury

A significant injury to a bone is referred to as a fracture. Some different types of fractures and fracture patterns are recognized (Fig. 2-4) (Table 2-5). Of all the different types of fractures, the stress fracture is the one most commonly encountered by the physical therapist. A stress fracture is a fatigue fracture of a bone caused by repeated submaximal stress.[221] The force required to generate a stress fracture is less

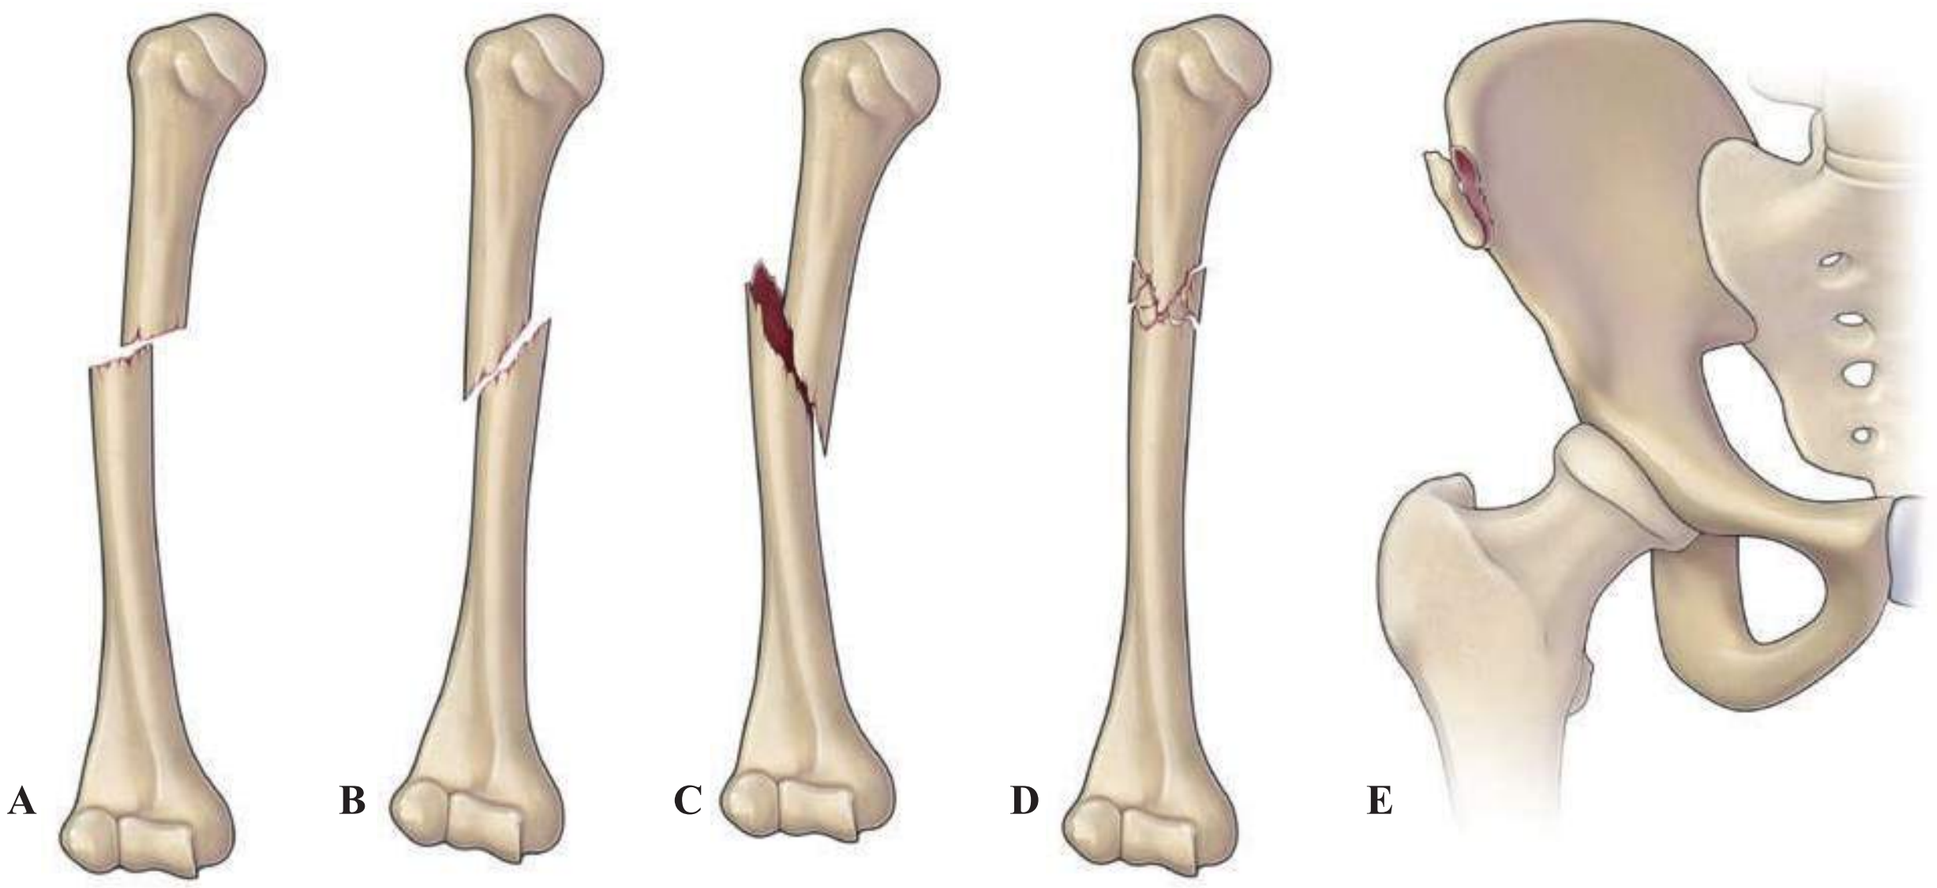

FIGURE 2-4 Fracture types. A: Transverse. B: Oblique. C: Spiral. D: Comminuted. E: Avulsion.

TABLE 2-5 Types of Fractures

Types of Fracture	Description
Avulsion	An injury to the bone where a tendon or ligament pulls off a piece of the bone.
Closed	When there is a closed fracture; there is no broken skin—the fractured bone does not penetrate the skin (but may be seen under the skin) and there is no contusion from external trauma.
Comminuted	A fracture that has more than two fragments of bone which have broken off. It is a highly unstable type of bone fracture with many bone fragments.
Complete	A fracture in which the bone has been completely fractured through its own width.
Complex	This type of fractured bone severely damages the soft tissue which surrounds the bone
Compound (open)	The bone breaks and fragments of the bone penetrate through the internal soft tissue of the body and break through the skin from the inside. There is a high risk of infection if external pathogenic factors enter into the interior of the body.
Compression	Occurs when the bone is compressed beyond its limits of tolerance. These fractures generally occur in the vertebral bodies as a result of a flexion injury or without trauma in patients with osteoporosis. Compression fractures of the calcaneus are also common when patients fall from a height and land on the heel.
Epiphyseal	A fracture of the epiphysis and physis—growth plate. These injuries are classified using the Salter–Harris classification.
Greenstick	The pathology of this type of fracture includes an incomplete fracture in which only one side of the bone breaks. The bone usually is "bent" and only fractured of the outside of the bend. It is mostly seen in children and is considered a stable fracture due to the fact that the whole bone has not been fractured. As long as the bone is kept rigid, healing is usually quick.
Hairline	This bone fracture involves minimal trauma to the bone and surrounding soft tissues. It is an incomplete fracture with no significant bone displacement and is considered a stable fracture. In this type of fracture the crack only extends into the outer layer of the bone but not completely through the entire bone. It is also known as a Fissure fracture.
Impaction	Occurs when one fragment is driven into another. This type of fracture is common in tibial plateau fractures.
Oblique	A fracture which goes at an angle to the axis of the bone.
Pathologic	A pathologic fracture occurs when a bone breaks in an area that is weakened by another disease process. Causes of weakened bone include tumors, infection, osteoporosis or osteopenia, and certain inherited bone disorders.
Spiral	In this pattern, a bone has been broken due to a twisting type motion. It is highly unstable and may be diagnosed as an oblique fracture unless a correct x-ray has been taken. The spiral fracture resembles a corkscrew type which runs parallel with the axis of the broken bone.
Stress	These fractures may extend through all or only part of the way through the bone. These types of fractures are far more common in women. They often occur in the spine, and lower extremity (most often in the fibula, tibia, or metatarsals). Stress fractures occur in a variety of age groups, ranging from young children to elderly persons. Stress fractures do not necessarily occur in association with a history of increased activity. Therefore, it is important to remember that the absence of a history of trauma or increased activity does not eliminate the possibility of stress or insuf ciency fracture as a cause of musculoskeletal pain.

than the maximum tolerated by bone, but its repetitive application causes a disruption in the bone homogeneity.[222] Stress fractures have been suggested to account for approximately 10% of all athletic injuries.[223–226] Although the site of stress fracture varies with different sports and activities, 80–90% of stress fractures occur in the lower limbs, with the tibia being the most commonly injured bone, accounting for approximately 50% of all cases.[227] Clinically, stress fractures can be difficult to diagnose due to a wide range of potential differential diagnoses, including soft tissue injuries, compartment syndromes, infection, and other overuse conditions. T us, the diagnosis of a stress fracture is contingent upon a detailed clinical examination that incorporates the patient history and contributing risk factors, as well as a thorough physical examination, and is most often confirmed with radiological imaging (scintigraphy, or MRI).[227] A premature return to full activity may increase the risk of complications.[219] For example, if a complete union is not obtained prior to return to full activity, an athlete risks delayed union or nonunion.[221] Because of their tendency to have nonunion or delayed union, certain stress fractures are classified as high risk, including:[219]

- anterior tibial diaphysis
- lateral femoral neck
- patella
- medial malleolus

- navicular
- fifth metatarsal base
- proximal second metatarsal
- sesamoids (great toe, tibial)
- talus
- femoral head

Low-risk stress fractures include the following:

- posteromedial tibial
- metatarsals
- calcaneus
- cuboid
- cuneiform
- fibula
- medial femoral neck
- femoral shaft
- pelvis

CLINICAL PEARL

Numerous studies have suggested that the use of ultrasound or a tuning fork can be used for the diagnosis of stress fractures. With ultrasound, the elicitation of pain as the ultrasound is applied over the fracture site has been suggested to be a good diagnostic indicator of an underlying stress fracture. The vibration of a tuning fork over the damaged periosteum to produce pain has also been advocated as a diagnostic tool. However, the findings from a study by Schneiders et al.[227] did not support the specific use of ultrasound or a tuning fork as stand-alone diagnostic tests.

Another fracture type that can be seen in the clinic, especially in those individuals with known osteoporosis or osteopenia, is the pathological fracture (see Chapter 5).

Healing

Bone healing is a complex physiologic process that follows an orderly cascade of events. The striking feature of bone healing, compared with healing in other tissues, is that repair is by the original tissue, not scar tissue. Regeneration is perhaps a better descriptor than repair. This is linked to the capacity for remodeling that intact bone possesses. Like other forms of healing, the repair of bone fracture includes the processes of inflammation, repair, and remodeling; however, the type of healing varies, depending on the method of treatment. In classic histologic terms, fracture healing has been divided into two broad phases: primary fracture healing and secondary fracture healing (Fig. 2-5).

- Primary osteonal (cortical) healing, involves a direct attempt by the cortex to reestablish itself once it has become interrupted. In primary cortical healing, bone on one side of the cortex must unite with bone on the other side of the cortex to reestablish mechanical continuity.

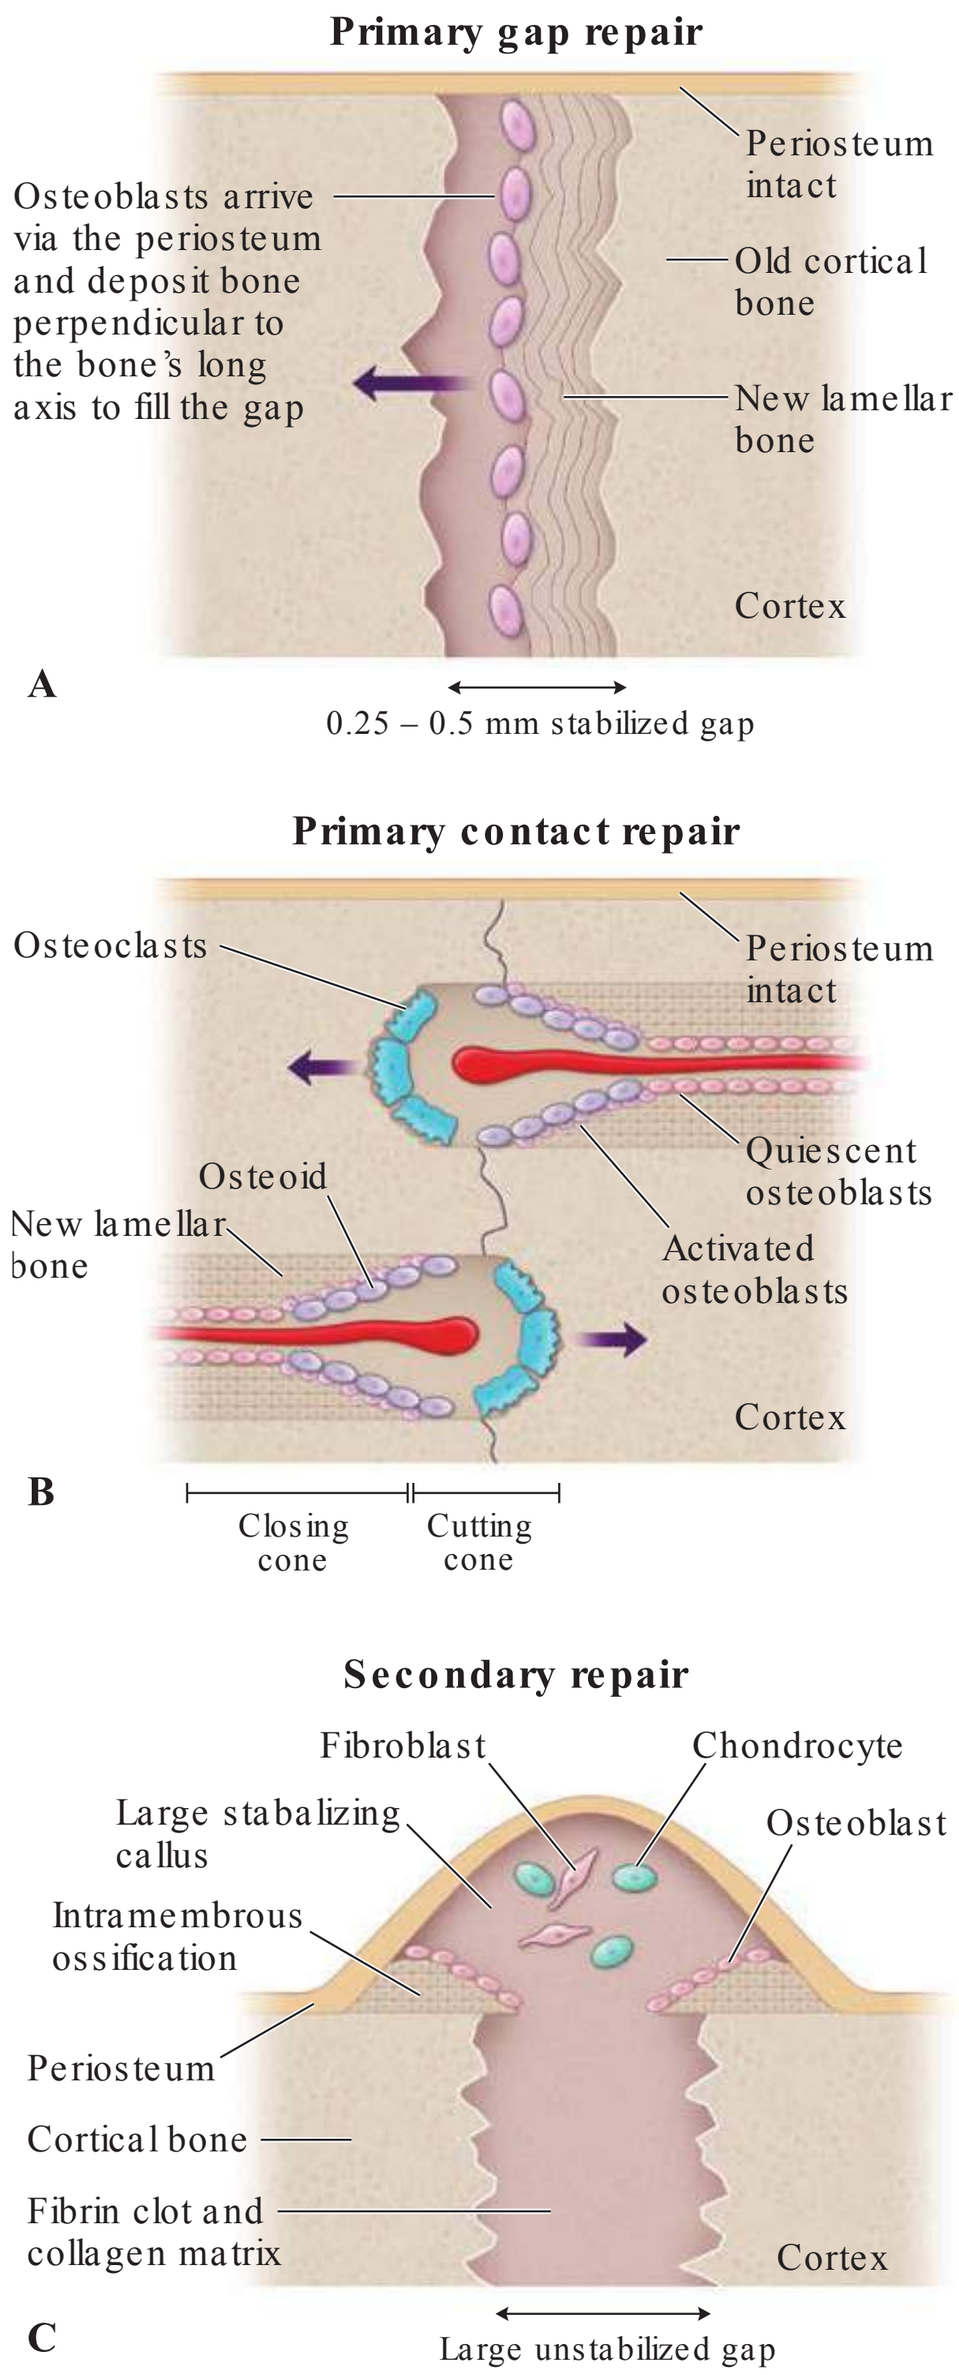

FIGURE 2-5 Fracture healing.

- Secondary callus healing involves responses in the periosteum and external soft tissues with the subsequent formation of a callus. The majority of fractures heal by secondary fracture healing.

Within these broader phases, the process of bone healing involves a combination of intramembranous and endochondral ossification (see Chapter 1). These two processes participate in the fracture repair sequence by at least four discrete stages of healing: the hematoma formation (inflammation or

granulation) phase, the soft callus formation (reparative or revascularization) phase, the hard callus formation (maturing or modeling) phase, and the remodeling phase.[228]

- Hematoma formation (inflammatory) phase. Initially, the tissue volume in which new bone is to be formed is filled with the matrix, generally including a blood clot or hematoma (Fig. 2-5).[85] At this phase, the matrix within the injury site is bordered by local tissues, which also are often traumatized resulting in focal necrosis and reduced blood flow.[85] An effective bone healing response will include an initial inflammatory phase characterized by the release of a variety of products, including fibronectin, PDGF, and TGF, an increase in regional blood flow, invasion of neutrophils and monocytes, removal of cell debris, and degradation of the local fibrin clot.
- Soft callus formation (reparative or revascularization) phase. This phase is characterized by the formation of connective tissues, including cartilage, and formation of new capillaries from preexisting vessels (angiogenesis). During the first 7–10 days of fracture healing, the periosteum undergoes an intramembranous bone formation response, and histologic evidence shows formation of woven bone opposed to the cortex within a few millimeters of the site of the fracture. Any differentiation is strongly influenced by the local oxygen tension and the mechanical environment, as well as by signals from local growth factors.[85] By the middle of the second week, abundant cartilage overlies the fracture site, and this chondroid tissue initiates biochemical preparations to undergo calcification. Thus, the callus becomes a triple-layered structure consisting of an outer proliferating part, a cartilaginous middle layer, and an inner portion of new bony trabeculae (Fig. 2-5). The cartilage portion is usually replaced with bone tissue as the healing progresses.
- Hard callus formation (modeling) phase. This phase is characterized by the systematic removal of the initial matrix and tissues that formed in the site, primarily through osteoclastic and chondroclasts resorption, and their replacement with more organized lamellar bone (woven bone) aligned in response to the local loading environment.[85] The calcification of fracture callus cartilage occurs by a mechanism almost identical to that which takes place in the growth plate. This calcification can occur either directly from mesenchymal tissue (intramembranous) or via an intermediate stage of cartilage (endochondral or chondroid routes). Osteoblasts can form woven bone rapidly, but the result is randomly arranged and mechanically weak. Nonetheless, bridging of a fracture by woven bone constitutes the so-called clinical union. Once cartilage is calcified, it becomes a target for the ingrowth of blood vessels. Radiographically, a fracture is considered healed when there is progressive callus formation to the point where the fracture line is no longer visible.
- Remodeling phase. By replacing the cartilage with bone, and converting the cancellous bone into compact bone, the callus is gradually remodeled. During this phase, the woven bone is remodeled into the stronger lamellar bone by the orchestrated action of osteoclast bone resorption and osteoblast bone formation (Fig. 2-5).

Radiologically or histologically, fracture gap bridging occurs by three mechanisms[228]:

1. Intercortical bridging (primary cortical union). This mechanism occurs when the fracture gap is reduced by normal cortical remodeling under conditions of rigid fixation. This mode of healing is the principle behind rigid internal fixation.[229]
2. External callus bridging by new bone arising from the periosteum and the soft tissues surrounding the fracture. Small degrees of movement at the fracture stimulate external callus formation.[230] This mode of healing is the aim in functional bracing[231] and intramedullary nailing.
3. Intramedullary bridging by endosteal callus. Normal periods of immobilization following a fracture range from as short as 3 weeks for small bones to about 8 weeks for the long bones of the extremities. Once the cast is removed, it is important that controlled stresses continue to be applied to the bone because the period of bone healing continues for up to 1 year.[232,233]

The three key determinants of fracture healing are the blood supply and the degree of motion experienced by the fracture ends.

- Angiogenesis is the outgrowth of new capillaries from existing vessels. The degree of angiogenesis that occurs depends on well-vascularized tissue on either side of the gap and sufficient mechanical stability to allow new capillaries to survive. Angiogenesis leads to osteogenesis.
- The amount of movement that occurs between fracture ends can be stimulatory or inhibitory to the cascade of bone formation, depending on their magnitude. Excessive interfragmentary movement prevents the establishment of intramedullary blood vessel bridging. However, small degrees of micromotion have been shown to stimulate blood flow at the fracture site and stimulate periosteal callus.[234] This concept is exploited by some available bone stimulators (see Augmented Healing). Successful restoration of osseous morphology and internal architecture is conditional on the remodeling process. According to Wolff's law, bone remodels along lines of stress.[235] Bone is constantly being remodeled as the circumferential lamellar bone is resorbed by osteoclasts and replaced with dense osteonal bone by osteoblasts.[236]
- The environment is another factor, which modulates the repair process; hormones have an impact on osteoblastic and osteoclastic activities (Table 2-6).

Augmented Healing

To date, some techniques have been developed to accomplish a quicker and more complete healing of fractures. These include the following:

- Pulsed electromagnetic fields (PEMF). A technique most commonly used for the treatment of nonunion fractures, failed fusions, and congenital pseudarthrosis. PEMF uses

TABLE 2-6 The Effect of Hormones on Healing

Hormone	Effect on Healing	Mechanism
Calcitonin	Positive	Decreased osteoclastic activity
Thyroid hormone	Positive	Increases rate of bone remodeling
Parathyroid hormone	Positive	Increases rate of bone remodeling
Growth hormone	Positive	Increases amount of callus

Data from Frenkel SR, Koval KJ. Fracture healing and bone grafting. In: Spivak JM, Di Cesare PE, Feldman DS, et al., eds. Orthopaedics: A Study Guide. New York, NY: McGraw-Hill; 1999:23–28.

electrical energy to direct a series of magnetic pulses through injured tissue such that each magnetic pulse induces a tiny electrical signal that stimulates cellular repair.

- Ultrasound. There is some evidence that pulsed ultrasound may reduce fracture healing time for fractures by stimulating a local hyperemia, an increase in aggregate gene expression, increased mineralization, and more rapid endochondral ossification.[237]
- Direct current. Direct current stimulation surrounding the fracture site has been observed to decrease the oxygen tension with a concomitant rise in local pH in the region of the anode.[238,239]
- Demineralized bone matrix (DBM). DBM derived from human tissues has demonstrated the ability to aid in the stimulation of an osteoinductive and an osteoconductive response allowing for improved bone growth and fusion.[240–242] There are currently two types:
  - Osteoinductive: there are several commercially available DBM substances, each with different amounts of DBM containing osteoinductive proteins.
  - Osteoconductive: osteoconductivity refers to the ability of some materials to serve as a scaffold onto which bone cells can attach, migrate, and grow and divide. In this way, the bone healing response is "conducted," through the graft site.

Treatment

Deciding the mode of fracture management requires a multifaceted approach. The initial medical approach involves stabilization of the fracture site, which prevents further blood loss and resets muscle tension. The medical team decides whether surgery is required or whether a conservative approach, such as casting would be more beneficial. If casting is chosen, the patient may be referred for physical therapy. During the period of casting, submaximal isometrics are initiated. Once a clinical union has been confirmed (the fracture line is no longer visible), the range-of-motion exercises are usually initiated.

Surgical Options for Fractures

The advantage of operative treatment is the anatomical reduction of fracture fragments and early mobilization.

Percutaneous Pinning. Percutaneous pinning is a minimally invasive form of internal fixation in which fractures are pinned using Kirschner wires. The pins are driven through the skin and cortex of the bone, across the reduced fracture, and into the opposite cortex.[243] This mode is commonly used in fractures of the phalanges, metacarpals, distal radius, proximal humerus, and metatarsals. The disadvantage of this type of treatment is that the pins can bend or break, and they cannot provide absolute stability.

External Fixation. This mode of treatment maintains traction and alignment of the bone without the need to confine the patient to a bed. The threaded traction pins are inserted into the bone proximal and distal to the fracture site, and the fracture is manually reduced and fixed in position with carbon fiber bars spanning the fracture site outside the skin.[243] Using fine wires in a circular fixator, across the subchondral metaphysis, is the least damaging to the medullary blood supply.[228] This is type of fixation may provide enough stability to allow rapid endosteal healing without external callus.[244]

Open Reduction and Internal Fixation. The aim of this mode of treatment is to reduce anatomically and provide absolute stability to as many of the fracture fragments as possible.[243] A fracture that is rigidly internally fixed produces no periosteal callus and heals by a combination of endosteal callus and primary cortical union.[228]

Locking Plates. Locking plates are fracture fixation devices with threaded screw holes, which allow screws to thread to the plate and function as a fixed-angle scaffold.

Intramedullary Nailing. Fracture fixation with intramedullary nails provide relative stability—unless the nail is locked proximally and distally and has tight fixation at the fracture site, the fixation may have rotational and angular instability.[243] An intermedullary nail blocks endosteal healing but allows enough movement to trigger periosteal callus.[228] Early mobilization of patients after femoral and tibial rodding is a major advance compared to the prolonged immobilization in traction.[243]

Nonoperative Options for Fractures

Nonoperative treatment is usually reserved for nondisplaced fractures with a low risk of displacement, for displaced fractures that are stable after acceptable reduction is achieved, or for patients for whom anesthesia and surgery are contraindicated.[243] Most fractures, especially in the upper extremity, can

be managed without surgery if acceptable reduction can be achieved by closed means. A variety of nonoperative devices can be used to treat fractures:[243]

- Splints and fracture braces: noncircumstantial coapted devices that lie along one or more surfaces of an extremity that are made of prefabricated material (molded plastic) or plaster, and secured with an elastic bandage. The aim of this type of splinting is to immobilize or passively correct stable fractures, and their use is usually temporary, used for days to a few weeks.
- Casting provides rigid circumferential support into which appropriate holes and three-point fixation can be incorporated. Casting more effectively immobilizes fracture fragments than either splinting or bracing. Casting is particularly useful for maintaining reduction of the ankle, tibia, pediatric forearm, and distal radius fractures.
- Skeletal traction is applied either manually or via weights and pulleys to overcome the shortening force of muscles across the fracture site. The configuration of the skeletal traction varies according to the specific bone involved, but its use is dwindling due to the successful development of surgical reduction and internal fixation.

POSTSURGICAL HEALING

Although many musculoskeletal conditions can be treated conservatively, surgical intervention is often indicated for cases in which a sufficient traumatic or degenerative injury has occurred. Over the years, the number of surgical procedures for orthopaedic conditions has increased considerably. However, although surgery can often correct the presenting problem, for the postsurgical patient to return to an appropriate level of function, some form of postsurgical rehabilitation is usually required. Indeed, a number of studies have reported that skilled intervention following most surgical procedures of the musculoskeletal system allows a patient to achieve greater independence and control over his or her life in a shorter timeframe than patients who do not receive these interventions.[245,246]

Postsurgical Complications

Although surgical procedures can offer many benefits, they are not without their complications. Some of the more serious of these complications include the following:

- Postsurgical infection. Postsurgical infections are perhaps the greatest challenge facing the modern-day surgeon. At any one time, 9% of hospitalized patients are being treated for a nosocomial infection.[247] Staphylococcus aureus, coagulase-negative staphylococci, Enterococcus spp., and Escherichia coli remain the most frequently isolated pathogens. An increasing proportion of infections are caused by antimicrobial-resistant pathogens, such as methicillin-resistant S. aureus (MRSA), or by Candida albicans.[248] Microorganisms may contain or produce toxins and other substances that increase their ability to invade a host, produce damage within the host, or survive on or in host tissue. For example, many gram-negative bacteria produce an endotoxin that stimulates cytokine production. In turn, cytokines can trigger the systemic inflammatory response syndrome that sometimes leads to multiple system organ failures.[248] In certain kinds of surgical procedures, some patient characteristics have been found to be possibly associated with an increased risk of an infection. These include coincident remote site infections or colonization, diabetes, cigarette smoking, systemic steroid use, obesity (> 20% of ideal body weight), extremes of age, poor nutritional status, and perioperative transfusion of certain blood products.[248–250] Although physical therapists are not directly involved in surgical procedures, they are a potential mode of transmission for infections. Hand washing has been found to be an important infection control measure, although improving compliance with hand washing has been a challenge for most hospital infection control programs.[251]
- Venous thromboembolism. A thrombus, or blood clot, is an obstruction of the venous or arterial system. If a thrombus is located in one of the superficial veins, it is usually self-limiting. Venous thromboembolism is a vascular disease that manifests as deep vein thrombosis (DVT) or pulmonary embolism (PE). A DVT most commonly appears in the lower extremity and is typically classified as being either proximal (affecting the popliteal and thigh veins) or distal (affecting the calf veins). Proximal DVT is the most dangerous form of lower extremity DVT because it is more likely to provoke a life-threatening PE (see later).

CLINICAL PEARL

DVT is caused by an alteration in the normal coagulation system. This alteration in the fibrinolytic system, which acts as a system of checks and balances, results in a failure to dissolve the clot. If the clot becomes dislodged, it enters into the circulatory system through which it can travel to become lodged in the lungs (PE), obstructing the pulmonary artery or branches that supply the lungs with blood. If the clot is large and completely blocks a vessel, it can cause sudden death.

Certain patients are at increased risk for DVT:[252–256]

- Strong risk factors include a fracture (pelvis, femur, and tibia), hip or knee replacement, major general surgery, major trauma, or spinal cord injury. A recent study indicated that up to 60% of patients undergoing total hip replacement surgery may develop a DVT without preventative treatment.[257,258]
- Moderate risk factors include arthroscopic knee surgery, central venous lines, chemotherapy, congestive heart or respiratory failure, hormone replacement therapy, malignancy, oral contraceptive therapy, cerebrovascular accident, pregnancy/postpartum, previous venous thromboembolism, and thrombophilia.

TABLE 2-7 Clinical Decision Rule for Outpatients Suspected of Having a Proximal Deep Vein Thrombosis

Clinical Finding	Score[a]
Active cancer (within 6 months of diagnosis or palliative care)	1
Paralysis, paresis, or recent plaster immobilization of lower extremity	1
Recently bedridden >3 days or major surgery within 4 weeks of application of clinical decision rule	1
Localized tenderness along distribution of the deep venous system (assessed by firm palpation in the center of the posterior calf, the popliteal space, and along the area of the femoral vein in the anterior thigh and groin)	1
Entire lower extremity swelling	1
Calf swelling by >3 cm compared with asymptomatic lower extremity (measured 10 cm below tibial tuberosity)	1
Pitting edema (greater in the symptomatic lower extremity)	1
Collateral superficial veins (nonvaricose)	1
Alternative diagnosis as likely or greater than that of DVT (most common alternative diagnoses on cellulitis, calf strain, and postoperative swelling)	−2

[a]Score interpretation: ≤0, probability of proximal lower extremity deep vein thrombosis (PDVT) of 3% (95% confidence interval = 1.7–5.9%); 1 or 2, probability of PDVT of 17% (95% confidence interval = 12–23%); ≥3, probability of PDVT of 75% (95% confidence interval = 63–84%).
Data from Wells PS, Anderson DR, Bormanis J, et al. Value of assessment of pretest probability of deep-vein thrombosis in clinical management. Lancet. 350:1795–1798, 1997.

- Weak risk factors include bed rest greater than 3 days, immobility due to sitting (e.g., prolonged air travel), increasing age, laparoscopic surgery, obesity, pregnancy/antepartum, and varicose veins.

The association of DVT with venous stasis, vessel-wall damage, and hypercoagulability was first proposed by Virchow in 1859.[259]

CLINICAL PEARL

Venous stasis: the major contributing factors that increase blood pooling in the lower extremities are general anesthesia associated with a decrease in blood flow velocity, increased age, hypotension, varicosities, congestive heart failure, postsurgical immobility, and possibly obesity.

Vessel-wall damage: several intraoperative factors during hip surgery, such as limb positioning, hip dislocation, local trauma, and retraction of local structures anterior to the hip have been demonstrated to lead to femoral vein injury and subsequent endothelial damage.[260]

Hypercoagulability: a variety of congenital and acquired conditions are associated with hypercoagulable states, including abnormalities of fibrinogen and/or plasminogen, adenocarcinoma, pregnancy, systemic lupus erythematosus, and nephrotic syndrome.

Two-thirds of the fatalities resulting from DVT occur within 30 minutes of the initial symptoms.[261–263] Both DVT and PE can be symptomatic or asymptomatic. Clinical signs of a DVT have traditionally been described as including swelling of the extremity, tenderness, or a feeling of cramping of the calf muscles that increases when the ankle is dorsiflexed (positive Homan's sign) or with weight bearing, vascular prominence, elevated temperature, tachycardia, and inflammation and discoloration or redness of the extremity. However, a purely clinical diagnosis is fraught with a high incidence of false positives and negatives. Musculoskeletal conditions that may mimic symptoms associated with DVT include hematoma, myositis, tendinopathy, Baker's cyst, synovitis, osteomyelitis, and tumors.[264] The clinical decision rule described by Wells et al. (Table 2-7)[265–269] is being most commonly recommended for outpatients suspected of having DVT.[270,271] More accurate diagnostic procedures, outside the scope of physical therapy, include contrast venography, Doppler and B-mode ultrasound, venous duplex imaging, impedance plethysmography, and I-125 fibrinogen uptake.

Prevention is the key with DVT. Methods of prevention may be classified as pharmacological and nonpharmacological. Pharmacological prevention includes anticoagulant drugs such as low-dose Coumadin (warfarin), low–molecular-weight heparin, adjusted-dose heparin, and heparin antithrombin III combination. These drugs work by altering the body's normal blood-clotting process. Second tier drugs include dextran, aspirin, and low-dose subcutaneous heparin. Nonpharmacological prevention attempts to counteract the effects of immobility, including calf and foot/ankle exercises, and compression stockings. A recent study has shown that substantial hyperemia (a mean 22% increase in venous outflow) occurs after the performance of active ankle pumps for 1 minute, and venous outflow remains greater than the baseline level for 30 minutes reaching a maximum 12 minutes after these exercises.[258] Although this does not provide sufficient evidence that exercise alone prevents DVT, it suggests that the active ankle pump does influence venous hemodynamics. Finally, inferior vena cava (IVC) filters and greenfield filters may be employed with a patient who has a contraindication to anticoagulation, previous complications with anticoagulants, or if anticoagulants have proved ineffective in the past.

- Pulmonary embolus.[272] T is is a part of the spectrum of diseases associated with venous thromboembolism. Under normal conditions, micro-thrombi (tiny aggregates of red cells, platelets, and fibrin) are formed and lysed continually within the venous circulatory system. T is dynamic equilibrium ensures local hemostasis in response to injury without permitting uncontrolled propagation of a clot. Under pathological conditions, micro-thrombi may escape the normal fibrinolytic system to grow and propagate. PE occurs when these propagating clots break loose and embolize to block pulmonary blood vessels. PE most commonly results from DVT occurring in the deep veins of the lower extremities, proximal to and including the popliteal veins and in the axillary or subclavian veins (deep veins of the arm or shoulder). PE is an extremely common and highly lethal postsurgical condition that is a leading cause of death in all age groups. A good clinician actively seeks the diagnosis as soon as any suspicion of PE whatsoever is warranted, because prompt diagnosis and treatment can dramatically reduce the mortality rate and morbidity of the disease. Unfortunately, the diagnosis is missed more often than it is made because PE often causes only vague and nonspecific symptoms. Symptoms that should provoke a suspicion of PE must include chest pain, chest wall tenderness, back pain, shoulder pain, upper abdominal pain, syncope, hemoptysis, shortness of breath, painful respiration, new onset of wheezing, any new cardiac arrhythmia, or any other unexplained symptom referable to the thorax. It is important to remember that many patients with PE are initially completely asymptomatic and most of those who do have symptoms have an atypical presentation. Pulmonary angiography remains the criterion standard for the diagnosis of PE but is rapidly being replaced by multidetector computed tomographic angiography (MDCTA), since the latter modality is significantly less invasive, is easier to perform, and offers equal sensitivity and specificity.

- Poor wound healing. Wound-healing abnormalities cause great physical and psychological stress to the affected patients and are extremely expensive to treat. T e rate of healing in acute surgical wounds is affected by both extrinsic factors (surgical technique, tension of wound suturing, maintenance of adequate oxygenation, cigarette smoking, prevention or eradication of infection, and types of wound dressing) and intrinsic factors (presence of shock or sepsis, control of diabetes mellitus, and the age, nutritional, and immune status of the patient).[273] Although many studies have documented relationships between malnutrition and poor wound healing, the optimal nutrient intake to promote wound healing is unknown. It is known, however, that vitamins A, C, and E, protein, arginine, zinc, and water play a role in the healing process.[274]

- Scars and adhesions. A surgery is a form of controlled macrotrauma to the musculoskeletal system. T e tissues respond to this trauma in much the same way that they do to any other form of trauma or injury. As part of the postsurgical rehabilitation process, the involved structure is usually immobilized to protect the surgical site from injury. However, prolonged immobilization of a connective tissue can produce significant changes in its histochemical and biomechanical structure. T ese changes include a fibro-fatty infiltration that can progress into fibrosis, creating adhesions around the healing site, and an increase in the microscopic cross-linking of collagen fibers resulting in an overall loss of extensibility of the connective tissues.[145,275–278] Unlike connective tissue, which is mature and stable with limited pliability, scar tissue is more vulnerable to breakdown.[22,44,279–281] Fortunately, controlled and skilled therapeutic interventions can reverse the detrimental effects of short-term immobilization. T ese include mobilization of the connective tissue with passive mobility techniques or active range of motion that help to restore the extensibility of the tissue. To assist with the overall healing of the incision, scar mobilization techniques may be performed to the patient's tolerance with lotion.

DETRIMENTAL EFFECTS OF IMMOBILIZATION

Continuous immobilization of connective and skeletal muscle tissues can cause some undesirable consequences. T ese include the following:

- Cartilage degeneration.[282] Immobilization of a joint causes atrophic changes in articular cartilage through a reduction of matrix proteoglycans and cartilage softening.[283] Softened articular cartilage is vulnerable to damage during weight bearing. T e reduction of the matrix proteoglycans concentration has been demonstrated to be highest in the superficial zone but also occurs throughout the uncalcified cartilage, diminishing with distance from the surface of the articular cartilage.[284]

- Decreased mechanical and structural properties *of* ligaments. One early study[11] showed that after 8 weeks of immobilization, the stiffness of a ligament decreased to 69% of control values, and even after 1 year of rehabilitation, the ligament did not return to its prior level of strength.

CLINICAL PEARL

Following a period of immobilization, connective tissues are more vulnerable to deformation and breakdown than normal tissues subjected to similar amounts of stress.[285]

- Decreased bone density.[144,232,286] T e interactions among systemic and local factors to maintain normal bone mass are complex. Bone mass is maintained because of a continuous coupling between bone resorption by osteoclasts and bone formation by osteoblasts, and this process is influenced by both systemic and local factors.[287] Mechanical forces acting on bone stimulate osteogenesis, and the absence of such forces inhibits osteogenesis. Marked osteopenia occurs in otherwise healthy patients in states of complete immobilization or weightlessness.[288,289]

TABLE 2-8 Structural Changes in the Various Types of Muscle Following Immobilization in a Shortened Position

	Muscle Fiber Type and Changes		
Structural Characteristics	**Slow Oxidative**	**Fast Oxidative Glycolytic**	**Fast Glycolytic**
Number of fibers	Moderate decrease	Minimal increase	Minimal increase
Diameter of fibers	Significant decrease	Moderate decrease	Moderate decrease
Fiber fragmentation	Minimal increase	Minimal increase	Significant increase
Myofibrils	Minimal decrease and disoriented	—	Wavy
Nuclei	Degenerated and rounded	Degenerated and rounded	Degenerated and rounded
Mitochondria	Moderate decrease, degenerated	Moderate decrease, degenerated	Minimal decrease, degenerated, swollen
Sarcoplasmic reticulum	Minimal decrease, orderly arrangement	Minimal decrease	Minimal decrease
Myofilaments	Minimal decrease, disorganized	Moderate decrease	Minimal decrease, wavy
Z band	Moderate decrease	—	Faint or absent
Vesicles	Abnormal configuration	—	—
Basement membrane	Minimal increase	—	—
Register of sarcomeres	Irregular projections, shifted with time	—	—
Fatty infiltration	Minimal increase	—	—
Collagen	Minimal increase between fibers	—	—
Macrophages	Minimal increased invasion	Minimal increased invasion	Minimal increased invasion
Satellite cells	Minimal increase	—	—
Target cells	Minimal increase	—	—

Data from Gossman MR, Sahrmann SA, Rose SJ. Review of length-associated changes in muscle. Experimental evidence and clinical implications. Phys Ther. 62:1799–1808, 1982, with permission from APTA.

In children, bone has a high modeling rate and appears to be more sensitive to the absence of mechanical loading than bone in adults.[290]

- Weakness or atrophy *of* muscles. Muscle atrophy is an imbalance between protein synthesis and degradation. General and selective muscle atrophy can occur with immobilization. General muscle atrophy typically occurs in one-joint muscles as two-joint muscles are "less" immobilized by typical immobilization methods.[291] Selective muscle atrophy occurs more often in type I fibers as they are more susceptible to the effects of inactivity and, as their numbers decline, the proportion of type IIa fibers increases.[292]

CLINICAL PEARL

Structural and metabolic changes in muscle cells can begin within 2 hours of complete immobilization,[293] and disuse atrophy can result in a loss in the cross-sectional area of muscle by as much as 14–17% within 3 hours or up to 42% in a few weeks.[294] The effects of immobilization also include changes to the myotendinous junction, evidenced by a 50% redirection in muscle–tendon contact area and lowered GAG levels at the junction.[295]

In addition to those effects listed in Table 2-8, immobilization can have the following negative effects on muscle:

- change in muscle resting length
- decrease in total muscle weight
- increase in muscle contraction time
- decrease in muscle tension produced
- decrease in protein synthesis
- increase in lactate concentration with exercise

The extent of the negative impact of immobilization depends on the general health of the patient, duration of the immobilization, and the position of the limb during immobilization. The clinician must remember that the restoration of full strength and range of motion may prove difficult if muscles are allowed to heal without early active motion, or in a shortened position, and that the patient may be prone to repeated strains.[153] The cause of muscle damage during exercised recovery from atrophy involves an altered ability of the muscle fibers to bear the mechanical stress of external loads (e.g., weight bearing) and movement associated with exercise. Strenuous exercise of atrophied muscle can result in primary or secondary sarcolemmal disruption, swelling or disruption of the sarcotubular system, distortion of the contractile components of myofibrils, cytoskeletal damage, and extracellular

myofiber matrix abnormalities.[67] T ese pathologic changes are similar to those seen in healthy young adults after sprint running or resistance training.[67] It appears that the act of contracting while the muscle is in a stretched or lengthened position, known as an eccentric contraction, can result in these injuries.[296] T us, range-of-motion exercises should be started once the swelling and tenderness have subsided to the point that the exercises are not unduly painful.[153]

CHAPTER 3

The Nervous System

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Describe the various components of the central and peripheral nervous systems.
2. Describe the anatomic and functional organization of the nervous system.
3. Describe the various components and distributions of the cervical, brachial, and lumbosacral plexuses.
4. Describe the difference between balance and proprioception.
5. Describe the role proprioception plays in function.
6. Describe and differentiate among the various joint mechanoreceptors.
7. Recognize the characteristics of a lesion to the central nervous system.
8. Outline the neurophysiology of pain and the methods by which pain is controlled.
9. Define concussion and describe its associated signs and symptoms.
10. List the findings and the impairments associated with the more common peripheral nerve lesions.
11. Perform a comprehensive examination of the neurologic system.
12. Describe some of the common pathologies of the nervous system.

OVERVIEW

In order to perform a comprehensive neuromusculoskeletal examination, the clinician must have a clear understanding of the anatomy, physiology, and function of the various components of the nervous system, and be able to recognize those signs and symptoms that indicate a compromise of the nervous system.

The nervous system is composed of only two principal types of cells—neurons and supporting cells. The neuron, which is classified according to structure or function, serves to store and process information, and is the functional unit of the nervous system. The supporting cell called the neuroglial cell, or simply glial, functions to provide structural and metabolic support for the neurons.[1] Unlike many cells, neurons cannot divide by mitosis but they do have some capability to regenerate. In contrast, glial cells retain limited mitotic abilities.

Anatomy

The human nervous system can be subdivided into two anatomic divisions: the central nervous system (CNS), comprising the brain and the spinal cord, and the peripheral nervous system (PNS), formed by the nerves and ganglia (cluster of nerve cell bodies located outside of the CNS) outside of the brain and spinal cord. The PNS is further subdivided into somatic and autonomic divisions. The somatic division, which includes the cranial (with the exception of cranial II) and the spinal nerves, innervates the skin, the muscles, and the joints, while the autonomic division innervates the glands and the smooth muscle of the viscera and the blood vessels.[2]

Although neurons come in various sizes and shapes, there are four functional parts for each nerve fiber (Fig. 3-1):

- Dendrite. Dendrites serve a receptive function and receive information from other nerve cells, or the environment.
- Axon. The axon cylinder, in which there is a bidirectional flow of axoplasm, conducts information and nutrition to the nerve cells and the tissues that the nerve innervates. Many axons are covered by myelin, a lipid-rich membrane. In myelinated fibers, there is a direct proportional relationship between fiber diameter and conduction velocity.[3] This membrane is divided into segments, approximately 1-mm long, by small gaps, called nodes of Ranvier, in which the myelin is absent.[4] Myelin, which has a high electrical resistance and low capacitance, serves to increase the nerve conduction velocity of neural transmissions through a process called salutatory conduction. The Schwann cell is responsible for laying down myelin around axons.
- Cell body. The cell body contains the nucleus of the cell and has important integrative functions.

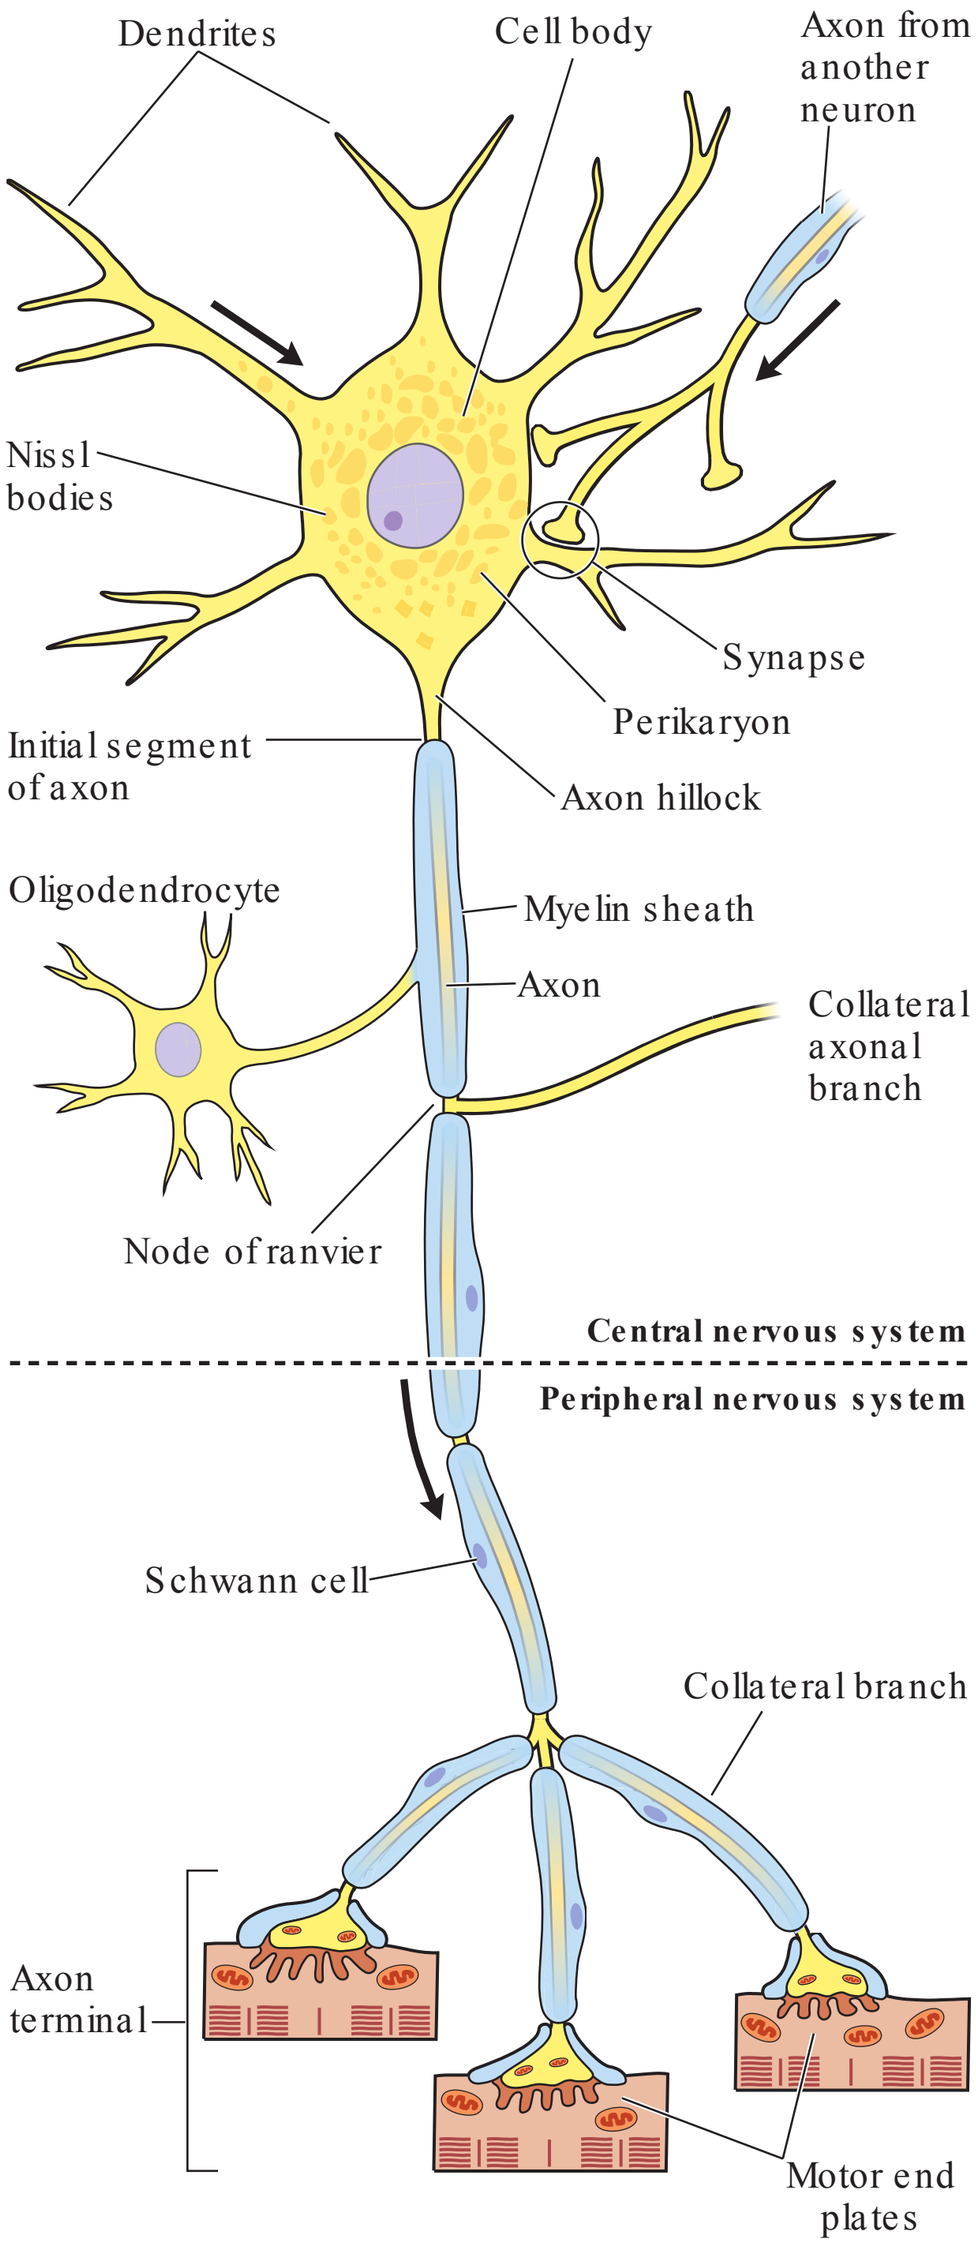

FIGURE 3-1 Schematic drawing of a neuron. (Reproduced, with permission, from Chapter 9. Nerve Tissue & the Nervous System. In: Mescher AL. eds. Junqueira's Basic Histology: Text & Atlas, 13e. New York, NY: McGraw-Hill; 2013.)

- Axon terminal. The axon terminal is the transmission site for action potentials, the messengers of the nerve cell.

Peripheral nerves are enclosed in three layers of tissue of differing character. From the inside outward, these are the endoneurium, perineurium, and epineurium.[1] The nerve fibers embedded in endoneurium form a funiculus surrounded by perineurium, a thin but strong sheath of connective tissue. A fluid exists in the endoneurial spaces, which following nerve injury can produce intraneural edema, which in turn can play a major role in acute and chronic nerve lesions.[3] The nerve bundles are embedded in a loose areolar connective tissue framework, called the epineurium. The epineurium that extends between the fascicles is termed the inner or the interfascicular epineurium, whereas that surrounding the entire nerve trunk is called the epifascicular epineurium.[5] The connective tissue outside the epineurium is referred to as the adventitia of the nerve or the epineural tissue.[5] Although the epineurium is continuous with the surrounding connective tissue, its attachment is loose, so that nerve trunks are relatively mobile, except where tethered by entering vessels or exiting nerve branches (see Chapter 11).[6] There are no connective tissue components in the spinal nerves comparable to the epineurium and the perineurium of the peripheral nerve; at least they are not developed to the same degree.[7] As a result, the spinal nerve roots are more sensitive to both tension and compression. The spinal nerve roots also are devoid of lymphatics and, thus, are predisposed to prolonged inflammation.[8]

The communication of information from one nerve cell to another occurs at junctions called synapses, where a chemical is released in the form of a neurotransmitter. A difference in concentration exists across the cell membrane of potassium, sodium, and chloride ions. These ions can selectively permeate ion channels in the membrane so that an unequal distribution of net charge occurs. The resting membrane potential results from an internal negativity resulting from the active transport of sodium from inside to outside the cell, and potassium from outside to inside the cell.[3]

Clinical Pearl

Membrane potential ranges between –70 and –90 mV.

Central nervous System

The CNS consists of the brain and an elongated spinal cord. The spinal cord participates directly in the control of body movements, the processing and transmission of sensory information from the trunk and the limbs, and the regulation of visceral functions.[2] The spinal cord also provides a conduit for the two-way transmission of messages between the brain and the body. These messages travel along the pathways, or tracts, that are fiber bundles of similar groups of neurons. These tracts may descend or ascend.

Clinical Pearl

Aggregates of spinal tracts are referred to as columns or lemnisci.

The spinal cord is normally 42–45-cm long in adults and is continuous with the medulla and brain stem at its upper end (Fig. 3-2A).[4] The conus medullaris serves as the distal end of the cord, and, in adults, the conus ends at the L1 or L2 level of the vertebral column. A series of specializations, the filum terminales and the coccygeal ligament, anchor the spinal cord and the dural sac inferiorly and ensure that the tensile forces applied to the spinal cord are distributed throughout its entire length.[9] The spinal cord has an external segmental

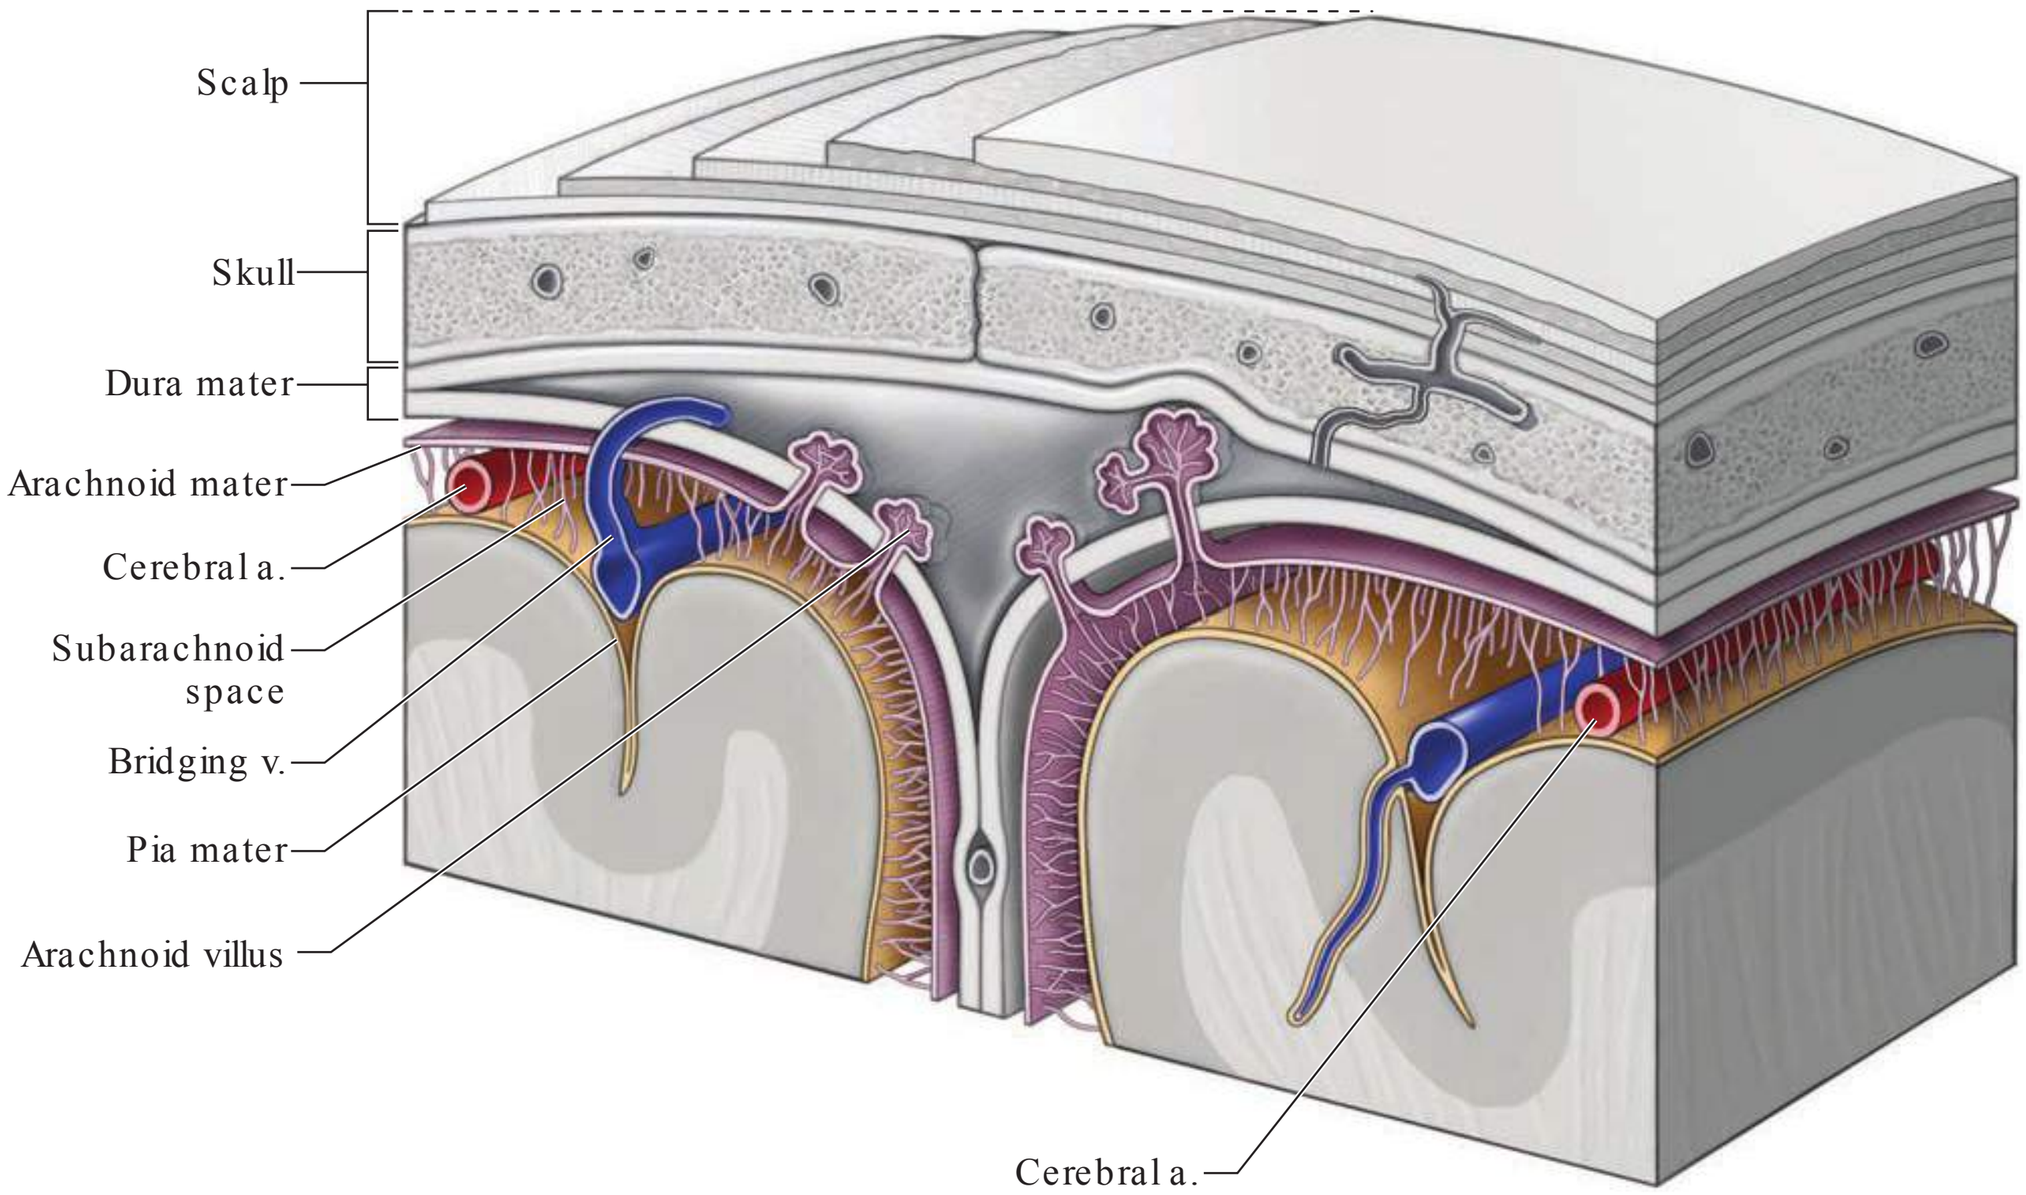

FIGURE 3-3 Schematic illustration of the relationship of the dura mater, arachnoid, and pia mater. (Reproduced, with permission, from Chapter 15. Scalp, Skull, and Meninges. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

organization. Each of the 31 pairs of spinal nerves that arise from the spinal cord has an anterior (ventral) root and a posterior (dorsal) root, with each root consisting of one to eight rootlets and bundles of nerve fibers.[4] A spinal (sensory) ganglion (posterior [dorsal] root ganglion), a swelling that contains nerve cell bodies, is located in the posterior (dorsal) root (Fig. 3-2B) of a typical spinal nerve (Fig. 3-2B).[4]

T ree membranes, or meninges, envelop the structures of the CNS: dura mater, arachnoid, and pia mater (Fig. 3-3). T e meninges and related spaces are important to both the nutrition and the protection of the spinal cord. T e cerebrospinal fluid that flows through the meningeal spaces, and within the ventricles of the brain, provides a cushion for the spinal cord. T e meninges also form barriers that resist the entrance of various noxious organisms.

Dura Mater

T e dura mater (Latin, tough mother) (Fig. 3-3) is the outermost and the strongest of the membranes and is composed of an inner meningeal layer and an outermost periosteal layer. T e dura runs uninterrupted from the interior of the cranium through the foramen magnum and surrounds the spinal cord throughout its distribution from the cranium to the coccyx at the second sacral level (S2).[9] T e dura also is attached to the posterior surfaces of C2 and C3.[10]

T e dura forms a vertical sac (dural sac) around the spinal cord, and its short lateral projections blend with the epineurium of the spinal nerves. T e dura is separated from the bones and the ligaments that form the walls of the vertebral canal by an epidural space, which can become partly calcified or even ossified with age.[4]

Arachnoid

T e arachnoid is a thin and delicate avascular layer, coextensive with the dura mater and the pia mater (Fig. 3-3). Even though the arachnoid and the pia mater are interconnected by trabeculae, there is a space between them, called the subarachnoid space (Fig. 3-3), which contains the cerebrospinal fluid. T e supposedly rhythmic flow of this cerebrospinal fluid is the rationale used by craniosacral therapists to explain their techniques, although there is no evidence of this finding in the literature.

Pia Mater

T e pia mater (Fig. 3-3) is the deepest of the layers. It is intimately related and firmly attached, via connective tissue investments, to the outer surface of the spinal cord and the nerve roots. T e pia mater conveys the blood vessels that supply the spinal cord and has a series of lateral specializations, the denticulate (dentate) ligaments, which anchor the spinal cord to the dura mater.[9] T ese ligaments, which derive their name from their tooth-like appearance, extend the whole length of the spinal cord.

Peripheral nervous System: Somatic nerves

T e somatic portion of the PNS consists of the cranial nerves (CNs) and the spinal nerves.

Cranial nerves

T e CNs, typically, are described as comprising 12 pairs, which are referred to by the Roman numerals I through XII (Fig. 3-4). T e CN roots enter and exit the brain stem to

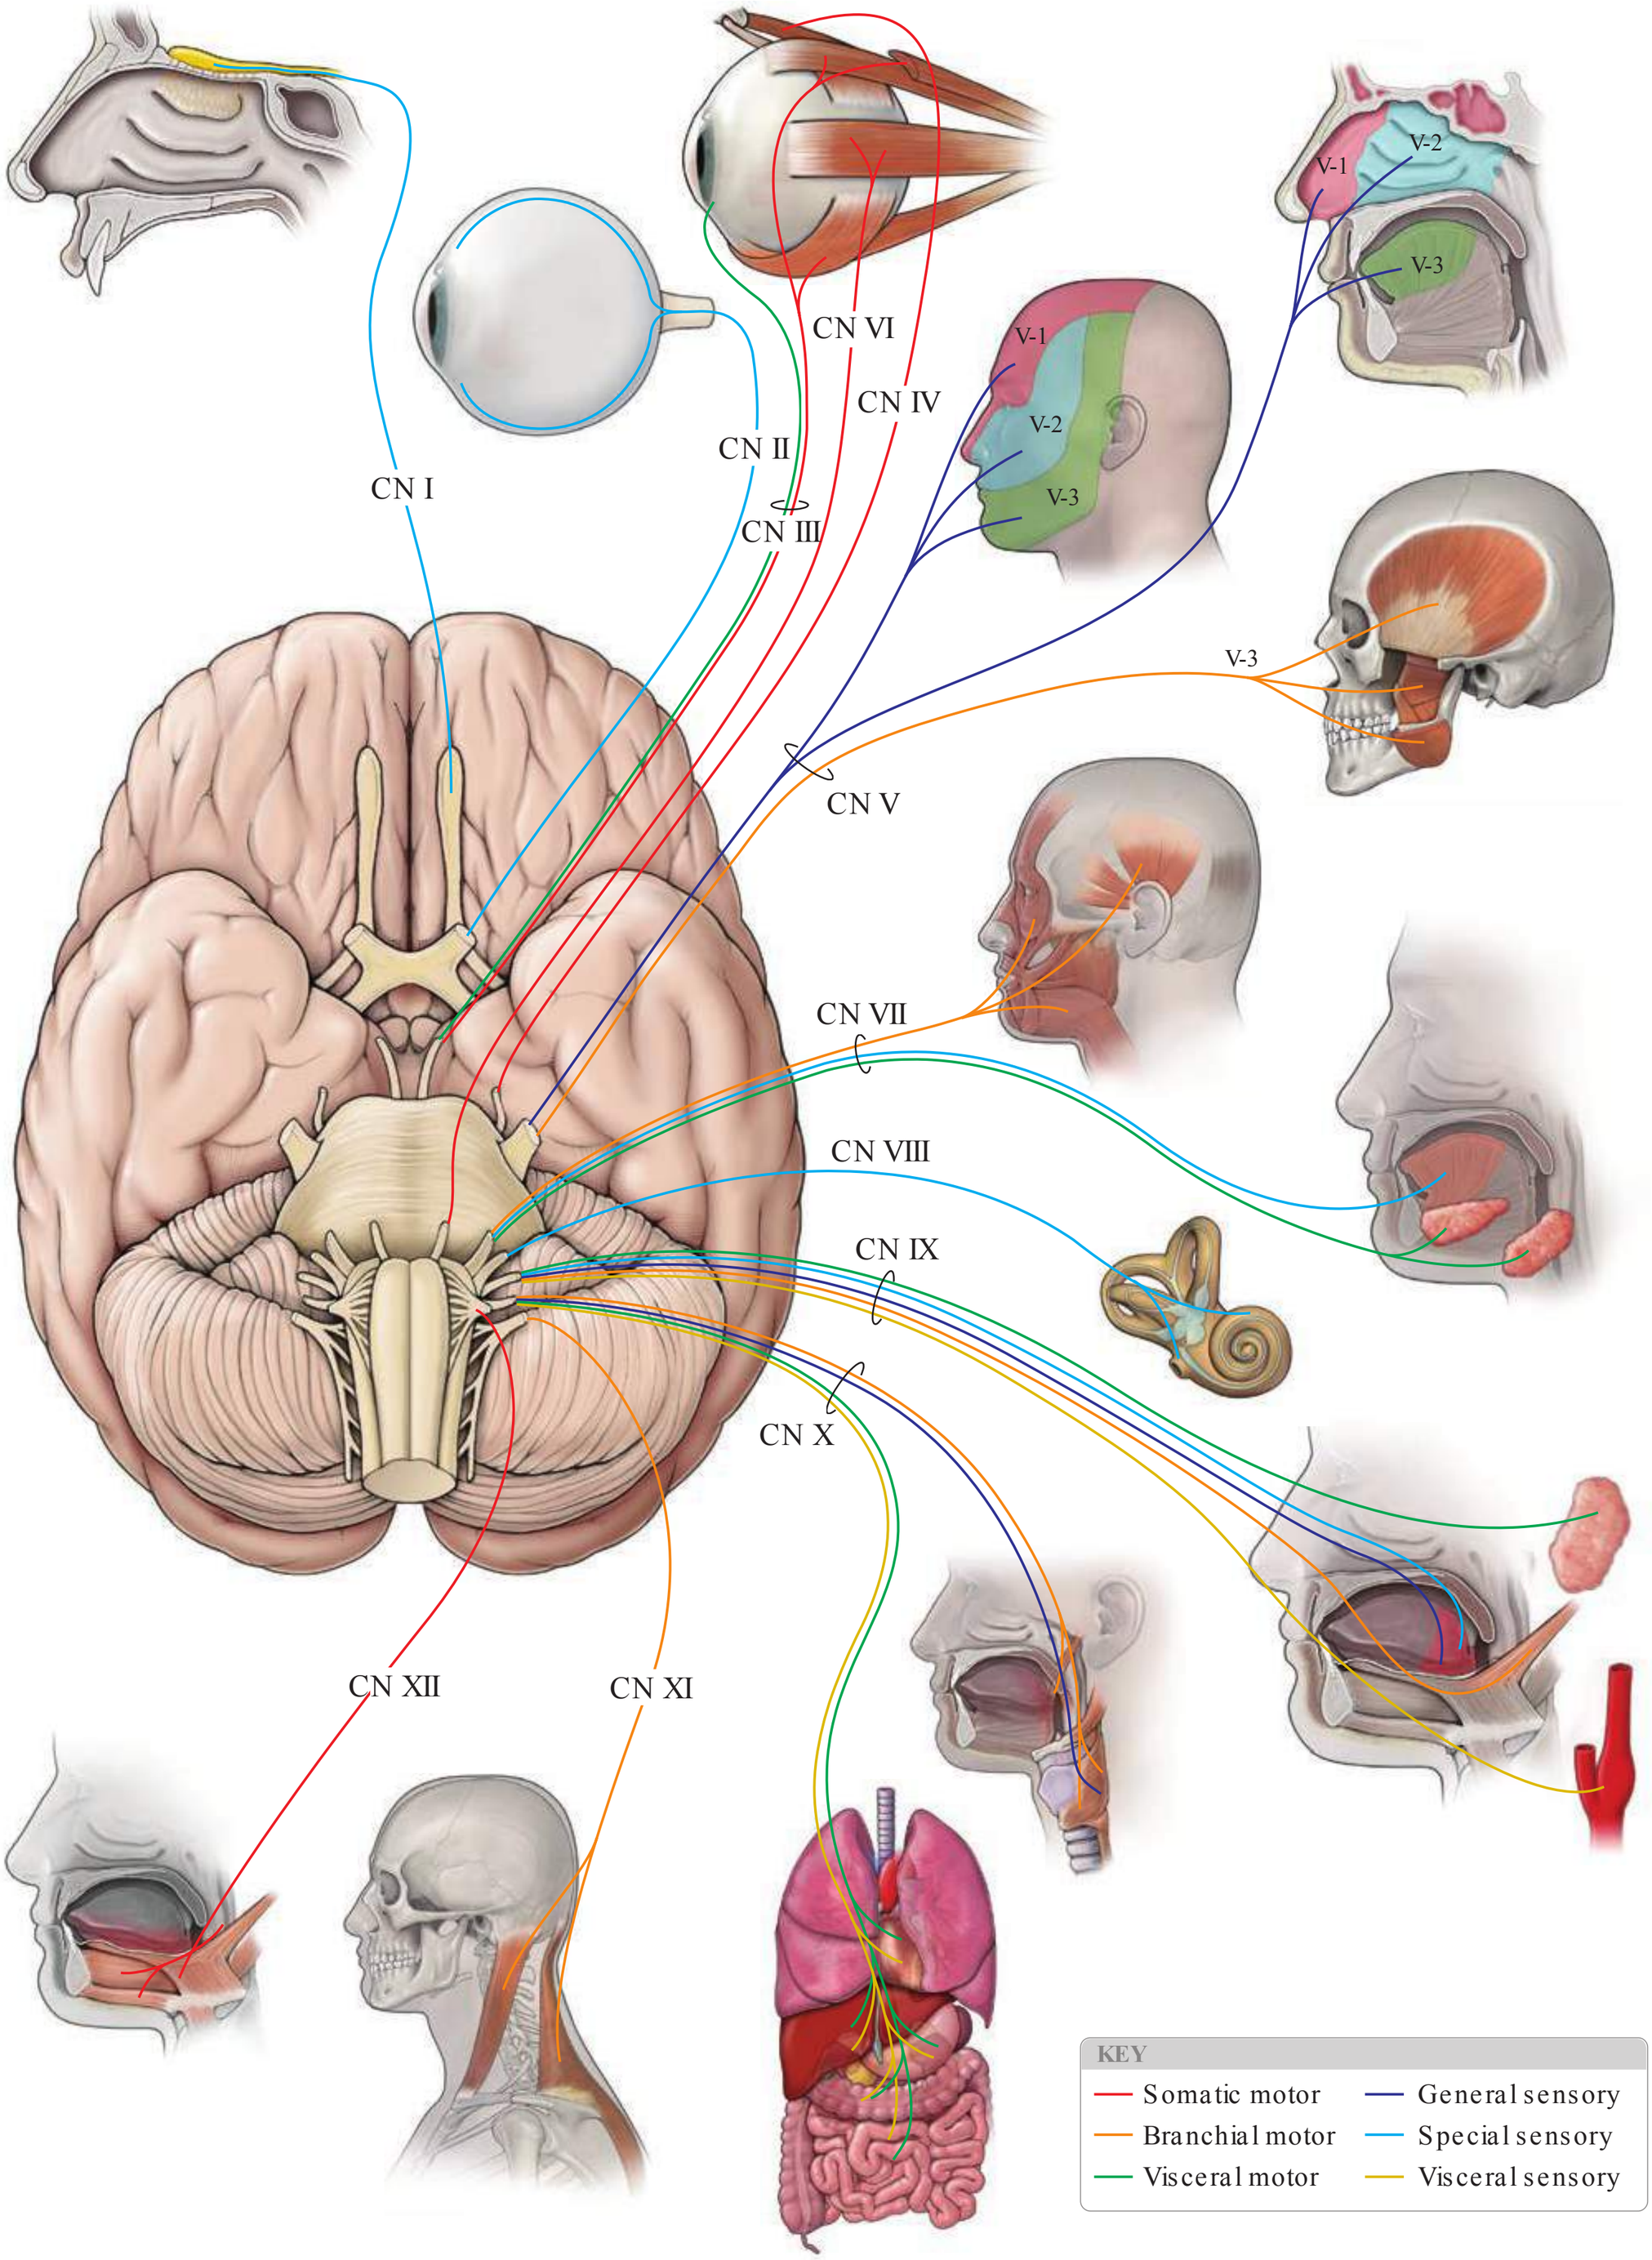

FIGURE 3-4 The CNs. (Reproduced, with permission, from Chapter 17. Cranial Nerves. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

provide sensory and motor innervation to the head and the muscles of the face. CN I (olfactory) and CN II (optic) are not true nerves but rather fiber tracts of the brain. The examination of the CN system is described later in this chapter (see section "Orthopaedic Neurologic Testing").

- **CN I (olfactory).** The olfactory tract (Fig. 3-4) arises from the olfactory bulb on the inferior aspect of the frontal lobe, just above the cribriform plate. From here it continues posteriorly as the olfactory tract and terminates just lateral to the optic chiasm. The olfactory nerve handles the sense of smell.
- **CN II (optic).** The fibers of the optic nerve arise from the inner layer of the retina and proceed posteriorly to enter the cranial cavity via the optic foramen, to form the optic chiasm (Fig. 3-4). The fibers from the nasal half of the retina decussate within the optic chiasm, whereas those from the lateral half do not. The optic nerve handles vision.
- **CN III (oculomotor).** The oculomotor nerve arises in the oculomotor nucleus and leaves the brain on the medial aspect of the cerebral peduncle (Fig. 3-4). It then extends from the interpeduncular fossa and runs between the posterior cerebral artery and the superior cerebellar artery, before leaving the cranial cavity and entering the cavernous sinus by way of the superior orbital fissure. The somatic portion of the oculomotor nerve supplies the levator palpebrae superioris muscle; the superior, medial, and inferior rectus muscles; and the inferior oblique muscles (Fig. 3-4). These muscles handle some eye movements. The visceral efferent portion of this nerve innervates two smooth intraocular muscles: the ciliary and the constrictor pupillae. These muscles handle pupillary constriction.
- **CN IV (trochlear).** The trochlear nerve arises from the trochlear nucleus, just caudal to the oculomotor nucleus at the anterior border of the periaqueductal gray (PAG) matter (Fig. 3-4). The fibers cross within the midbrain and then emerge contralaterally on the posterior surface of the brain stem, before entering the orbit via the superior orbital fissure, to supply the superior oblique muscle.

Note: Because nerves III, IV, and VI are examined together, CN V is described after CN VI.

- **CN VI (abducens).** The abducens nerve originates from the abducens nucleus within the inferior aspect of the pons. Its long intracranial course to the superior orbital fissure makes it vulnerable to pathology in the posterior and middle cranial fossa. The nerve innervates the lateral rectus muscle.
- **CN V (trigeminal).** The trigeminal nerve is so named because of its tripartite division into the maxillary, ophthalmic, and mandibular branches (V-1, V-2, and V-3 respectively in Fig. 3-4). All three of these branches contain sensory cells, but the ophthalmic and the maxillary are exclusively sensory, the latter supplying the soft and hard palate, maxillary sinuses, upper teeth and upper lip, and mucous membrane of the pharynx. The mandibular branch carries sensory information but also represents the motor component of the nerve, supplying the muscles of mastication, both pterygoids, the anterior belly of digastric, tensor tympani, tensor veli palatini, and mylohyoid.

The spinal nucleus and the tract of the trigeminal nerve cannot be distinguished either histologically or on the basis of afferent reception from the cervical nerves. Consequently, the entire column can be viewed as a single nucleus and, legitimately, may be called the trigeminocervical nucleus.

- **CN VII (facial).** The facial nerve is made up of a sensory (intermediate) root, which conveys taste, and a motor root, the facial nerve proper, which supplies the muscles of facial expression, the platysma muscle, and the stapedius muscle of the inner ear (Fig. 3-4). The intermediate root, together with the motor nerve and CN VIII, travels through the internal acoustic meatus to enter the facial canal of the temporal bone. From here, the intermediate nerve swells to form the geniculate ganglion and gives off the greater superficial petrosal nerve, which eventually innervates the lacrimal and salivary glands via the pterygopalatine ganglion and the chorda tympani nerve, respectively. The facial nerve proper exits the skull through the stylomastoid foramen.
- **CN VIII (vestibulocochlear).** The vestibulocochlear nerve subserves two different senses: balance and hearing. The cochlear portion of the nerve arises from spiral ganglia, and the vestibular portion arises from the vestibular ganglia in the labyrinth of the inner ear (Fig. 3-4). The cochlear portion is concerned with the sense of hearing, whereas the vestibular portion is a part of the system of equilibrium, the vestibular system.

The vestibular system includes the vestibular apparatus of the inner ear, the vestibular nuclei and their neural projections, and the exteroreceptors throughout the body, especially in the upper cervical spine and the eyes.[11]

The apparatus of the inner ear consists of the static labyrinth, which comprises three semicircular canals (SCC) (Fig. 3-5), each orientated at right angles to the other. The labyrinth includes specialized sensory areas that are located in the utricle and the saccule (Fig. 3-5), within which otoliths are located (Fig. 3-5).

A series of filaments line the basement membrane of the SCC and project into endolymph, which deforms these filaments when head motion occurs. This deformation is registered by receptor cells, and when sudden perturbations occur, the frequency of nerve impulses along the afferent nerve supply of the cell body is altered.

Unlike the filaments of the SCC, the filaments of the utricle and saccule do not project into endolymph but instead insert into a gelatinous mass, within which the otolith is embedded. Deformation of these filaments is produced by the weight of the otolith against the cilia, as the gelatinous mass is displaced during head movement.

The otoliths are responsible for providing information about gravitational forces, as well as vertical and horizontal motion. The filaments of the saccule also provide information about vertical motion. At rest, the endolymphatic fluid, or the gelatinous membrane, is stationary. When motion of the head occurs, the endolymphatic fluid, or the gelatinous membrane, initially remains stationary because of its inertia, while the

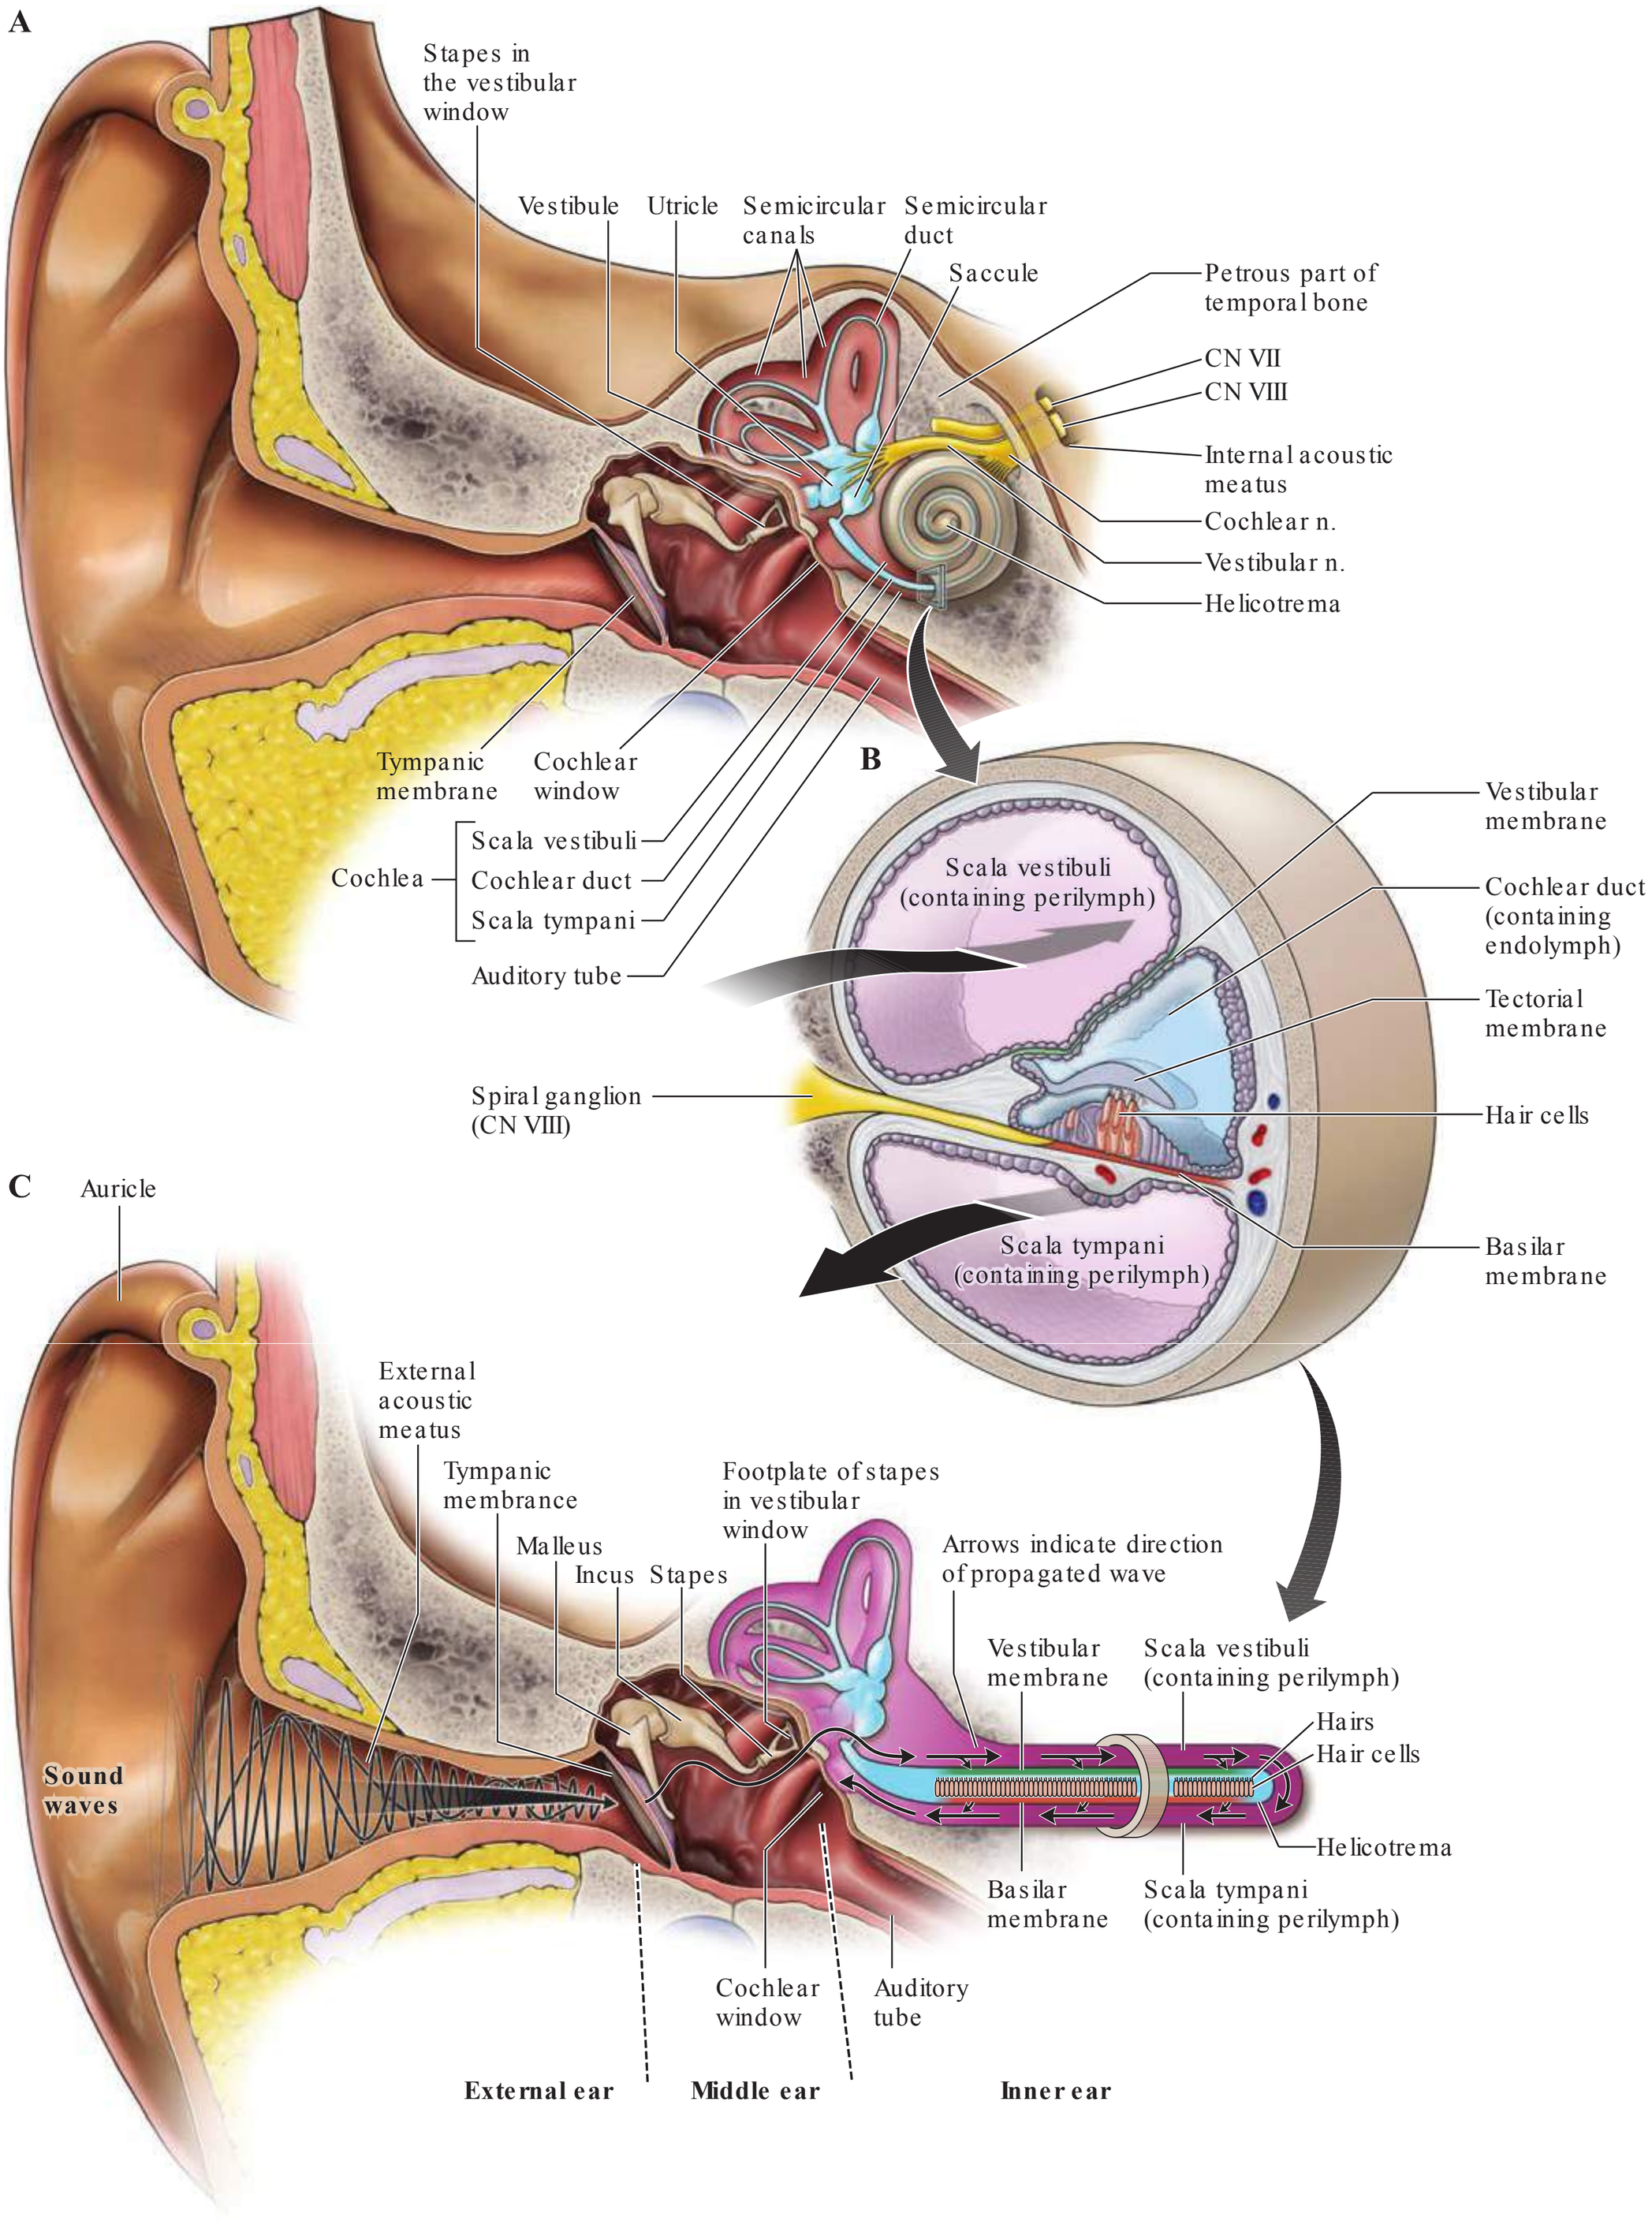

FIGURE 3-5 The apparatus of the inner ear. (Reproduced, with permission, from Chapter 19. Ear. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

canals move. This relative motion produces a dragging effect on the filaments and either increases or decreases the discharge rate, depending on the direction of shear. At the end of the head movement, the fluid and the membrane continue to move, and the cilia are now dragged in the opposite direction before coming to rest. In essence, the SCC receptors transmit a positive signal when movement begins, no signal when the motion has finished, and a normal level after the sensory cell has returned to its original position. As this occurs, other sensory cells orientated in the opposite direction react in the reverse fashion.

Clinical Pearl

The SSC detectors are so sensitive that they can detect angular accelerations as low as 0.2 degrees per second,[12] a rate of acceleration that would turn the head through 90 degrees in 30 seconds and produce a terminal velocity of 6 degrees per second: about as fast as the movement of the second hand of a watch.[13]

- **CN IX (glossopharyngeal).** The glossopharyngeal nerve (Fig. 3-4) contains a somatic motor, visceral efferent, visceral sensory, and somatic sensory fiber. The motor fibers originate in the nucleus ambiguous, leaving the lateral medulla to join the sensory nerve, which arises from cells in the superior and petrous ganglia. The glossopharyngeal nerve exits the skull through the jugular foramen and serves some functions, including supplying taste fibers for the posterior third of the tongue.
- **CN X (vagus).** The functions of the vagus nerve (Fig. 3-4) are numerous and include the motor parasympathetic fibers to all the organs except the suprarenal (adrenal) glands, from its origin down to the second segment of the transverse colon. The vagus also controls some skeletal muscles, including:
  - Cricothyroid muscle
  - Levator veli palatini muscle
  - Salpingopharyngeus muscle
  - Palatoglossus muscle
  - Palatopharyngeus muscle
  - Superior, middle, and inferior pharyngeal constrictors
  - Muscles of the larynx

  The vagus nerve is thus responsible for such varied tasks as heart rate, gastrointestinal peristalsis, sweating, speech, and breathing. It also has some afferent fibers that innervate the inner (canal) portion of the outer ear.
- **CN XI (accessory).** The accessory nerve consists of a cranial component and a spinal component. The cranial root originates in the nucleus ambiguous and is often viewed as an aberrant portion of the vagus nerve. The spinal portion of the nerve arises from the lateral parts of the anterior horns of the first five or six cervical cord segments and ascends through the foramen magnum. The spinal portion of the accessory nerve supplies the sternocleidomastoid (SCM) and the trapezius muscles (Fig. 3-4).
- **CN XII (hypoglossal).** The hypoglossal nerve is the motor nerve of the tongue, innervating the ipsilateral side of the tongue (Fig. 3-4) as well as forming the descendens hypoglossi, which anastomoses with other cervical branches to form the ansa hypoglossi. The latter, in turn, innervates the infrahyoid muscles.

Spinal nerves

There are a total of 31 symmetrically arranged pairs of spinal nerves, each derived from the spinal cord.[14] The spinal nerves are divided topographically into eight cervical pairs (C1–8), 12 thoracic pairs (T1–12), five lumbar pairs (L1–5), five sacral pairs (S1–5), and a coccygeal pair (Fig. 3-2A).

The posterior (dorsal) and anterior (ventral) roots of the spinal nerves are located within the vertebral canal (Fig. 3-2B). The portion of the spinal nerve that is not within the vertebral canal, and that usually occupies the intervertebral foramen, is referred to as a peripheral nerve. As the nerve roots begin to exit the vertebral canal, they must penetrate the dura mater before passing through dural sleeves within the intervertebral foramen. The dural sleeves are continuous with the epineurium of the nerves.

Essentially, there are four branches, or rami, of spinal nerves:[4]

- Posterior (dorsal) rami (Fig. 3-2B). This is type usually consists of a medial sensory branch and a lateral motor branch.
- Anterior (ventral) rami (Fig. 3-3B). Except in the thoracic nerves T2–12, the anterior (ventral) rami of the spinal nerves combine and then split again into networks of nerves referred to as nerve plexuses. There are four plexuses of spinal nerves: the cervical, brachial, lumbar, and sacral.
- Communicating rami. The rami serve as a connection between the spinal nerves and the sympathetic trunk. Only the thoracic and upper lumbar nerves contain a white ramus communicans, but the gray ramus is present in all spinal nerves.
- Meningeal or recurrent meningeal (also known as sinuvertebral). These nerves carry sensory and vasomotor innervation to the meninges.

There are three functional types of nerve fibers in the major nerve trunks, which vary in quantity depending on the particular nerve: afferent (sensory), autonomic (visceral efferent) (see PNS: Autonomic Nervous System [ANS]), and motor (somatic efferent) (Table 3-1). The faster nerve fibers such as A delta fibers are more concerned with speed and quality of human movement whereas the C fibers conduct far more slowly and are more involved with nociception and, by the compounds they release, the health of surrounding tissue.[3]

Afferent (sensory) Nerves. The sensory nerves carry afferents (a nerve conveying impulses from the periphery to the CNS) from a portion of the skin. They also carry efferents (a nerve conveying impulses from the CNS to the periphery) to the skin structures. When a sensory nerve is compressed, symptoms occur in the area of the nerve distribution. This is area of distribution, called a dermatome, is a well-defined portion of the skin and follows the segmental distribution

TABLE 3-1 Classification of Afferent, Cutaneous, and Efferents

Type	Conduction Velocity (m/s)	Function
Afferents		
I	70–120	Provide input from muscle and tendon receptors
II	36–72	Afferents from muscle spindles
III	27–68	Pressure/nociceptive afferents from joints and aponeuroses
IV	1–4	Pain
Cutaneous		
Aα, β	30–70	Tactile receptors
Aδ	12–30	Cold; fast nociception
C	0.5–1.0	Warmth; tissue damage nociception
Efferents		
α	60–100	Extrafusal muscle fibers
γ	10–30	Intrafusal muscle fibers
B	3–30	Preganglionic autonomic
C	0.5–2.0	Postganglionic autonomic

of the underlying muscle innervation. Figure 3-6 is an approximate representation of the various dermatomes on the anterior trunk for the cervical and thoracic nerves. However, there is no current, diagnostically accurate dermatome illustration, and so it is important to remember that textbooks commonly used in medical and allied health programs contain multiple, conflicting dermatome maps, most of which rely on research from the 1940s.[15] For example, the majority show the cutaneous distribution of the fourth lumbar spinal nerve (L4 dermatome) either running from the lateral aspect of the thigh to the medial side of the great toe, or confined to the medial portion of the leg distal to the knee.[15] Consequently, any diagnosis related to the integrity of the nervous system cannot be based on sensory testing alone.

Clinical Pearl

- A dermatome is the area of skin supplied by a single nerve root. Pain dermatomes have less overlap than light-touch dermatomes.[16]
- A myotome is a muscle or group of muscles supplied by a single nerve root.
- A sclerotome is an area of bone or fascia supplied by a single nerve root.

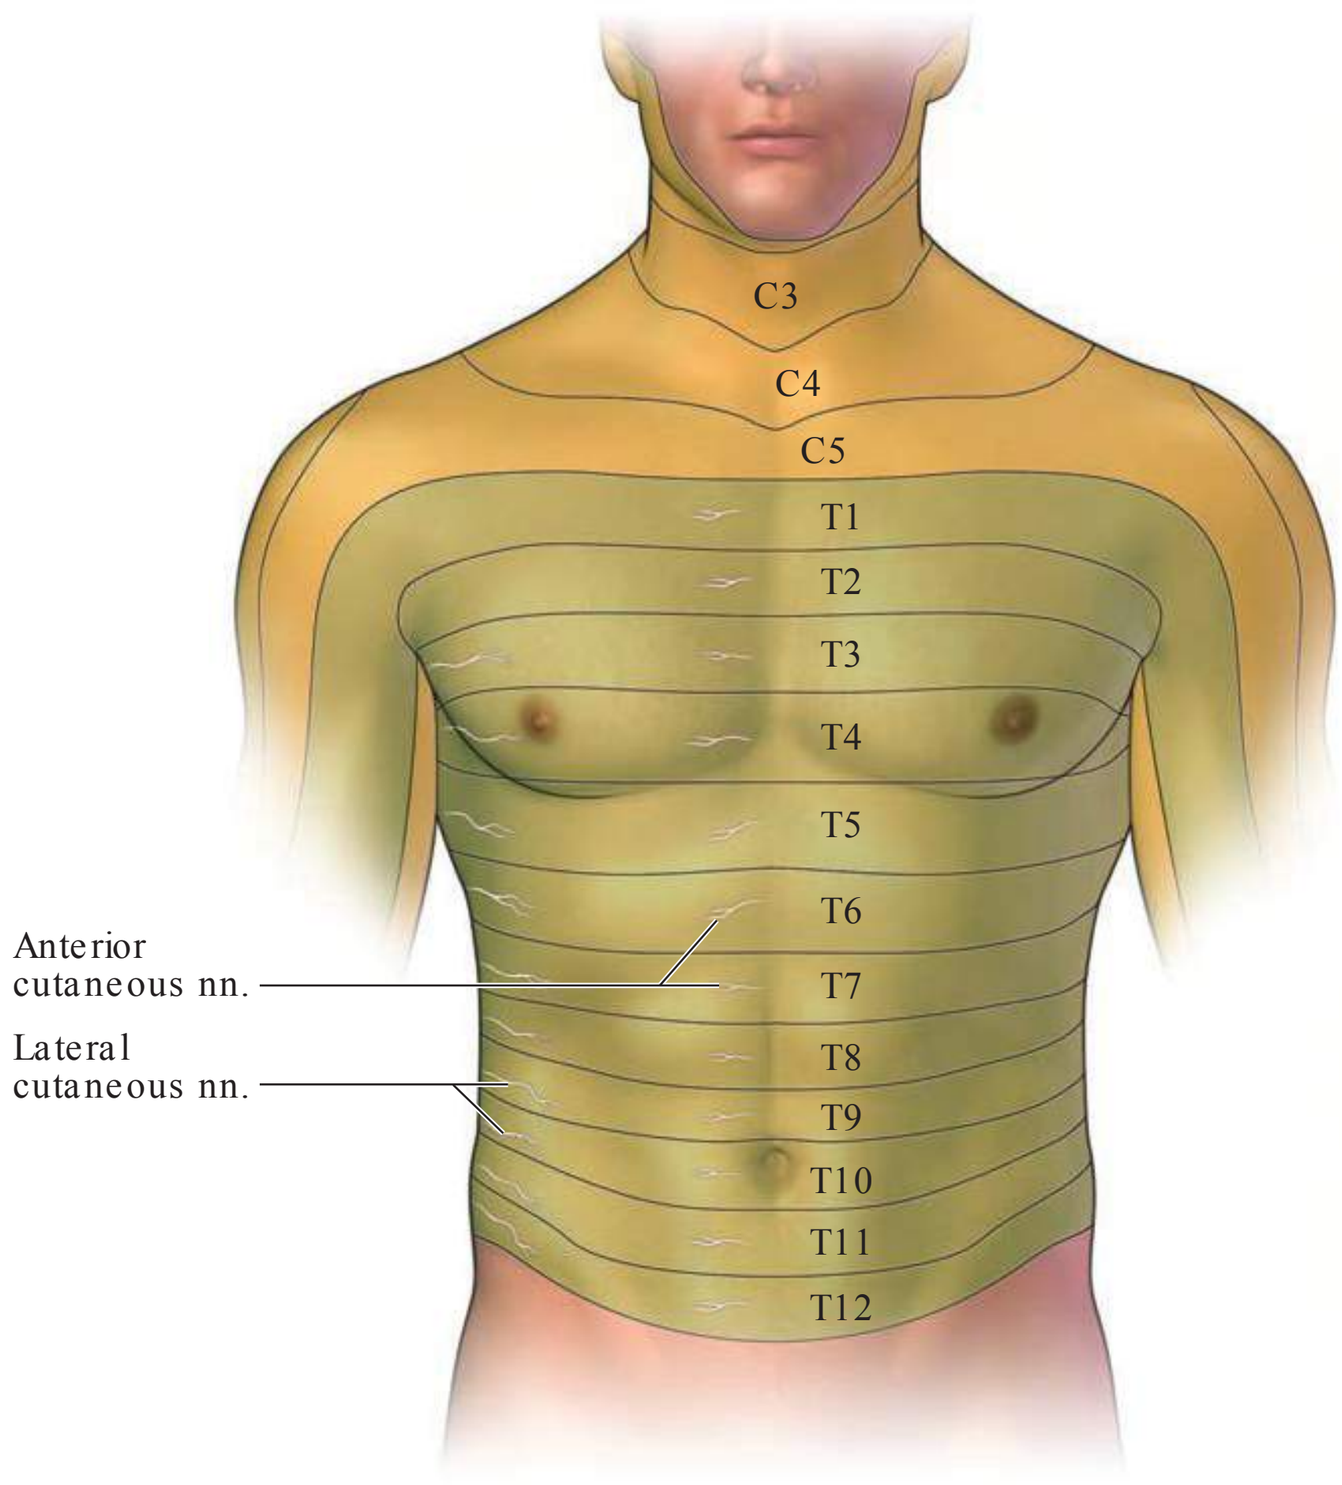

FIGURE 3-6 Segmental distribution of the body. (Reproduced, with permission, from Chapter 2. Anterior Thoracic Wall. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

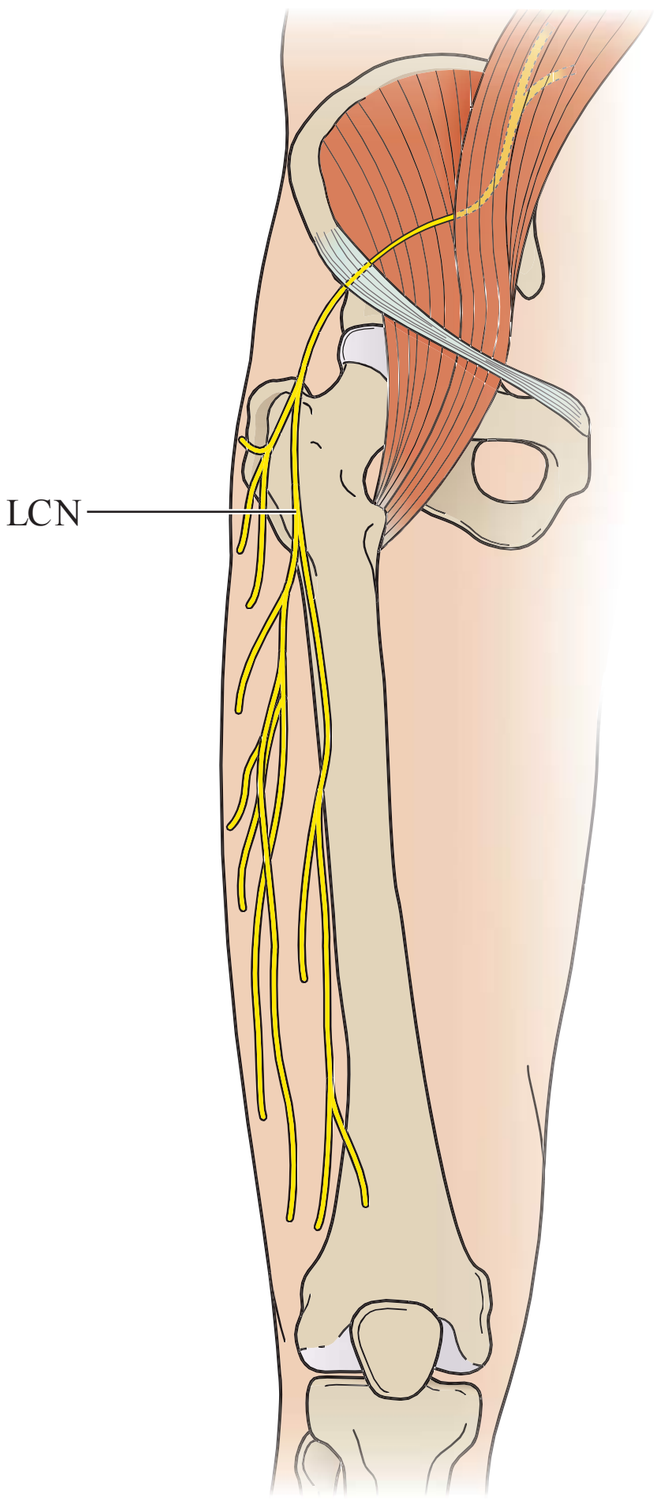

FIGURE 3-7 LCN of the thigh.

Examples of sensory nerves in the body are the lateral (femoral) cutaneous nerve (LCN) of the thigh (Fig. 3-7), the saphenous nerve, and the interdigital nerves (see later).

Cl In ICAl PEARl

Discrepancies exist in the literature regarding the anatomy and incidence of the C1 posterior (dorsal) roots, ganglia, and rami. In a study by Tubbs et al.[17], 30 adult cadavers, with a mean age of 72 years were examined. C1 and C2 spinal nerves were identified in 100% of the specimens examined. In 46.6% of specimens, C1 posterior (dorsal) rootlets were identified and of these, 28.5% had an associated posterior (dorsal) root ganglion. In 50% of specimens, the spinal accessory nerve joined with posterior (dorsal) rootlets of C1. C1 in these cases did not possess a dorsal root ganglion. Thus, in those individuals who do not have a C1 posterior (dorsal) root, there is no C1 dermatome. However, if present, the C1 dermatome covers a small area in the central part of the neck close to the occiput.[4]

Motor (somatic efferent). T e motor nerves carry efferents to muscles and return sensation from muscles and associated ligamentous structures. Any nerve that innervates a muscle also mediates the sensation from the joint upon which that muscle acts. Examples of a motor nerve include the suprascapular nerve and the posterior (dorsal) scapular nerve. A hierarchical recruitment pattern exists in the nervous system for muscle recruitment called the law *of* parsimony.[18] T e law of parsimony states that the nervous system tends to activate the fewest muscles or muscle fibers possible for the control of a given joint action. T is hierarchical pattern of muscle recruitment makes practical sense from an energy perspective.[18]

Cl In ICAl PEARl

A mixed nerve is a combination of skin, sensory, and motor fibers to one trunk. Some examples of a mixed nerve are the median nerve, the ulnar nerve at the elbow as it enters the tunnel of Guyon, the fibular (peroneal) nerve at the knee, and the ilioinguinal nerve.

Cervical Plexus

T e eight pairs of cervical nerves are derived from cord segments between the level of the foramen magnum and the middle of the seventh cervical vertebra.[19] T e spinal nerves from C3 to C7, exiting from the intervertebral foramen, divide into a larger anterior (ventral) ramus and a smaller posterior (dorsal) ramus. T e anterior (ventral) ramus of the cervical spinal nerve travels on the transverse process in an anterior–lateral direction to form the cervical plexus and brachial plexus. T e posterior (dorsal) ramus of the spinal nerve runs posteriorly around the superior articular process, supplying the facet (zygapophyseal) joint, ligaments, deep muscles, and skin of the posterior aspect of the neck.[9]

Each nerve joins with a gray communicating ramus from the sympathetic trunk and sends a small, recurrent meningeal branch back into the spinal canal to supply the dura with sensory and vasomotor innervation. It also branches into anterior and posterior primary divisions, which are mixed nerves that pass to their respective peripheral distributions. T e motor branches carry a few sensory fibers that convey proprioceptive impulses from the neck muscles.

Cl In ICAl PEARl

Two studies[20,21] that analyzed magnetic resonance imaging (MRI) and computed tomography (CT) images of the cervical intervertebral foramen found that the cervical nerve root is located in the lower part of the interpedicular foramen and occupies the major inferior part of the intertransverse foramen. Anteriorly, compression of the nerve roots is likely caused by protruding discs and osteophytes of the uncovertebral region, whereas the superior articular process, the ligamentum flavum, and the periradicular fibrous tissues often affect the nerve posteriorly.[22–25]

- Posterior primary divisions. T e C1 (suboccipital) nerve is the only branch of the first posterior primary divisions. It is a motor nerve, serving the muscles of the suboccipital triangle, with very few, if any, sensory fibers.[19]

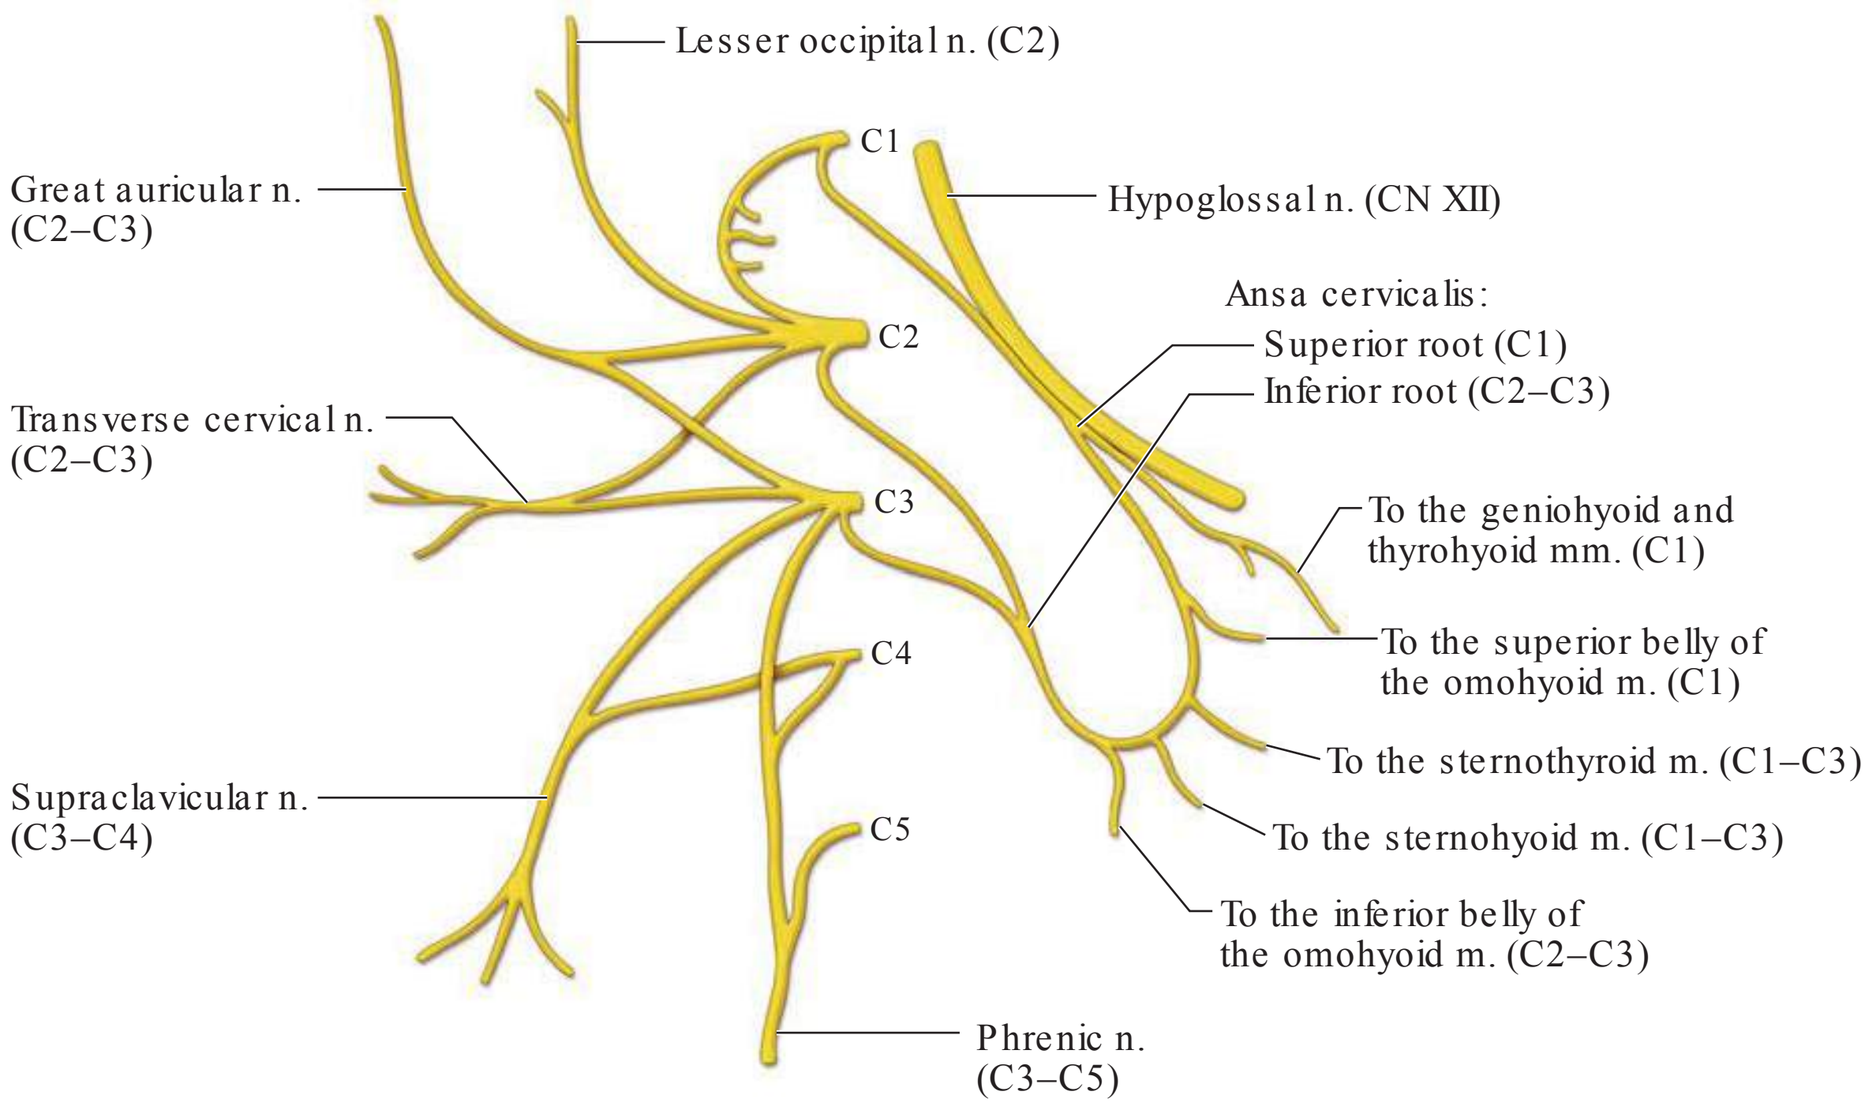

FIGURE 3-8 The cervical plexus. (Reproduced, with permission, from Chapter 25. Overview of the Neck. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

- Anterior primary divisions. The cervical plexus is formed by the anterior primary divisions of the first four cervical nerves (C1–4) (Fig. 3-8).
  - Cervical plexus (C1–4).
  - Sensory branches (see Fig. 3-6).
- Small occipital nerve (C2, 3). This nerve (Fig. 3-8) supplies the skin of the lateral occipital portion of the scalp, the upper median part of the auricle, and the area over the mastoid process.[19]
- Great auricular nerve (C2, 3). This nerve (Fig. 3-8) supplies sensation to the ear and the face via the ascending ramus of the mandible. The nerve lies on or just below the deep layer of the investing fascia of the neck. It arises from the anterior rami of the second and third cervical nerves and emerges from behind the sternocleidomastoid (SCM) muscle, before ascending on it to cross over the parotid gland.
- Cervical cutaneous nerve (cutaneous coli) (C2, 3). This nerve supplies the skin over the anterior portion of the neck.
- Supraclavicular branches (C3, 4). These nerves supply the skin over the clavicle and the upper deltoid and pectoral regions, as low as the third rib.
- Communicating branches. The ansa cervicalis nerve (Fig. 3-8) is formed by the junction of two main nerve roots, derived entirely from anterior (ventral) cervical rami. A loop is formed at the point of their anastomosis, and sensory fibers are carried to the dura of the posterior fossa of the skull via the recurrent meningeal branch of the hypoglossal nerve. The communication with the vagus nerve from C1 is of undetermined function.
- Muscular branches. Communication with the hypoglossal nerve from C1 to C2 (Fig. 3-8) carries motor fibers to the geniohyoid and thyrohyoid muscles and to the sternohyoid and sternothyroid muscles by way of the superior root of the ansa cervicalis (Fig. 3-8). The nerve to the thyrohyoid branches from the hypoglossal nerve and runs obliquely across the hyoid bone to innervate the thyrohyoid. The nerve to the superior belly of the omohyoid branches from the superior root (Fig. 3-8) and enters the muscle at a level between the thyroid notch, and a horizontal plane 2-cm inferior to the notch. The nerves to the sternohyoid and sternothyroid share a common trunk, which branches from the loop (Fig. 3-8). The nerve to the inferior belly of the omohyoid also branches from the loop (Fig. 3-8). The loop is most frequently located just deep to the site where the superior belly (or tendon) of the omohyoid muscle crosses the internal jugular vein. There is a branch to the SCM muscle from C2, and there are branches to the trapezius muscle (C3–4) via the subtrapezial plexus.

Smaller branches to the adjacent vertebral musculature supply the rectus capitis lateralis and rectus capitis anterior (C1), the longus capitis (C2, 4) and longus colli (C1–4), the scalenus medius (C3, 4) and scalenus anterior (C4), and the levator scapulae (C3–5).

The phrenic nerve (C3–5) (see Fig. 3-8) passes obliquely over the scalenus anterior muscle and between the subclavian artery and the vein to enter the thorax behind the sternoclavicular (S-C) joint, where it descends vertically through the superior and middle mediastinum to the diaphragm.[19] Motor branches supply the diaphragm. Sensory branches supply the pericardium, the diaphragm, and part of the costal and mediastinal pleurae.

Cl In ICAl PEARl

The phrenic nerve is the largest branch of the cervical plexus and plays a vital role in respiration.

Phrenic nerve involvement has been described in several neuropathies, including critical illness, polyneuropathy, Guillain–Barré syndrome, brachial neuritis, and hereditary motor and sensory neuropathy type 1.[26,27] The symptoms depend largely on the degree of involvement, and whether one or both of the nerves are involved.[19]

- Unilateral paralysis of the diaphragm causes few or no symptoms except with heavy exertion.
- Bilateral paralysis of the diaphragm is characterized by dyspnea upon the slightest exertion and difficulty with coughing and sneezing.[26,27]
- Phrenic neuralgia, which can result from neck tumors, aortic aneurysm, and pericardial or other mediastinal infections, is characterized by pain near the free border of the ribs, beneath the clavicle, and deep in the neck.[26,27]

Brachial Plexus

The brachial plexus (Fig. 3-9) arises from the anterior divisions of the fifth cervical through the first thoracic nerve roots, with occasional contributions from the fourth cervical and the second thoracic roots. The roots of the plexus, which consist of C5 and C6, join to form the superior (upper) trunk; C7 becomes the middle trunk, and C8 and T1 join to form the inferior (lower) trunks. Each of the trunks divides into anterior and posterior divisions, which then form cords (Fig. 3-9). The anterior divisions of the upper and middle trunk form the lateral cord, the anterior division of the inferior (lower) trunk forms the medial cord, and all three posterior divisions unite to form the posterior cord. The three cords, named for their relationship to the axillary artery, split to form the main branches of the plexus. These branches give rise to the peripheral nerves: musculocutaneous (lateral cord), axillary and radial (posterior cord), ulnar (medial cord), and median (medial and lateral cords).[28] Numerous smaller nerves arise from the roots, the trunks, and the cords of the plexus. Peripheral nerve injuries of the upper extremity and their respective clinical findings are listed in Table 3-2.

From the Roots

- The origin of the posterior (dorsal) scapular nerve (C5) frequently shares a common trunk with the long thoracic nerve (Fig. 3-9). The former passes through the scalenus medius anterior internally, and scalenus posterior laterally,

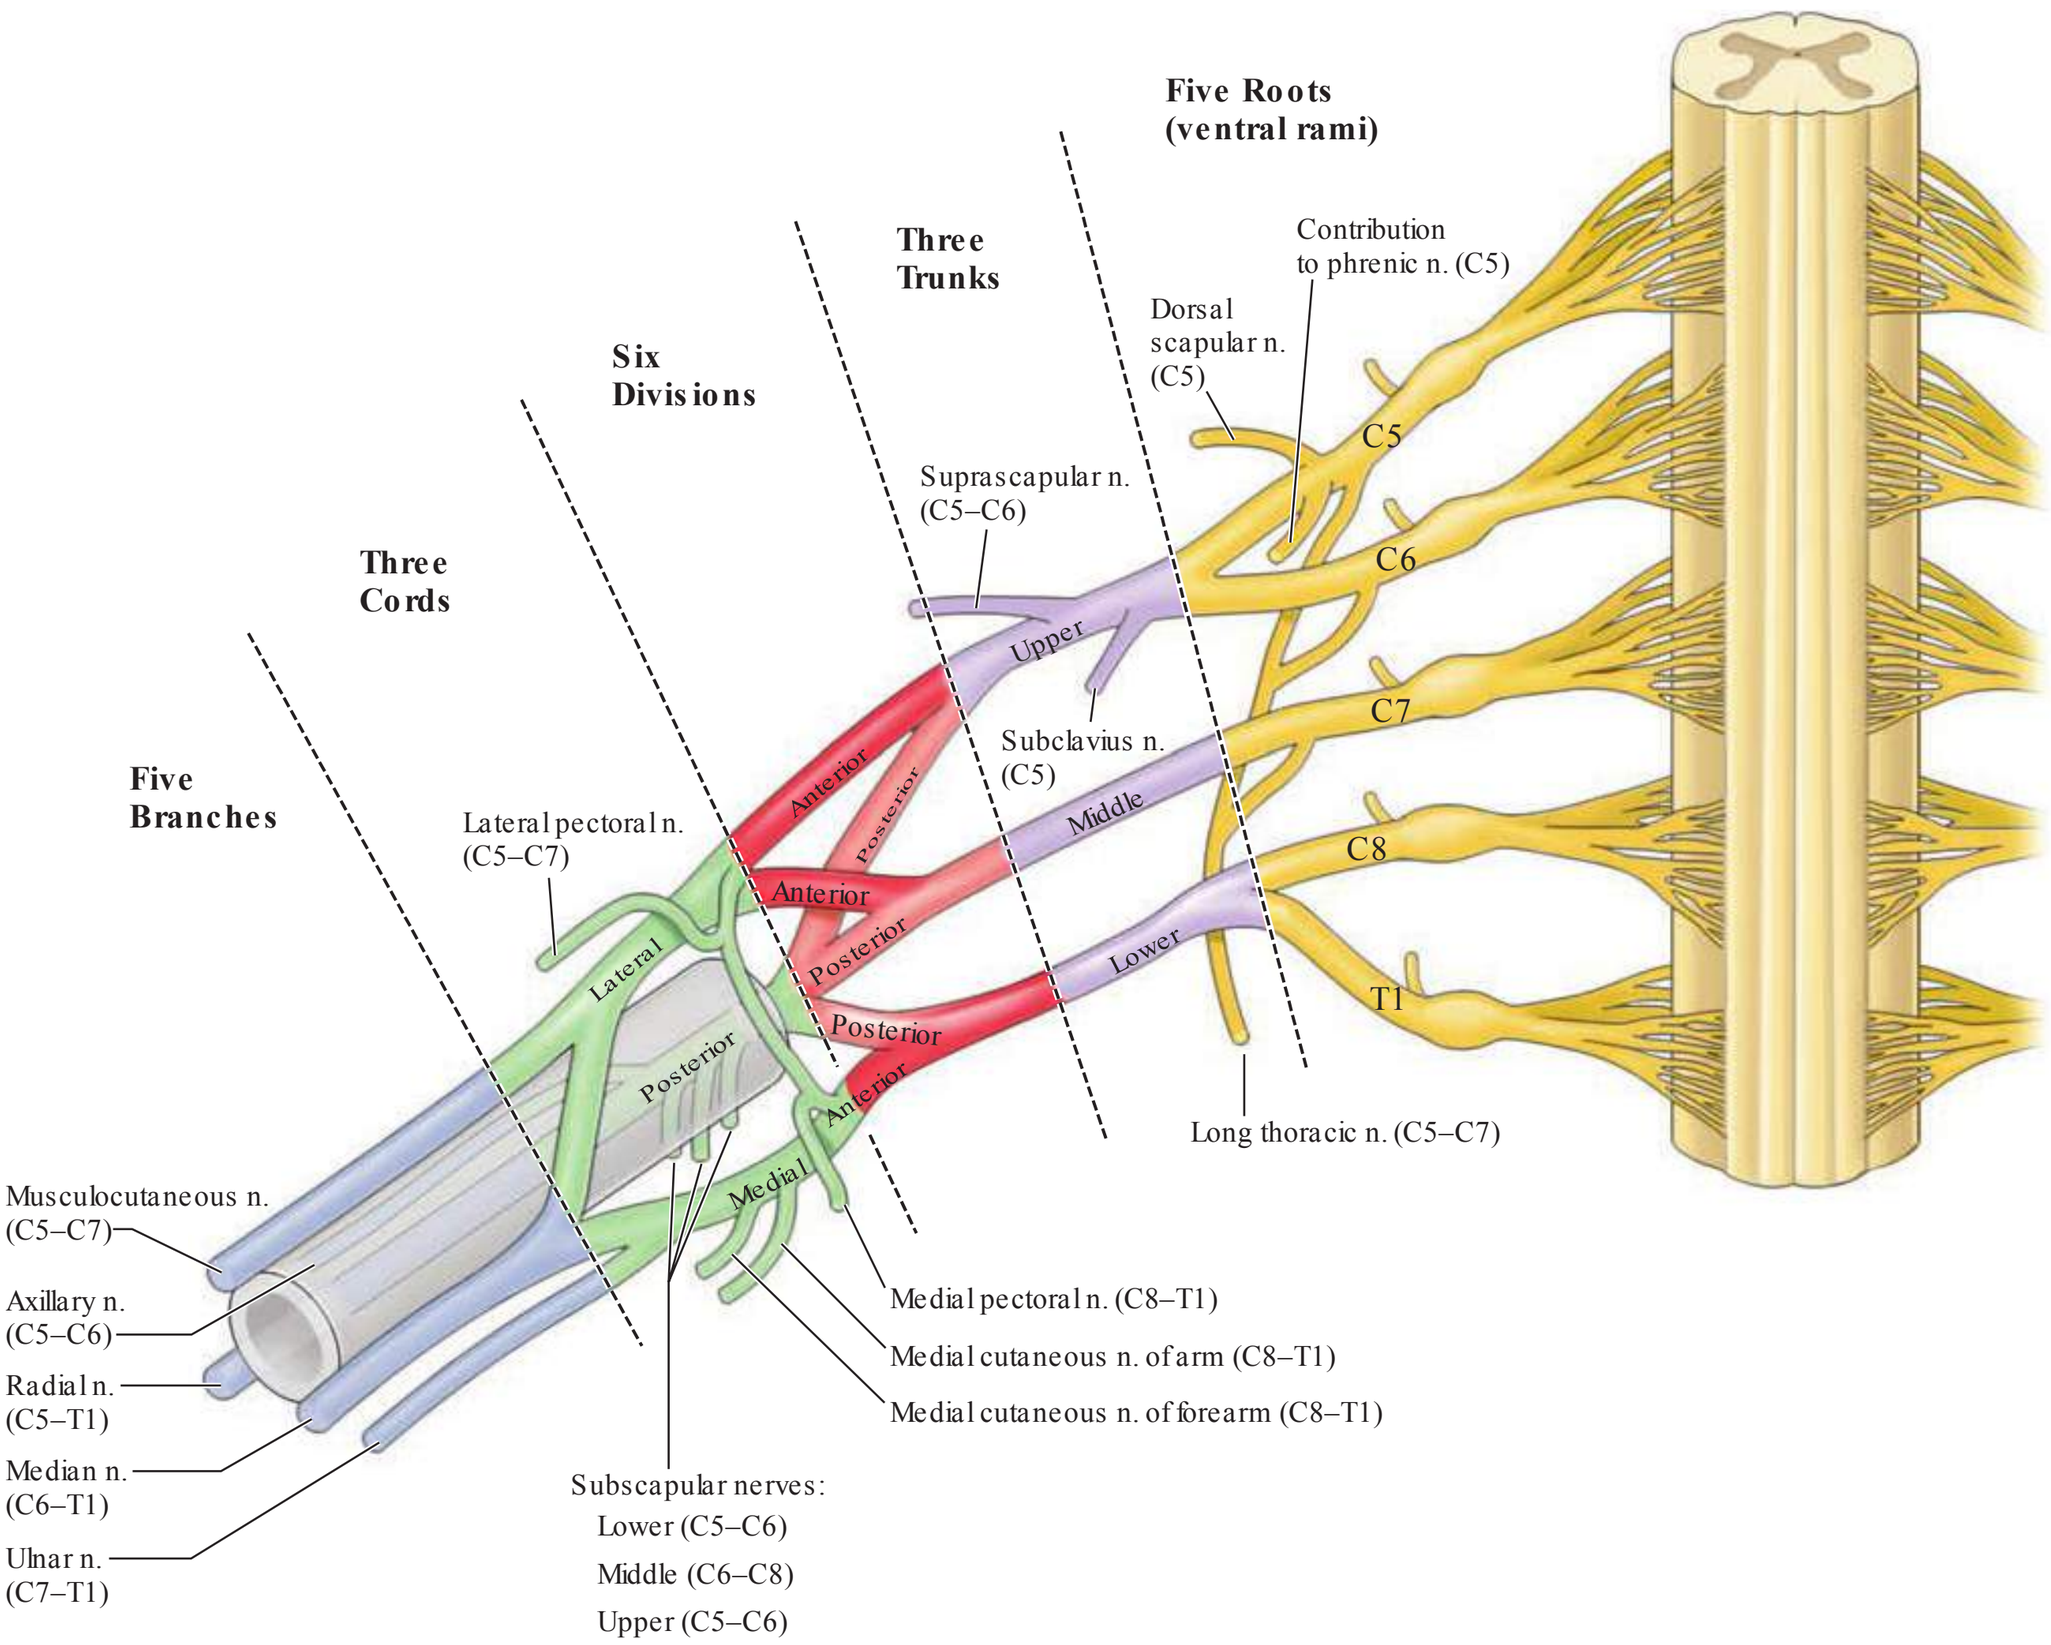

FIGURE 3-9 The brachial plexus. (Reproduced, with permission, from Chapter 29. Overview of the Upper Limb. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

TABLE 3-2 Peripheral Nerve Injury Related to the Cords of the Brachial Plexus

Cord and Nerve	Level of Injury	Motor Loss	Cutaneous Loss
Posterior cord: radial (C5–T1)	Plexus—proximal to axillary nerve	All muscles innervated by radial nerve All muscles innervated by axillary nerve	Throughout radial and axillary distribution
	Axilla (brachioaxillary angle)	Triceps (medial and lateral heads) and anconeus	Posterior brachial cutaneous
	Spiral groove	All muscles innervated by radial nerve except medial head of triceps	Posterior antebrachial cutaneous
	Proximal to lateral epicondyle	Brachialis, brachioradialis, ECRL, and ECRB	
	Arcade of Frohse	Supinator, all muscles innervated by posterior interosseous nerve	Superficial radial (Wartenberg syndrome)
Posterior cord: axillary nerve (C5–6)	Axilla (quadrangular space)	Teres minor and deltoid	Lateral arm
Medial and lateral cord: median nerve (C5–T1)	Plexus (proximal to the joining of the medial and lateral cords)—thoracic outlet syndrome	All muscles innervated by median, musculocutaneous, and ulnar nerves	Throughout median, musculocutaneous, and ulnar distributions
	Ligament of Struthers—proximal to medial epicondyle	Pronator teres	
	Cubital fossa exit—between two heads of the pronator teres	Pronator teres, FCR, FDS, PL, and lumbricales I and II	
	Forearm	Anterior interosseous: FDP (I and II), FPL, and PQ median muscular branch: Thenar muscles (APB, FPB, and OP) and lumbricales I and II	Palmar branch: radial half of thumb Digital branch: posterior (dorsal) tips of thumb, index, and middle finger and radial half of ring finger
Lateral: musculocutaneous nerve (C5–7)	Coracobrachialis	Coracobrachialis Biceps Brachialis	
	Elbow		Lateral antebrachial cutaneous nerve: Lateral forearm
	Cubital tunnel	FCU, FDP, adductor pollicis, lumbricales, and interossei	Posterior and anterior aspects on the ulnar side of the hand
	Between the two heads of the FCU	FDP and FCU	
	Proximal to wrist	Deep branch: all hand muscles innervated by the ulnar nerve Superficial branch: Palmaris brevis	Medial: ulnar nerve (C8–T1)
	Guyon canal	Muscles of the hypothenar eminence (hand of benediction) and interossei	Ulnar aspect of the hand

ECRL, extensor carpi radialis longus; ECRB, extensor carpi radialis brevis; FCR, flexor carpi radialis; FDS, flexor digitorum superficials; PL, palmaris longus; FDP, flexor digitorum profundus; FPL, flexor pollicis longus; PQ, pronator quadratus; APB, abductor pollicis brevis; FPB, flexor pollicis brevis; OP, opponens pollicis; FCU, flexor carpi ulnaris; DIP, distal interphalangeal.

with the presence of some tendinous tissues. Leaving the long thoracic nerve, it often gives branches to the shoulder and the subaxillary region, before the branches join the long thoracic nerve again. The posterior (dorsal) scapular nerve supplies the rhomboids and the levator scapulae muscles. Posterior (dorsal) scapular nerve lesions can result from a forward posture of the head and the neck as this position increases tension in the anterior cervical spine, producing the potential for hypertonicity and hypertrophy of the medial scalene.[29] The chief complaint is usually one of scapular pain radiating to the lateral shoulder and arm.

- A small branch from C5 passes to the phrenic nerve.
- Smaller branches from C6 to C8 extend to the scaleni and longus colli muscles.
- The first intercostal nerve extends from T1.
- The long thoracic nerve (C5–7) is purely a motor nerve that originates from the anterior (ventral) rami of the fifth, the sixth, and the seventh cervical roots (Fig. 3-9). It is the sole innervation to the serratus anterior muscle. The fifth and the sixth cervical roots, along with the posterior (dorsal) scapular nerve, pass through the scalenus medius muscle, whereas the seventh cervical root passes anterior

to it.[30] The nerve then travels beneath the brachial plexus and clavicle to pass over the first rib. From there, it descends along the lateral aspect of the chest wall, where it innervates the serratus anterior muscle. The long thoracic nerve extends as far inferior as the eighth or the ninth rib. Its long and relatively superficial course makes it susceptible to injury from any of the following causes.[10,31–33]

- Entrapment of the fifth and sixth cervical roots, as they pass through the scalenus medius muscle.
- Compression of the nerve during traction to the upper extremity by the undersurface of the scapula, as the nerve crosses over the second rib.
- Compression and traction to the nerve by the inferior angle of the scapula during general anesthesia, or with vigorous passive abduction of the arm.
- Lesions of the long thoracic nerve are common and are the single most common peripheral nerve lesion at the shoulder. The most common cause of long thoracic nerve injury results from carrying a heavy object on the shoulder. Other causes include postinfection, postinjection, postpartum, and postoperative origins.[34] Similar to other peripheral nerve injuries, trauma to the nerve can be caused by a direct blow or a traction force to the nerve. The traction injury can occur when concurrent head rotation away, side bending away, and neck flexion, are coupled with the arm positioned overhead.[35–37] Other mechanisms that have been attributed to long thoracic nerve dysfunction include lifting weights overhead, driving a golf ball, and serving a tennis ball.[38]

The typical clinical presentation includes the following:

- Vague pain in the neck and the scapula region.
- An inability to fully elevate the arm overhead.
- Shoulder flexion and abduction are weak and limited in AROM due to the loss of the trapezius–serratus anterior force couple (see Chapter 16). The clinician should note the presence of winging of the scapula when testing the serratus anterior.

Conservative intervention includes protection of the serratus anterior with a brace or restraint,[34,37,39] galvanic stimulation to the serratus anterior, muscle taping,[40] strengthening exercises for the rhomboids, pectoralis, trapezius, and serratus anterior muscles.[35,38,41] The average rate of return ranges from 3–7 months[30,34] to 2 years.[38]

From the Trunks

A nerve extends to the subclavius muscle (C5–6) from the superior (upper) trunk, or fifth root. The subclavius muscle acts mainly on the stability of the S-C joint, with more or less intensity, according to the degree of the clavicular interaction with the movements of the peripheral parts of the superior limb, and seems to act as a substitute for the ligaments of the S-C joint.[42]

The suprascapular nerve originates from the superior (upper) trunk of the brachial plexus formed by the roots of C5 and C6 (see Fig. 3-9) at Erb's point.

From the Cords

- The medial and lateral pectoral nerves extend from the medial and lateral cords, respectively (see Fig. 3-9). They supply the pectoralis major and pectoralis minor muscles. The pectoralis major muscle has dual innervation.[43] The lateral pectoral nerve (C5–7), which is more medial in the muscle, travels with the thoracoacromial vessels, and innervates the clavicular and sternal heads. The medial pectoral nerve (C8–T1) shares a course with the lateral thoracic vessels and provides innervation to the sternal and costal heads.[44] The main trunk of these nerves can be found near the origin of the vascular supply of the muscle.
- The three subscapular nerves from the posterior cord consist of:
  - The upper subscapular nerve (C5–6), which supplies the subscapularis muscle (see Fig. 3-9).
  - The thoracodorsal nerve, or middle subscapular nerve, which arises from the posterior cord of the brachial plexus with its motor fiber contributions from C6, C7, and C8 (see Fig. 3-9). This nerve courses along the posterior–lateral chest wall, along the surface of the serratus anterior, and deep to the subscapularis, giving rise to branches that supply the latissimus dorsi.
  - The lower subscapular nerve (C5–6) to the teres major and part of the subscapularis muscle (see Fig. 3-9).
  - Sensory branches of the medial cord (C8–T1[45,46] or T1 alone[46]) comprise the medial cutaneous (antebrachial) nerve to the medial surface of the forearm and the medial cutaneous (brachial) nerve to the medial surface of the arm (see Fig. 3-9).

Obstetric Brachial Plexus lesions

The pathomorphologic spectrum of traumatic brachial plexus impairments most often includes combinations of various types of injuries: compression of spinal nerves, traction injuries of spinal roots and nerves, and avulsions of spinal roots.[47] If the rootlets are traumatically disconnected from the spinal cord, they normally exit the intradural space; in rare cases, however, they may also remain within the dural space.

Brachial plexus injuries are most commonly seen in children and usually are caused by birth injuries, although more advanced birthing techniques and an increase in the number of Caesarian births in the United States are producing a decline in incidence. However, difficult deliveries continue to cause such lesions.[48] Although multiple potential risk factors have been cited, including maternal demographic variables, diabetes, hypertension, prior Caesarian delivery, uterine abnormalities, induction of labor, prolonged second stage (adjusted by parity and epidural use), assisted vaginal delivery, and neonatal birth weight, no specific risk factor has been identified.[49] Stretch (neurapraxia or axonotmesis) and incomplete rupture are more common in obstetric brachial plexus palsy than complete rupture or avulsion.

Obstetrical brachial plexus palsy is classified into upper (involving C5, C6, and usually C7 roots), lower (predominantly C8 and T1), and total (C5–C8 and T1) plexus palsies.[50,51] Upper brachial plexus palsy, although described first

by Duchenne,[52] ironically bears the name Erb's palsy.[53] Most cases of obstetric brachial plexus palsy involve Erb's palsy, and the lesion is always supraclavicular. Lower brachial plexus palsy is extremely rare in birth injuries[46,54] and is referred to as Klumpke's palsy.[55]

The infant with Erb's palsy typically shows the classic "waiter's tip" posture of the paralyzed limb.[56,57] The arm lies internally rotated at the side of the chest, the elbow is extended (paralysis of C5, 6) or slightly flexed (paralysis of C5–C7), the forearm is pronated, and the wrist and the fingers are flexed. This posture occurs because of paralysis and atrophy of the deltoid, biceps, brachialis, and brachioradialis muscles.[58]

Klumpke's paralysis is characterized by paralysis and atrophy of the small hand muscles and flexors of the wrist (the so-called claw-hand). Prognosis of this type is more favorable. If the sympathetic rami of T1 are involved, Horner syndrome (ptosis, enophthalmos, facial reddening, and anhydrosis) may be present.

Clinical Pearl

- Mononeuropathy: injury to a single peripheral nerve (e.g., the radial nerve).
- Polyneuropathy: involvement of more than one peripheral nerve. Occurs in such systemic diseases as diabetes.

Peripheral nerves of the Upper Quadrant

Peripheral nerves are subject to entrapment at various anatomical locations in the upper extremities.

Spinal Accessory nerve

The spinal accessory, or simply the accessory, nerve is formed by the union of CN XI (see Cranial Nerves) and the spinal nerve roots of C3 and C4, and innervates the trapezius and the SCM muscles. Thus, dysfunction of this nerve causes paralysis of the SCM and the trapezius muscles.

Isolated lesions to this nerve result from forces acting across the glenohumeral (G-H) joint. Combined lesions of the spinal accessory and the axillary nerve result from forces acting broadly across the scapulothoracic joint. These lesions are associated with fractures of the clavicle and/or scapula and subclavian vascular lesions.[59]

The superficial course of the nerve also makes it susceptible to injury during operative procedures or blunt trauma,[60] and to stretch-type injuries,[61,62] such as during a manipulation of the shoulder under anesthesia.[63] However, the stretch-type injuries do not always involve the SCM.[64] Accessory nerve paresis can also result from a serious pathology such as a tumor at the base of the skull, or from surgery.[65]

Clinical findings for this condition include:

- neck, shoulder, and medial scapular pain;
- decreased cervical lordosis;
- a downwardly rotated scapula;
- winging of the scapula;
- trapezius weakness, especially with active arm elevation.

A confirmatory test includes resisted adduction of the scapula while the clinician applies counterpressure at the medial border of the inferior scapular angle. This will highlight weakness on the affected side.

Conservative intervention for this condition involves patient education to avoid traction to the nerve, specific upper, middle, and lower trapezius strengthening, neuromuscular electrical stimulation to the upper and lower trapezius, cervical proprioceptive neuromuscular facilitation (PNF) techniques, scapular PNF techniques, prone-on-elbows scapular stabilization exercises (see Chapter 25), and shoulder elevation strengthening. McConnell taping is also used to facilitate the middle and lower trapezius muscle.[63]

Suprascapular nerve (C5–6)

The suprascapular nerve (Fig. 3-9) travels downward and laterally behind the brachial plexus and parallel to the omohyoid muscle beneath the trapezius to the superior edge of the scapula, through the suprascapular notch. The roof of the suprascapular notch is formed by the transverse scapular ligament. The suprascapular artery and vein initially run with the nerve and then run above the transverse suprascapular ligament over the notch. After passing through the notch, the nerve supplies the suprascapular muscle. It also provides articular branches to the G-H and acromioclavicular (A-C) joints and provides sensory and sympathetic fibers to two-thirds of the shoulder capsule, and to the G-H and A-C joints. The nerve then turns around the lateral edge of the scapular spine to innervate the infraspinatus.

It is commonly taught that the suprascapular nerve provides the motor supply to the supraspinatus and infraspinatus muscles and sensory innervation to the shoulder joint but that it has no cutaneous representation. However, cutaneous branches are present in the proximal one-third of the arm,[66–68] and their distribution overlaps with that of the supraclavicular and axillary nerves.

Clinical Pearl

Pain related to suprascapular nerve entrapment may radiate to the lateral neck or posterior and lateral aspects of the G-H capsule area.

The suprascapular nerve may be injured by compression, traction, or laceration.[69] A direct blow at Erb's point can cause a compression-type injury.[69] Compression neuropathy of the suprascapular nerve often occurs in the scapular notch under the transverse scapular ligament, or at the spinoglenoid notch. This compression occurs through extraneural inflammation, lipoma or cyst development, scarring following distal clavicle resection, or ligament entrapment.[29,35,70,71]

In the case of a ligament entrapment, the cause can be acute trauma resulting from a fall on an outstretched hand (FOOSH), scapular fracture, or overuse injuries involving repetitive overhead motions.[70,72,73] Entrapment of this nerve may be misdiagnosed as rotator cuff tendonitis, a tear of the rotator cuff, or cervical disk disease.[72,74]

As the suprascapular nerve is a mixed nerve, the patient presentation usually includes the following:

- A dull, deep ache at the posterior and lateral aspects of the shoulder, which may have a burning quality.
- Muscle atrophy and weakness of the supraspinatus and infraspinatus.
- Changes in G-H biomechanics with an increase of scapular elevation occurring during arm elevation. T is may produce impingement-like findings and complicate the diagnosis.
- Full external rotation of the G-H joint and passive horizontal adduction are painful.[75] Electromyography (EMG) is the definitive test for suprascapular neuropathy.[76]

Conservative intervention includes rest, ice, analgesics, and a series of perineural injections of corticosteroid to help reduce neural inflammation. A home exercise program of scapular pivoter strengthening (see Chapter 16), scapulohumeral coordination exercises (see Chapter 16), and activity-specific training may be indicated.[35]

Surgical intervention, involving neurolysis, cyst removal, or the excision of the transverse scapular ligament is indicated if symptoms persist.

Musculocutaneous nerve (C5–6)

T e musculocutaneous nerve (Fig. 3-10) is the terminal branch of the lateral cord, which in turn is derived from the anterior division of the upper and middle trunks of the fifth through seventh cervical nerve roots.[77,78]

T e nerve arises from the lateral cord of the brachial plexus at the level of the insertion of the pectoralis minor[78,79] and proceeds caudally and laterally, giving one or more branches to the coracobrachialis, before penetrating this muscle 3–8 cm below the coracoid process.[78,80] T e nerve then courses through, and supplies, the biceps brachii and brachialis muscles, before emerging between the biceps brachii and the brachioradialis muscles 2–5 cm above the elbow (see Fig. 3-11). At this level, now called the lateral cutaneous (antebrachial) nerve of the forearm, it divides into anterior and posterior divisions to innervate the anterior–lateral aspect of the forearm (Fig. 3-10).[78]

Atraumatic isolated musculocutaneous neuropathies are rare. Reported cases have been associated with positioning during general anesthesia,[81] peripheral nerve tumors, and strenuous upper extremity exercise without apparent underlying disease.[82–85] Mechanisms proposed for the exercise-related cases include entrapment within the coracobrachialis,[82–84] as well as traction between a proximal fixation point at the coracobrachialis and a distal fixation point at the deep fascia at the elbow.[78] Injury to this nerve can also result from demanding physical work involving shoulder flexion and repetitive elbow flexion with a pronated forearm.[82,85,86] Although rare, an isolated lesion to the musculocutaneous nerve can result in weakness of the biceps, coracobrachialis, and brachialis (Table 3-2). T ese muscles help stabilize the elbow and the G-H joint and maintain the static position of the arm.[87]

T e typical clinical presentation includes:

- Reports or evidence of muscle wasting and sensory changes to the lateral side of the forearm;
- weakness of the biceps, brachialis, and coracobrachialis;
- diminished biceps reflex;
- decreased sensation at the lateral forearm; and
- positive EMG study.

Conservative intervention includes cessation of the strenuous activity and a gradual return to activity with resolution of symptoms.[85]

Cl In ICAl PEARl

Although a musculocutaneous lesion would be expected to demonstrate a weakness of elbow flexion, one would not expect to see weakness in all shoulder motions, with an injury isolated to the proximal musculocutaneous nerve.

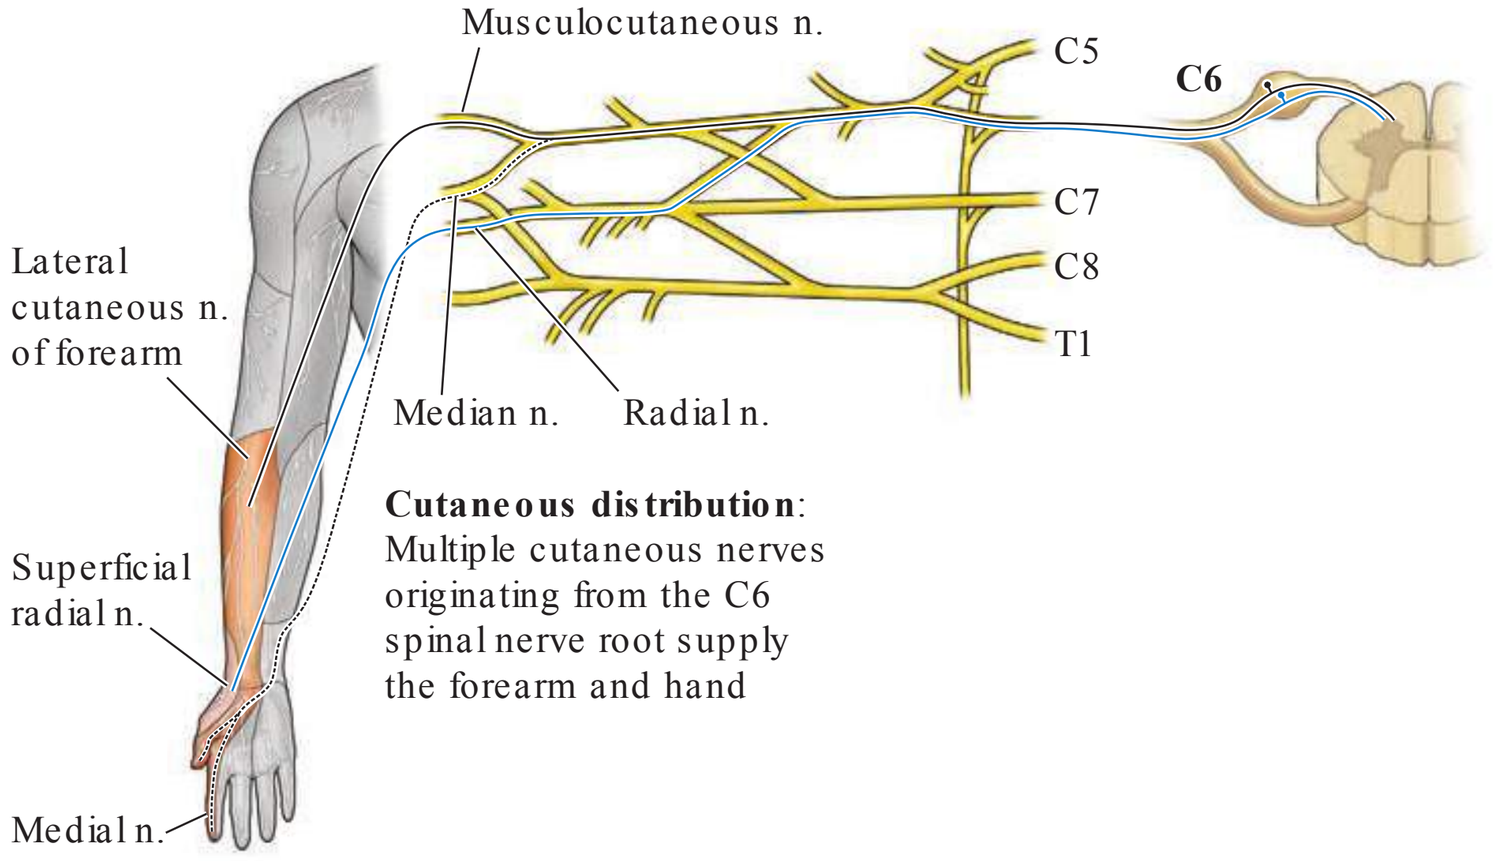

FIGURE 3-10 The musculocutaneous (C5–6) nerve. (Reproduced, with permission, from Chapter 29. Overview of the Upper Limb. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

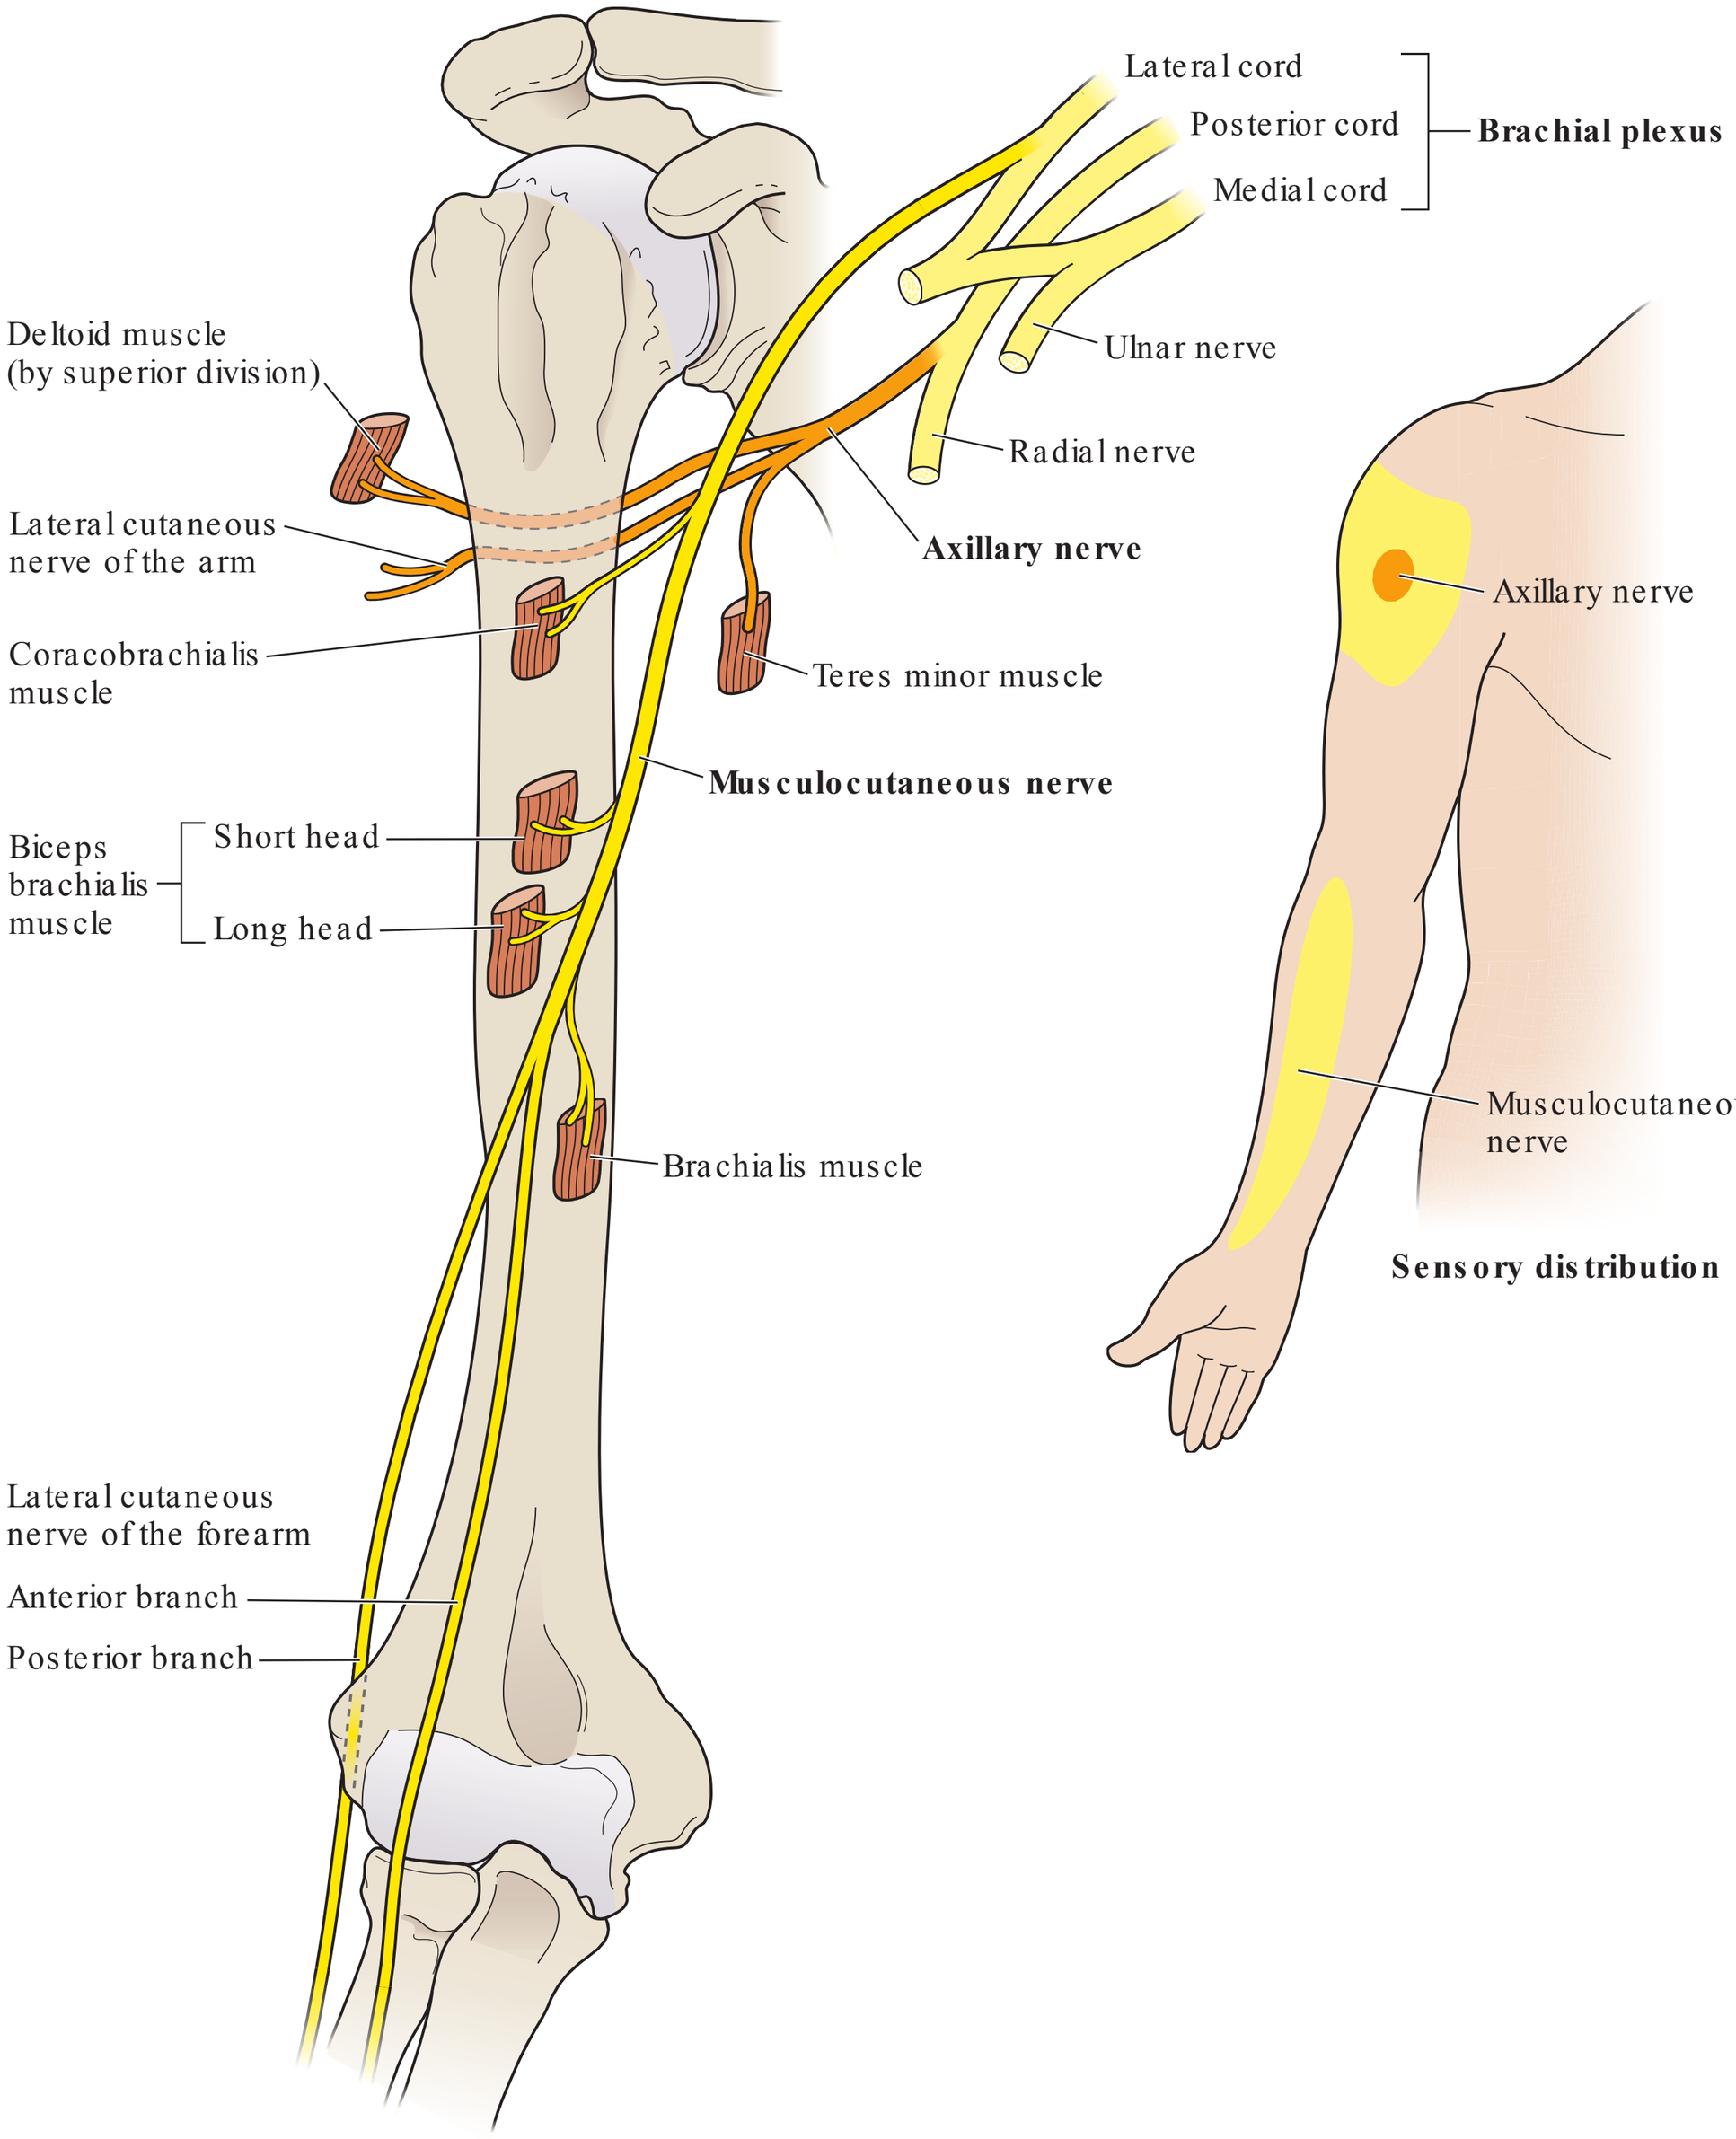

FIGURE 3-11 The musculocutaneous (C5–6) and axillary (C5–6) nerves. (Reproduced, with permission, from Appendix C. Spinal Nerves and Plexuses. In: Waxman SG. eds. Clinical Neuroanatomy, 27e. New York, NY: McGraw-Hill; 2013.)

Axillary nerve (C5–6)

The axillary nerve is the last nerve of the posterior cord of the brachial plexus before the latter becomes the radial nerve (see Fig. 3-11). The axillary nerve arises as one of the terminal branches of the posterior cord of the brachial plexus, with its neural origin in the fifth and sixth cervical nerve roots. The axillary nerve crosses the anterior–inferior aspect of the subscapularis muscle, where it then crosses posteriorly through the quadrilateral space and divides into two major trunks. Along its course across the subscapular muscle, the axillary nerve releases its first articular branch to the inferior–anterior G-H joint capsule. The posterior trunk of the axillary nerve gives a branch to the teres minor muscle and the posterior deltoid muscle, before terminating as the superior

TABLE 3-3	Injury Findings Related to Nerves of the Brachial Plexus
Spinal accessory nerve	Inability to abduct the arm beyond 90 degree Pain in shoulder with abduction
Musculocutaneous nerve	Weak elbow flexion with forearm supinated
Long thoracic nerve	Pain on flexing fully extended arm Inability to flex fully extended arm Winging of scapula at 90 degree of forward flexion
Suprascapular nerve	Increased pain on forward shoulder flexion Pain increased with scapular abduction Pain increased with cervical rotation to opposite side
Axillary nerve	Inability to abduct arm with neutral rotation
Suprascapular nerve compression or injury	Supraspinatus and infraspinatus weakness and atrophy (if compression prior to innervation of supraspinatus) Infraspinatus weakness and atrophy alone (if compression at the spinoglenoid notch)
Thoracic outlet syndrome	Symptoms reproduced by Roos test, Wright maneuver, Adson test, or hyperabduction test (variable) Diminution of pulse with Adson test, Wright maneuver, Halsted test, or hyperabduction test (variable)
Brachial plexus (stinger or burner)	History of traction force to neck rotation, neck side bending, shoulder abduction, or shoulder external rotation, with simultaneous scapula and clavicular depression Tenderness over brachial plexus Weakness in muscles innervated by involved portion of the plexus C5 (deltoid, supraspinatus, and infraspinatus) most commonly involved C6 (elbow flexors) second most commonly involved Sensory loss in involved nerve distribution Transient burning and pain

lateral cutaneous (brachial) nerve of the arm (see Fig. 3-11). The anterior trunk continues, giving branches to supply the middle and anterior deltoid muscle.

The axillary nerve is susceptible to injury at several sites, including the origin of the nerve from the posterior cord, the anterior–inferior aspect of the subscapularis muscle and G-H joint capsule, the quadrilateral space, and within the subfascial surface of the deltoid muscle (Table 3-3).

Axillary nerve lesions may result from acute G-H dislocation, surgery to the G-H complex, blunt trauma to the axilla, secondary hematoma and fibrous formation, entrapment, and tractioning.[35,86,88,89]

The typical clinical presentation includes:

- deep pain in the axilla, or in the anterior shoulder in the case of a G-H dislocation;
- tingling in the deltoid aspect of the shoulder;
- atrophy may be seen in the deltoid and teres minor;
- weakness when elevating the arm in flexion and abduction[35];
- manual muscle testing will reveal a weakness of the deltoid and teres minor; and
- sensory testing should highlight a loss of sensation at the lateral deltoid region.

The diagnostic test for this lesion is to ask the patient to abduct the arm to 90 degrees and to bring it back into horizontal extension. A patient with an axillary lesion will demonstrate extreme difficulty with this.[90]

Intervention for this lesion is initially conservative and consists of thermal modalities, protection, and strengthening exercises.[35] Surgical exploration may be indicated in cases of complete denervation.

Radial nerve (C6–8, T1)

The radial nerve (Fig. 3-12) is the largest branch of the brachial plexus. Originating at the lower border of the pectoralis minor as the direct continuation of the posterior cord, it derives fibers from the last three cervical and first thoracic segments of the spinal cord. During its descent down the arm, the radial nerve accompanies the profunda artery behind, and around, the humerus and in the musculospiral groove. It pierces the lateral intermuscular septum and reaches the lower anterior side of the forearm, where its terminal branches arise.

CLINICAL PEARL

The radial nerve is frequently entrapped at its bifurcation in the region of the elbow, where the common radial nerve becomes the sensory branch and a deep or posterior interosseous branch.

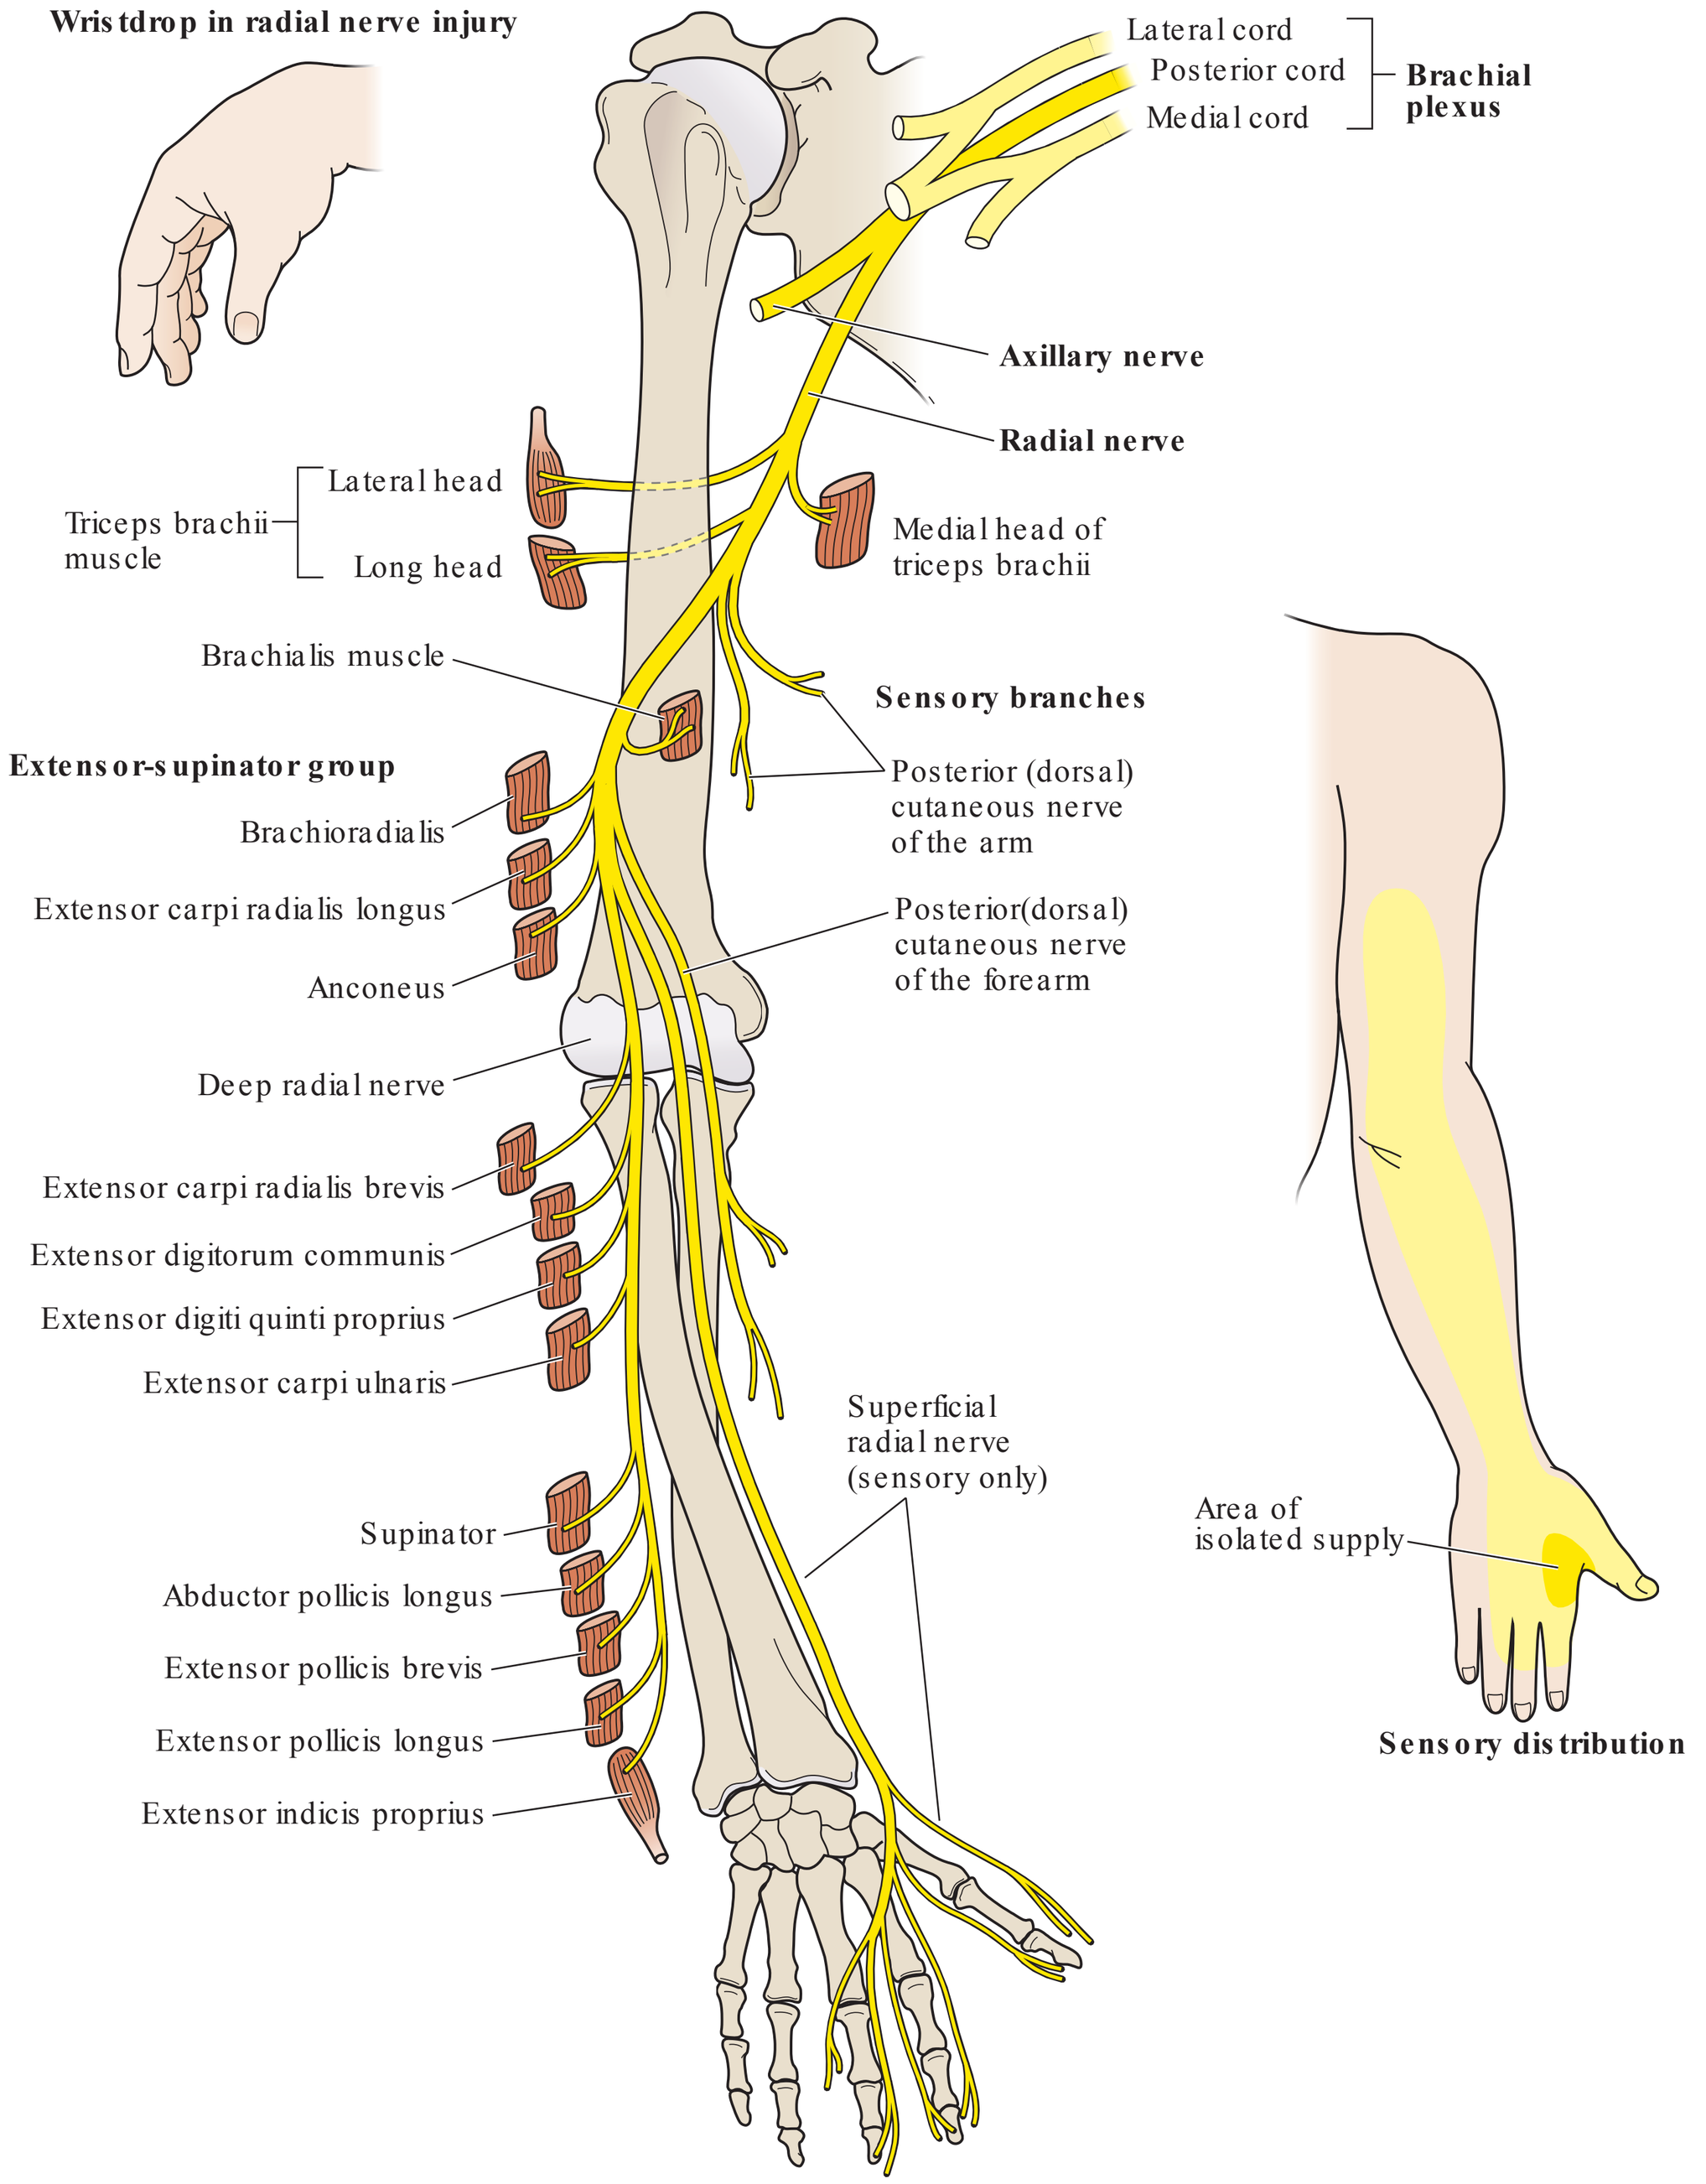

FIGURE 3-12 The radial nerve (C6–8, T1). (Reproduced, with permission, from Appendix C. Spinal Nerves and Plexuses. In: Waxman SG. eds. Clinical Neuroanatomy, 27e. New York, NY: McGraw-Hill; 2013.)

The radial nerve crosses the elbow immediately anterior to the radial head, just beneath the heads of the extensor origin of the extensor carpi radialis brevis (ECRB), and then divides, with the deep branch running through the body of the supinator muscle to the posterior aspect of the forearm.

The radial nerve in the arm supplies the triceps, the anconeus, and the upper portion of the extensor–supinator group of forearm muscles. In the forearm, the posterior interosseous nerve innervates all of the muscles of the six extensor compartments of the wrist, with the

exception of the ECRB and extensor carpi radialis longus (ECRL).

The skin areas supplied by the radial nerve include the posterior (dorsal) cutaneous (brachial) nerve of the arm, to the posterior (dorsal) aspect of the arm; the posterior (dorsal) cutaneous (antebrachial) nerve of the forearm, to the posterior (dorsal) surface of the forearm; and the superficial radial nerve, to the posterior (dorsal) aspect of the radial half of the hand (see Fig. 3-12). The isolated area of supply is a small patch of skin over the posterior (dorsal) aspect of the first interosseous space (see Fig. 3-12).

Four radial nerve entrapments are commonly cited: high radial nerve palsy, posterior interosseous nerve syndrome (PINS), radial tunnel syndrome, and superficial radial nerve palsy (see Chapter 17). The major disability associated with radial nerve injury is a weak grip, which is weakened because of poor stabilization of the wrist and the finger joints (Table 3-3). In addition, the patient demonstrates an inability to extend the thumb, the wrist, and the elbow, as well as the proximal phalanges. Pronation of the forearm and adduction of the thumb also are affected, and the wrist and the fingers adopt a position termed wrist drop. The triceps and other radial reflexes are absent, but the sensory loss is often slight, owing to overlapping innervation.

The site of the entrapment of the radial nerve can often be determined by the clinical findings, as follows:

- If the impairment occurs at a point below the triceps innervation, the strength of the triceps remains intact.
- If the impairment occurs at a point below the brachioradialis branch, some supination is retained.
- If the impairment occurs at a point in the forearm, the branches to the small muscle groups, extensors of the thumb, extensors of the index finger, extensors of the other fingers, and extensor carpi ulnaris may be affected.
- If the impairment occurs at a point on the posterior aspect of the wrist, only sensory loss on the hand is affected.

Conservative intervention for a radial nerve lesion depends on the location and the severity. As with all peripheral nerve injuries, every attempt must be made to maintain the appropriate function of the muscle or muscles innervated by the nerve, while helping to prevent contracture in those muscles antagonistic to the denervated muscle by using stretching techniques. In addition, muscle strengthening is prescribed for those uninvolved agonistic and synergistic muscles.

Median nerve (C6-8, T1)

The trunk of the median nerve derives its fibers from the lower three (sometimes four) cervical and the first thoracic segment of the spinal cord. Although it has no branches in the upper arm, the nerve trunk descends along the course of the brachial artery and passes onto the anterior aspect of the forearm, where it gives off muscular branches, including the anterior interosseous nerve. It then enters the hand, where it terminates with both muscular and cutaneous branches (Fig. 3-13). The sensory branches of the median nerve supply the skin of the palmar aspect of the thumb and the lateral 2½ fingers as well as the distal ends of the same fingers (see Fig. 3-13).

The anterior interosseous nerve arises from the posterior aspect of the median nerve, approximately 5-cm distal to the medial humeral epicondyle, and passes with the main trunk of the median nerve between the two heads of the pronator teres.[28] It continues along the palmar aspect of the flexor digitorum profundus (FDP) and then passes between the FDP and the flexor pollicis longus (FPL), running in close proximity to the interosseous membrane, to enter the pronator quadratus.[28] The anterior interosseous nerve provides motor innervation to the FPL; the medial part of FDP, involving the index and sometimes the middle finger; and to the pronator quadratus. It also sends sensory fibers to the distal radioulnar, radiocarpal, intercarpal, and carpometacarpal joints.[91] Variations in the distribution of the nerve have been noted; it may supply all or none of the FDP and part of the flexor digitorum superficialis.[92]

The clinical features of median nerve impairment (Table 3-3), depending on the level of injury, include the following:[19]

- Paralysis is noted in the flexor–pronator muscles of the forearm (resulting in weakness or loss of pronation), all of the superficial palmar muscles, except the flexor carpi ulnaris (FCU), and all of the deep palmar muscles, except the ulnar half of the FDP and the thenar muscles that lie superficial to the tendon of the FPL.
- At the wrist, there is weak flexion and radial deviation, and the hand inclines to the ulnar side.
- In the hand, an ape-hand deformity can be present (see Fig. 3-13). This deformity is associated with
  - an inability to oppose or flex the thumb or abduct it in its own plane;
  - a weakened grip, especially in the thumb and index finger, with a tendency for these digits to become hyperextended and the thumb adducted;
  - an inability to flex the distal phalanx of the thumb and index finger;
  - weakness of middle finger flexion; and
  - atrophy of the thenar muscles.
- There is a loss of sensation to a variable degree over the cutaneous distribution of the median nerve, most constantly over the distal phalanges of the first two fingers.
- Pain is present in many median nerve impairments anywhere along its distribution.
- Atrophy of the thenar eminence is seen early. Atrophy of the flexor–pronator groups of muscles in the forearm is seen after a few months.
- The skin of the palm is frequently dry, cold, discolored, chapped, and at times keratotic.

The most common condition associated with median nerve entrapment is carpal tunnel syndrome (see Chapter 18). The various interventions for median nerve entrapment are discussed in Chapters 17 and 18.

Ulnar nerve (C8, T1)

The ulnar nerve is the largest branch of the medial cord of the brachial plexus. It arises from the medial cord of the brachial plexus and contains fibers from the C8 and T1 nerve roots, although C7 may contribute some fibers (Fig. 3-14). The ulnar

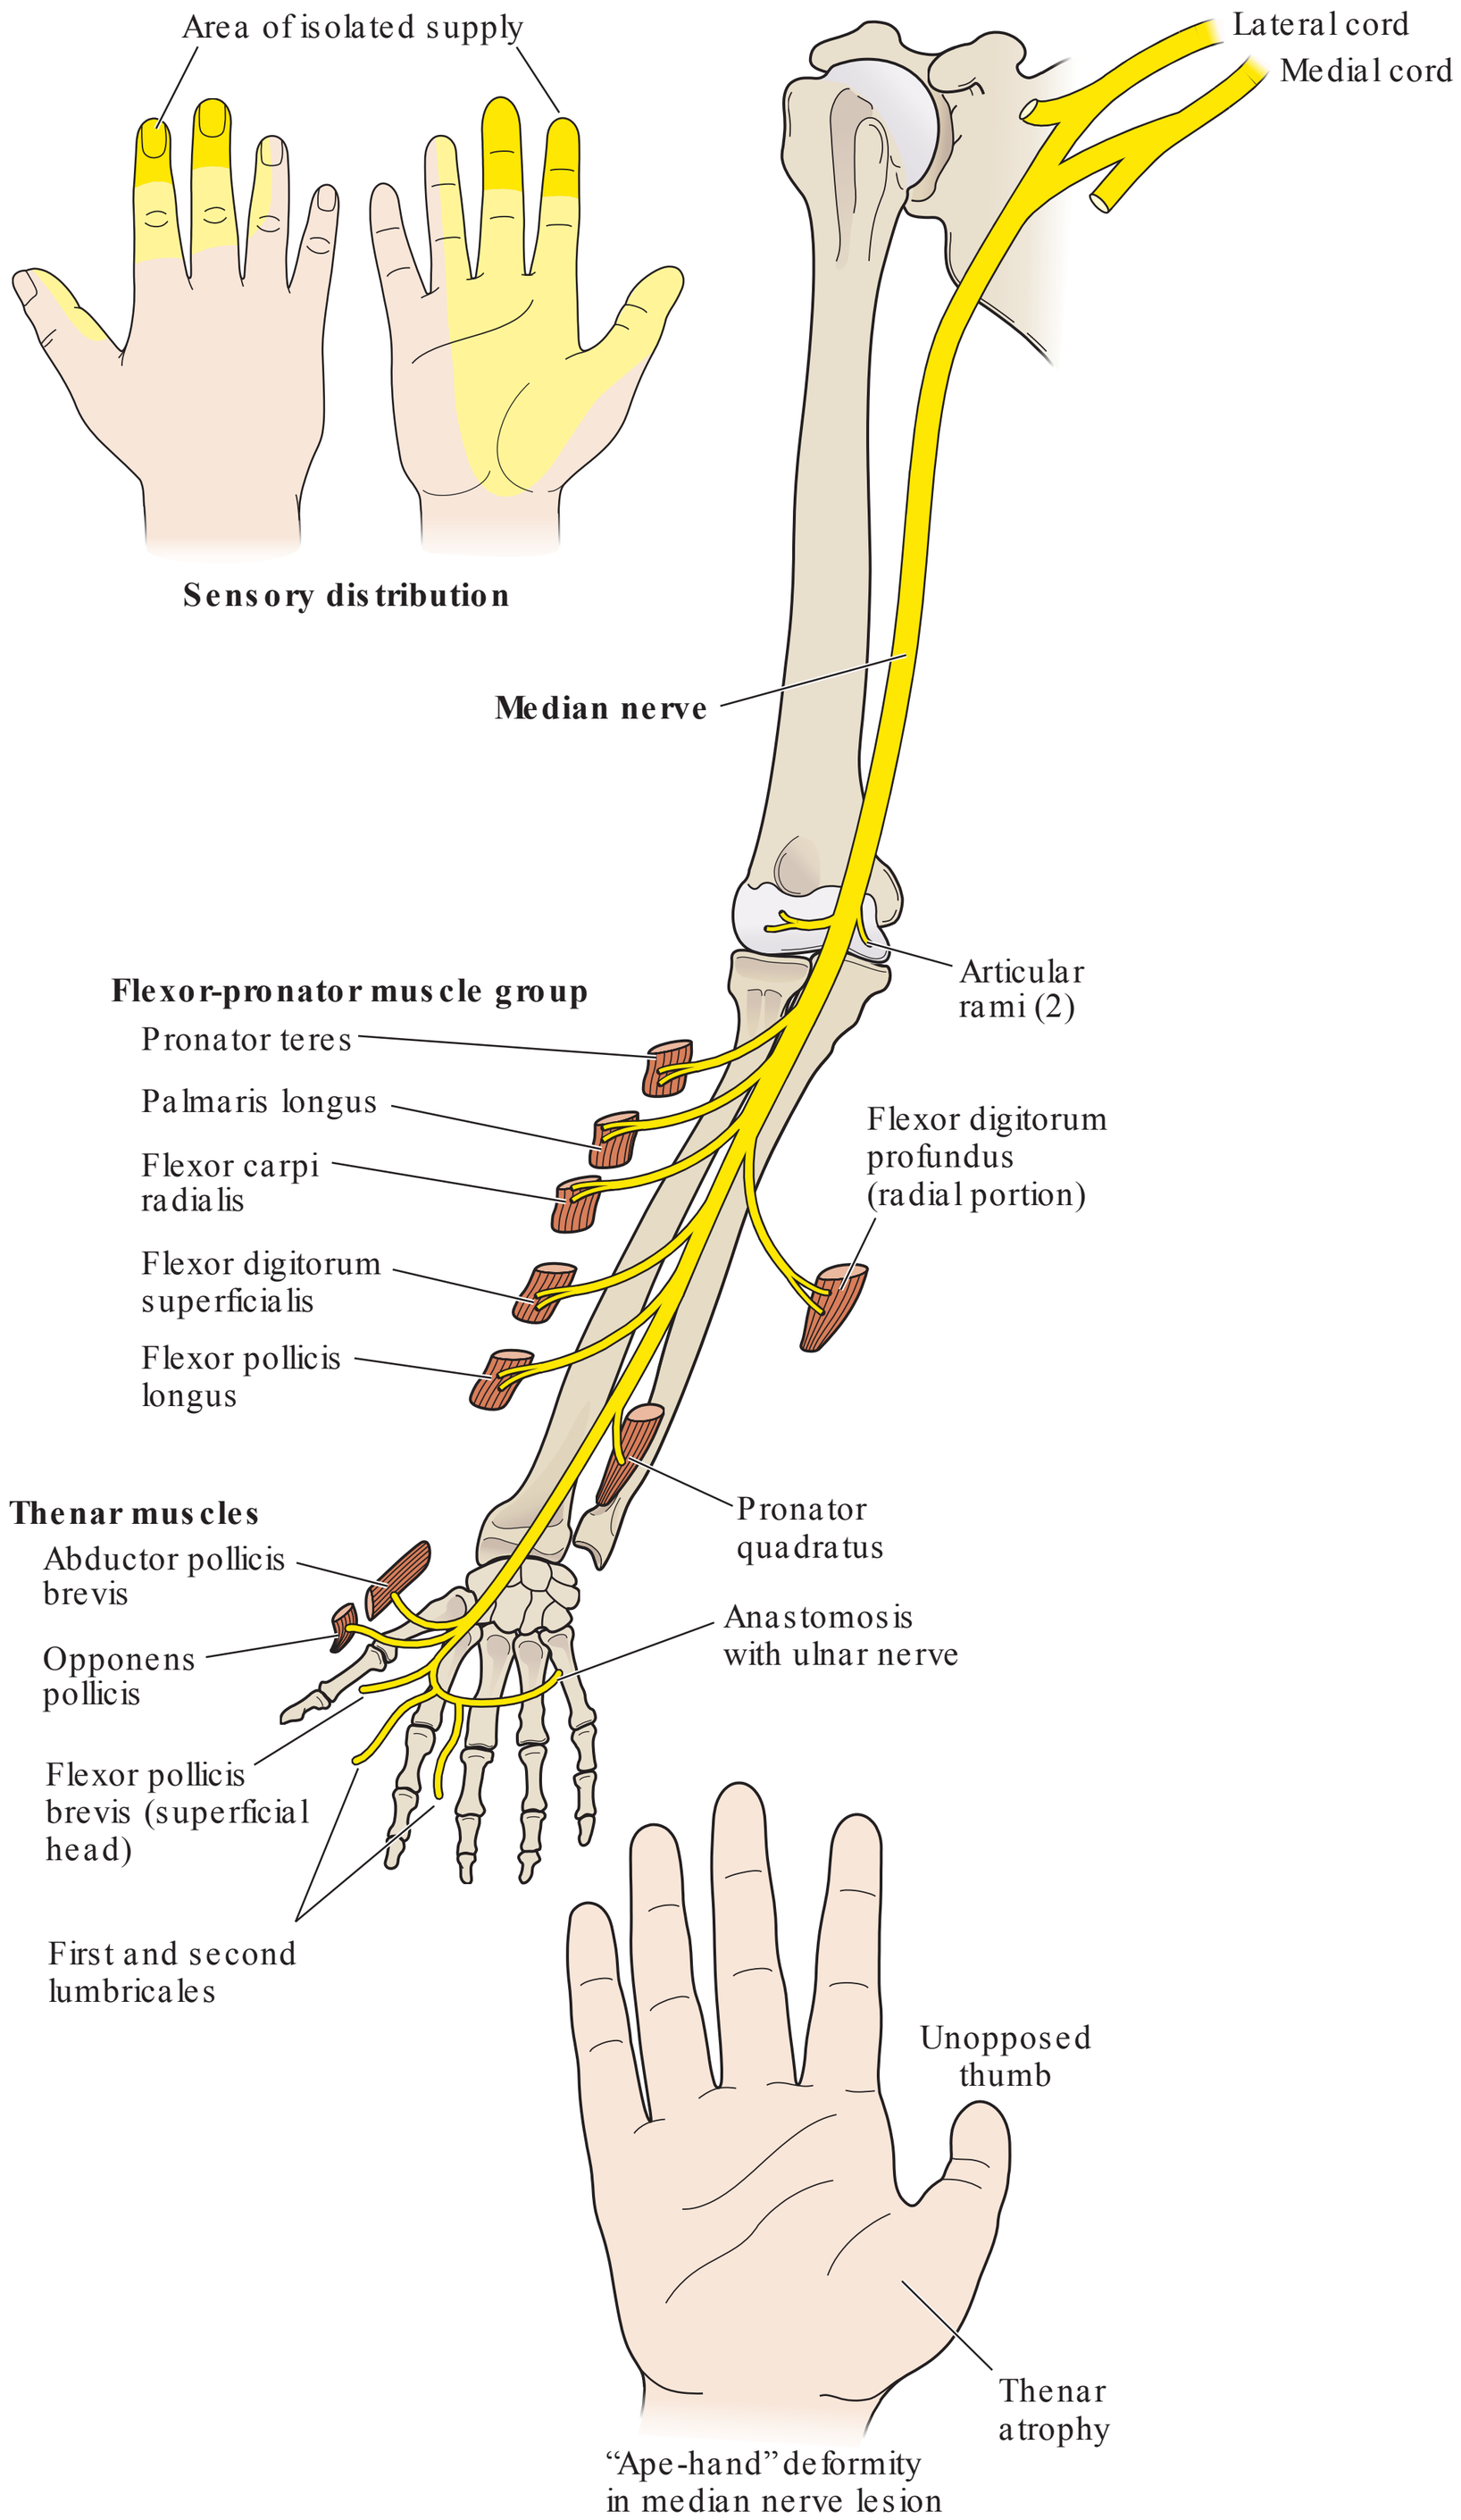

FIGURE 3-13 The median nerve (C6–8, T1). (Reproduced, with permission, from Appendix C. Spinal Nerves and Plexuses. In: Waxman SG. eds. Clinical Neuroanatomy, 27e. New York, NY: McGraw-Hill; 2013.)

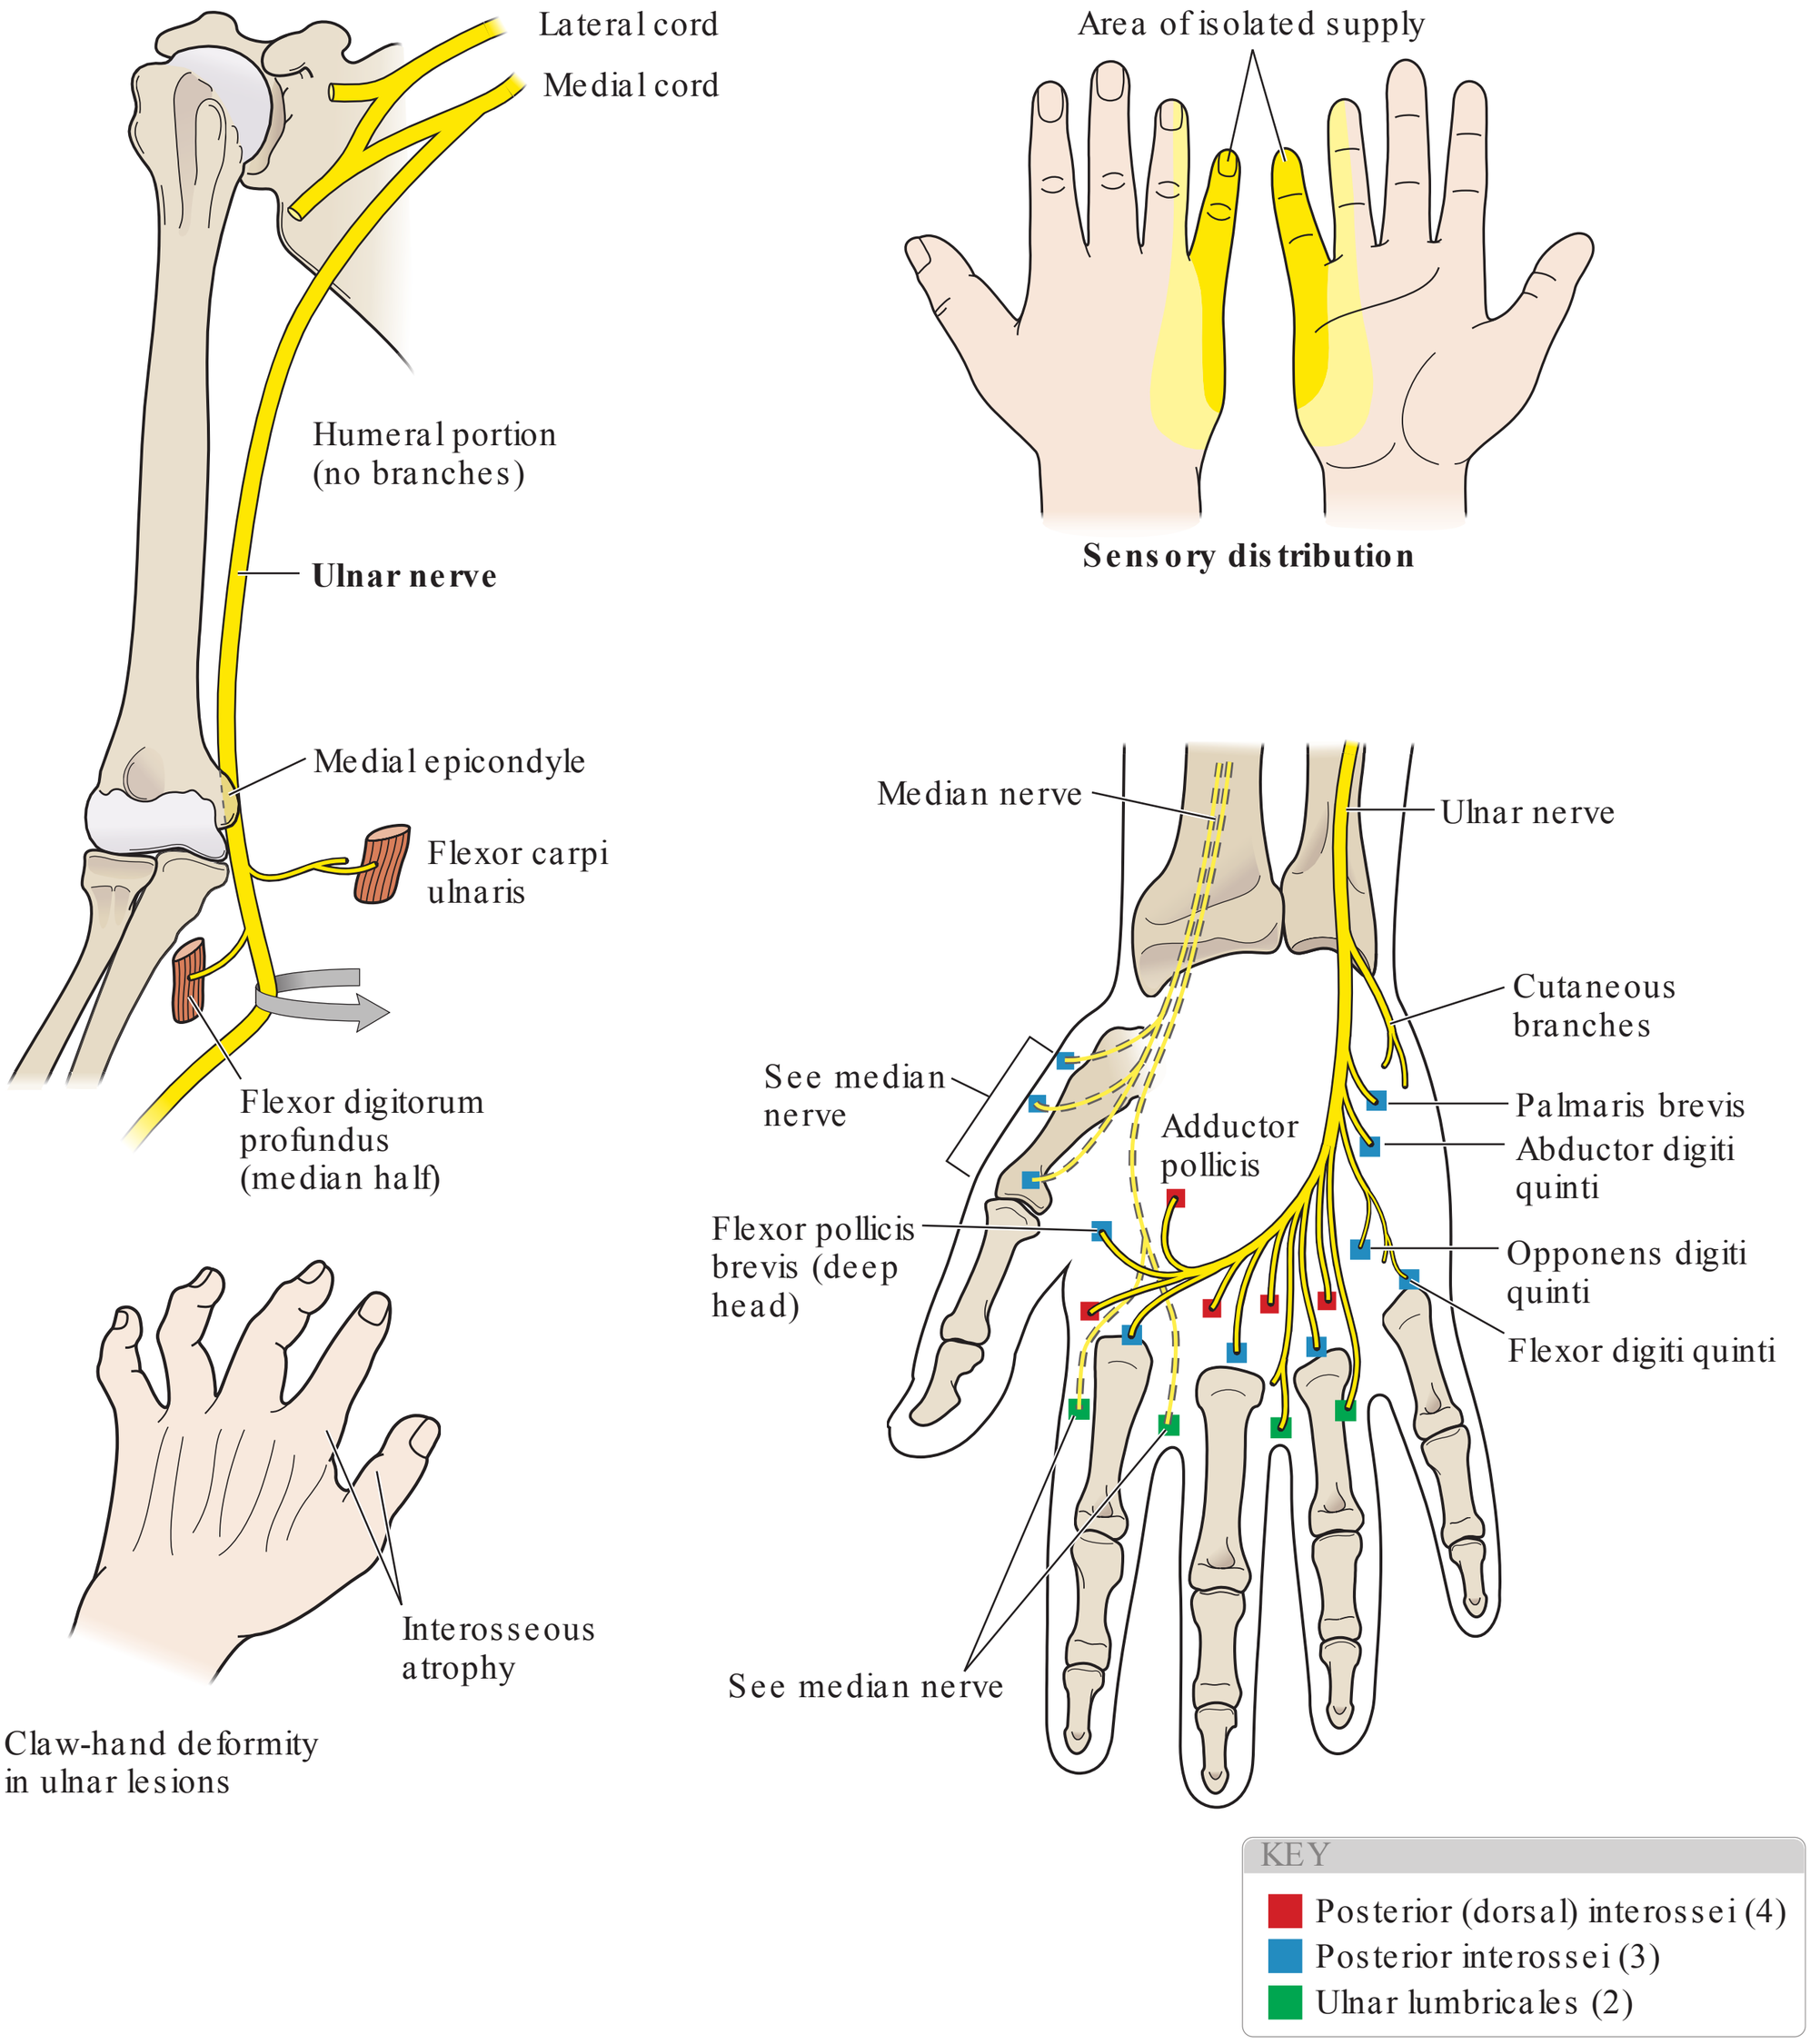

FIGURE 3-14 The ulnar nerve (C8, T1). (Reproduced, with permission, from Appendix C. Spinal Nerves and Plexuses. In: Waxman SG. eds. Clinical Neuroanatomy, 27e. New York, NY: McGraw-Hill; 2013.)

nerve continues along the anterior compartment of the arm, and it passes through the medial intermuscular septum at the level of the coracobrachialis insertion. As the ulnar nerve passes into the posterior compartment of the arm, it courses through the arcade of Struthers, which is a potential site for its compression.

At the level of the elbow, the ulnar nerve passes posterior to the medial epicondyle, where it passes through the cubital tunnel. From there, the ulnar nerve passes between the two heads of the FCU origin and traverses the deep flexor–pronator aponeurosis. T is aponeurosis is superficial to the FDP, but deep to the FCU and flexor digitorum superficialis muscles.[93,94]

Cl In ICAl PEARl

The intraneural topography of the ulnar nerve differs at various levels of the arm. At the medial epicondyle, the sensory fibers to the hand and the motor fibers to the intrinsic muscles are superficial, whereas the motor fibers to FCU and FDP are deep.[95] This may explain the common finding in "cubital tunnel syndrome" (see Chapter 17) of sensory loss and weakness of the ulnarly innervated intrinsic muscles, but relative sparing of the FCU and FDP.[96]

T e ulnar nerve enters the forearm by coursing posterior to the medial humeral condyle and passing between the heads of the FCU, before resting on the FDP[97] (see Fig. 3-14). It then continues distally to the wrist passing between the FCU and the FDP muscles, which it supplies. Proximal to the wrist, the palmar cutaneous branch of the ulnar nerve arises. T is branch runs across the palmar aspect of the forearm and the wrist outside of the tunnel of Guyon to supply the proximal part of the ulnar side of the palm. A few centimeters more distally to the tunnel, a posterior (dorsal) cutaneous branch arises and supplies the ulnar side of the dorsum of the hand, the posterior (dorsal) aspect of the fifth finger, and the ulnar half of the forefinger. T e ulnar nerve supplies the FCU, the ulnar head of the FDP, and all of the small muscles deep and medial to the long flexor tendon of the thumb, except the first two lumbricales (see Fig. 3-14, indicated by terminal branches in hand). Its sensory distribution includes the skin of the little finger and the medial half of the hand and the ring finger (see Fig. 3-14).

T e clinical features of ulnar nerve impairment (Table 3-3) include the following:[19]

- Claw-hand (see Fig. 3-14), resulting from the unopposed action of the extensor digitorum communis in the fourth and fifth digits.
- An inability to extend the second and distal phalanges of any of the fingers.
- An inability to adduct or abduct the fingers, or to oppose all the fingertips, as in making a cone with the fingers and the thumb.
- An inability to adduct the thumb.
- At the wrist, flexion is weak and ulnar deviation is lost. T e ulnar reflex is absent.
- Atrophy of the interosseous spaces (especially the first) and of the hypothenar eminence.
- A loss of sensation on the ulnar side of the hand and ring finger and, most markedly, over the entire little finger.
- Partial lesions of the ulnar nerve may produce only motor weakness or paralysis of a few of the muscles supplied by the nerve. Lesions that occur in the distal forearm or at the wrist spare the deep flexors and the FCU.

T e conservative interventions for the various ulnar nerve entrapments are discussed in Chapters 17 and 18.

Thoracic nerves

In the thoracic region, there is great variability in the topography of the nerves and the structures that they serve.[98] Typically, the spinal root arises from the lateral end of the spinal nerve but, in 25% of cases, the spinal root is made up of two parts that arise from the superior border of the spinal nerve.[99] T e thoracic spinal nerves are segmented into posterior (dorsal) primary and anterior (ventral) primary divisions. As elsewhere, the dermatomes of this region are considered to represent the cutaneous region innervated by one spinal nerve through both of its rami.[100]

Anterior (Ventral) Rami

T ere are 12 pairs of thoracic anterior (ventral) rami. T e anterior (ventral) rami (anterior branches) from T2 through T11 become intercostal nerves. T e 12th anterior (ventral) ramus, the subcostal nerve, is located below the last rib. T e intercostal nerve has a lateral branch, providing sensory distribution to the skin of the lateral aspect of the trunk, and an anterior branch, supplying the intercostal muscles, parietal pleura, and the skin over the anterior aspect of the thorax and the abdomen. All of the intercostal nerves mainly supply the thoracic and the abdominal walls, with the upper two also supplying the upper limb. T e thoracic anterior (ventral) rami of T3–6 supply only the thoracic wall, whereas the lower five rami supply both the thoracic and the abdominal walls. T e subcostal nerve supplies both the abdominal wall and the gluteal skin.

Each anterior (ventral) ramus is connected with an adjacent sympathetic ganglion by gray and white rami communicantes (Fig. 3-15). T e communicating rami are branches of the spinal nerves that transmit sympathetic autonomic fibers to and from the sympathetic chain of ganglia. T e fibers pass from spinal nerve to chain ganglia through the white ramus and in the reverse direction through the gray. In the cervical, lower lumbar, and sacral levels, only gray rami are present and function to convey fibers from the sympathetic chain to the spinal nerves, a mechanism that ensures that all spinal nerves contain sympathetic fibers.

From each intercostal nerve, a collateral and lateral cutaneous branch leave before the main nerve reaches the costal angle. T e intercostobrachial nerve arises from the lateral collateral branch of the second intercostal nerve, pierces the intercostal muscles in the midaxillary line, and then traverses the central portion of the axilla, where a posterior axillary branch gives sensation to the posterior axillary fold. From here, the nerve passes into the upper arm along the posterior–medial border to supply the skin of this region[101] and to connect with the posterior cutaneous branch of the radial nerve.

Posterior (Dorsal) Rami

T e distribution of all posterior (dorsal) rami is similar. T e thoracic posterior (dorsal) rami travel posteriorly, close to the vertebral zygapophyseal joints, before dividing into medial and lateral branches:

- T e medial branches supply the short, medially placed back muscles (the iliocostalis thoracis, spinalis thoracis, semispinalis thoracis, thoracic multifidus rotatores thoracis, and intertransversarii muscles) and the skin of the back as far as the midscapular line. T e medial branches of the upper six thoracic posterior (dorsal) rami pierce the rhomboids and trapezius, reaching the skin in close proximity to the vertebral spines, which they occasionally supply.
- T e lateral branches supply smaller branches to the sacrospinalis muscles. T e lateral branches increase in size the more inferior they are. T ey penetrate, or pass, the longissimus thoracis to the space between it and the iliocostalis cervicis, supplying both these muscles, as well as the levatores costarum. T e 12th thoracic lateral branch sends a filament medially along the iliac crest, which then passes down to the anterior gluteal skin.

As mentioned previously, the recurrent meningeal or sinuvertebral nerve is functionally also a branch of the spinal

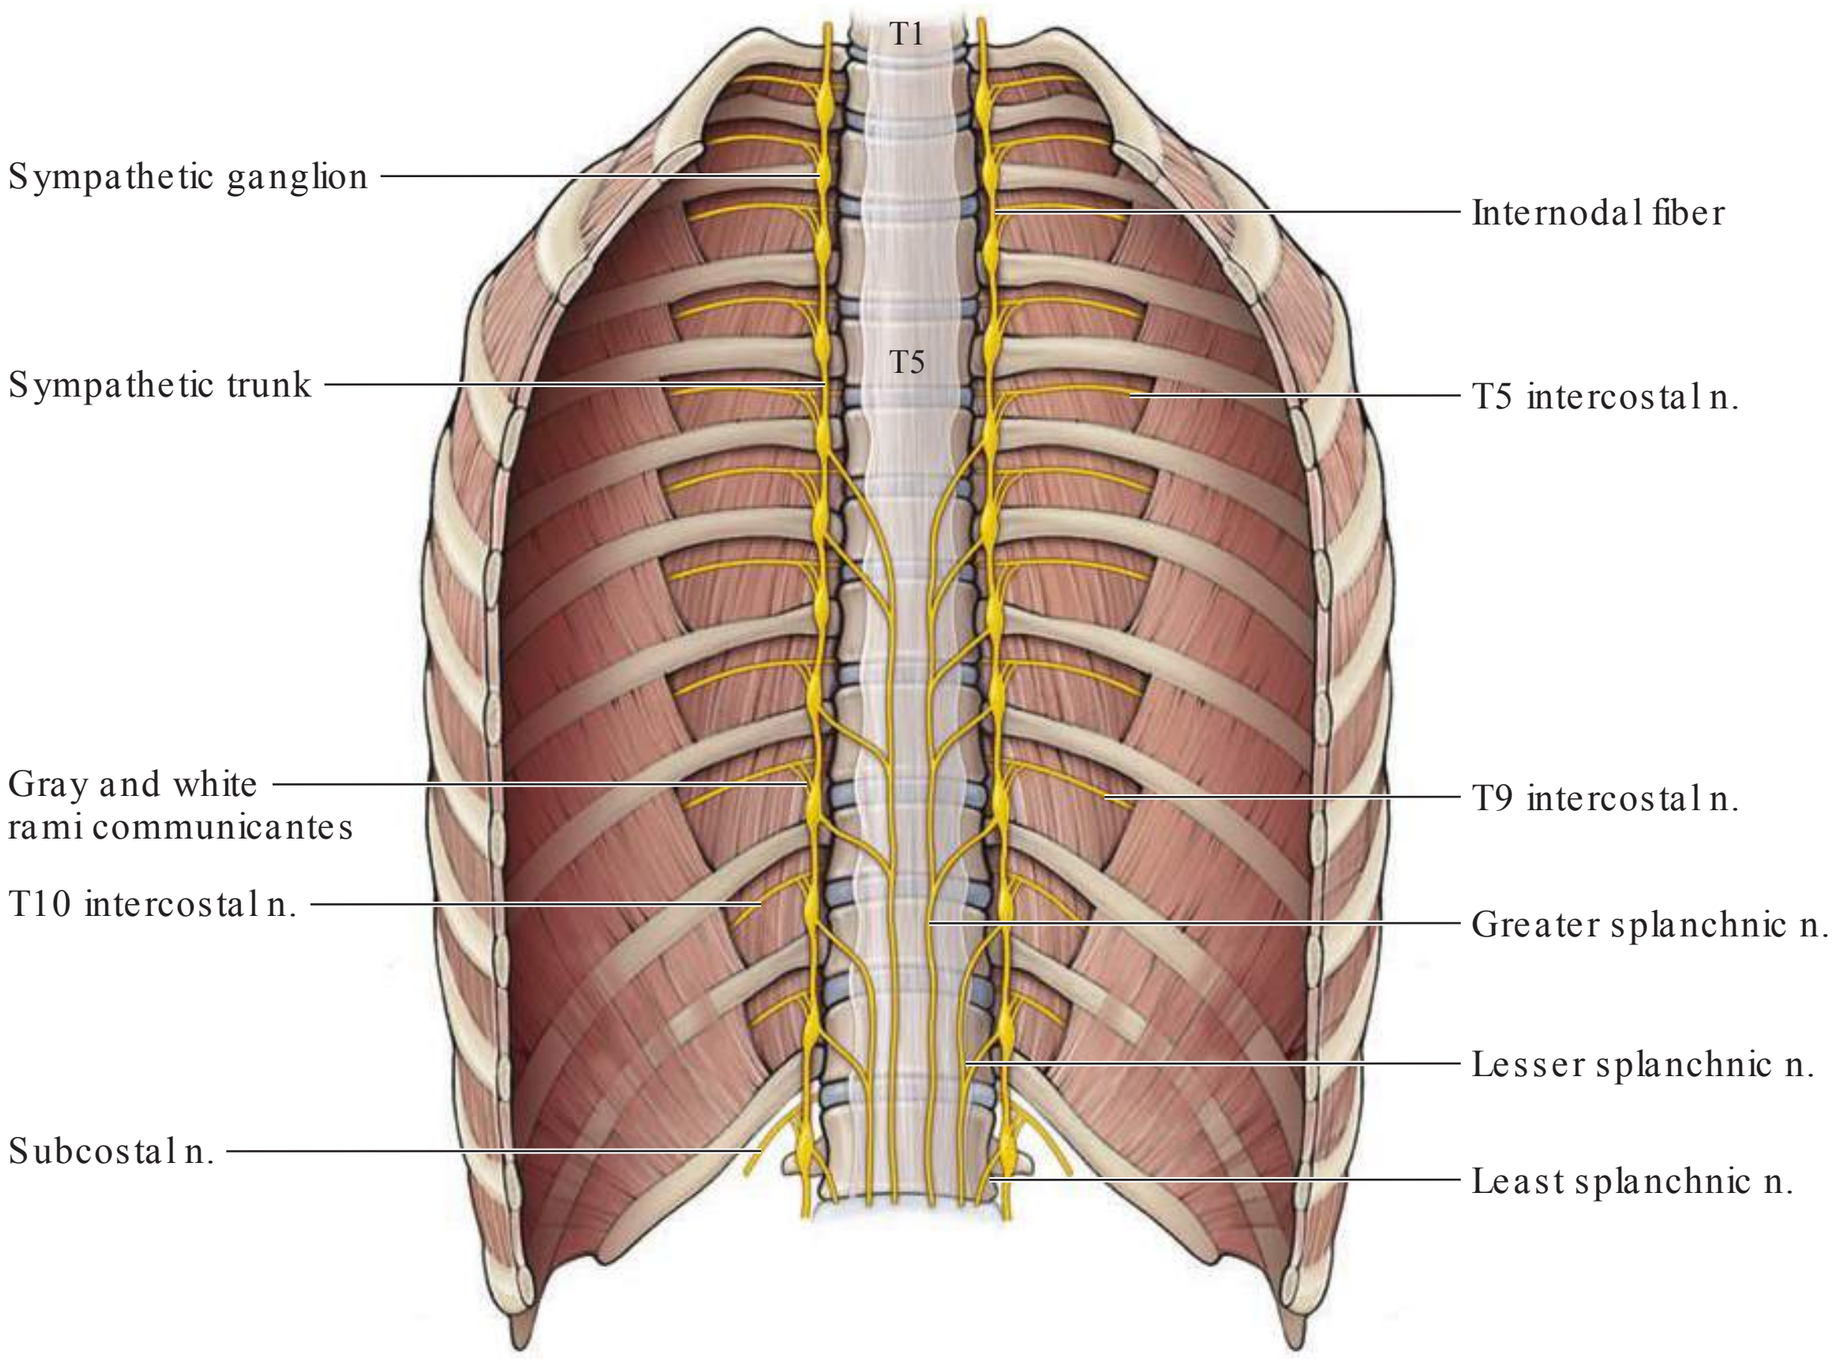

FIGURE 3-15 Thoracic spinal nerves. (Reproduced, with permission, from Chapter 5. Superior and Posterior Mediastina. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

nerve. This nerve passes back into the vertebral canal through the intervertebral foramen, supplying the anterior aspect of the dura mater, outer third of the annular fibers of the intervertebral disks, vertebral body, and the epidural blood vessel walls, as well as the posterior longitudinal ligament.[102]

The thoracic nerves may be involved in the same types of impairments that affect other peripheral nerves. A loss of function of one, or more, of the thoracic nerves may produce partial or complete paralysis of the abdominal muscles, and a loss of the abdominal reflexes in the affected quadrants. With unilateral impairments of the nerve, the umbilicus usually is drawn toward the unaffected side when the abdomen is tensed (Beevor sign), indicating a paralysis of the lower abdominal muscles as a result of a lesion at the level of the 10th thoracic segment.

A specific syndrome, called the T4 syndrome,[103–105] has been shown to cause vague pain, numbness, and paresthesia in the upper extremity and generalized posterior head-and-neck pain.

Lumbar Plexus

The lumbar plexus (Fig. 3-16) is formed from the anterior (ventral) nerve roots of the second, third, and fourth lumbar nerves (in approximately 50% of cases, the plexus also receives a contribution from the last thoracic nerve), as they lie between the quadratus lumborum muscle and the psoas muscle. It then travels anteriorly into the body of the psoas muscle to form the, femoral, obturator nerves, and LCN of the thigh.

L1, L2, and L4 divide into upper and lower branches (see Fig. 3-16). The upper branch of L1 forms the iliohypogastric and ilioinguinal nerves. The lower branch of L1 joins the upper branch of L2 to form the genitofemoral nerve (see Fig. 3-16). The lower branch of L4 joins L5 to form the lumbosacral trunk.

- Iliohypogastric nerve (*T*12, L1) (see Fig. 3-17). This nerve emerges from the upper lateral border of the psoas major and then passes laterally around the iliac crest between the transversus abdominis and internal oblique muscles, before dividing into lateral and anterior cutaneous branches. The lateral (iliac) branch supplies the skin of the upper lateral part of the thigh while the anterior (hypogastric) branch descends anteriorly to supply the skin over the symphysis.

- Ilioinguinal nerve (L1) (see Fig. 3-17). This nerve is smaller than the iliohypogastric nerve. It emerges from the lateral border of the psoas major to follow a course slightly inferior to that of the iliohypogastric, with which it may anastomose. It pierces the internal oblique, which it supplies before emerging from the superficial inguinal ring to supply the skin of the upper medial part of the thigh and the root of the penis and scrotum or mons pubis and labium majores. An entrapment of this nerve results in pain in the groin region, usually with radiation down to the proximal inner surface of the thigh, sometimes aggravated by increasing tension on the abdominal wall through standing erect.

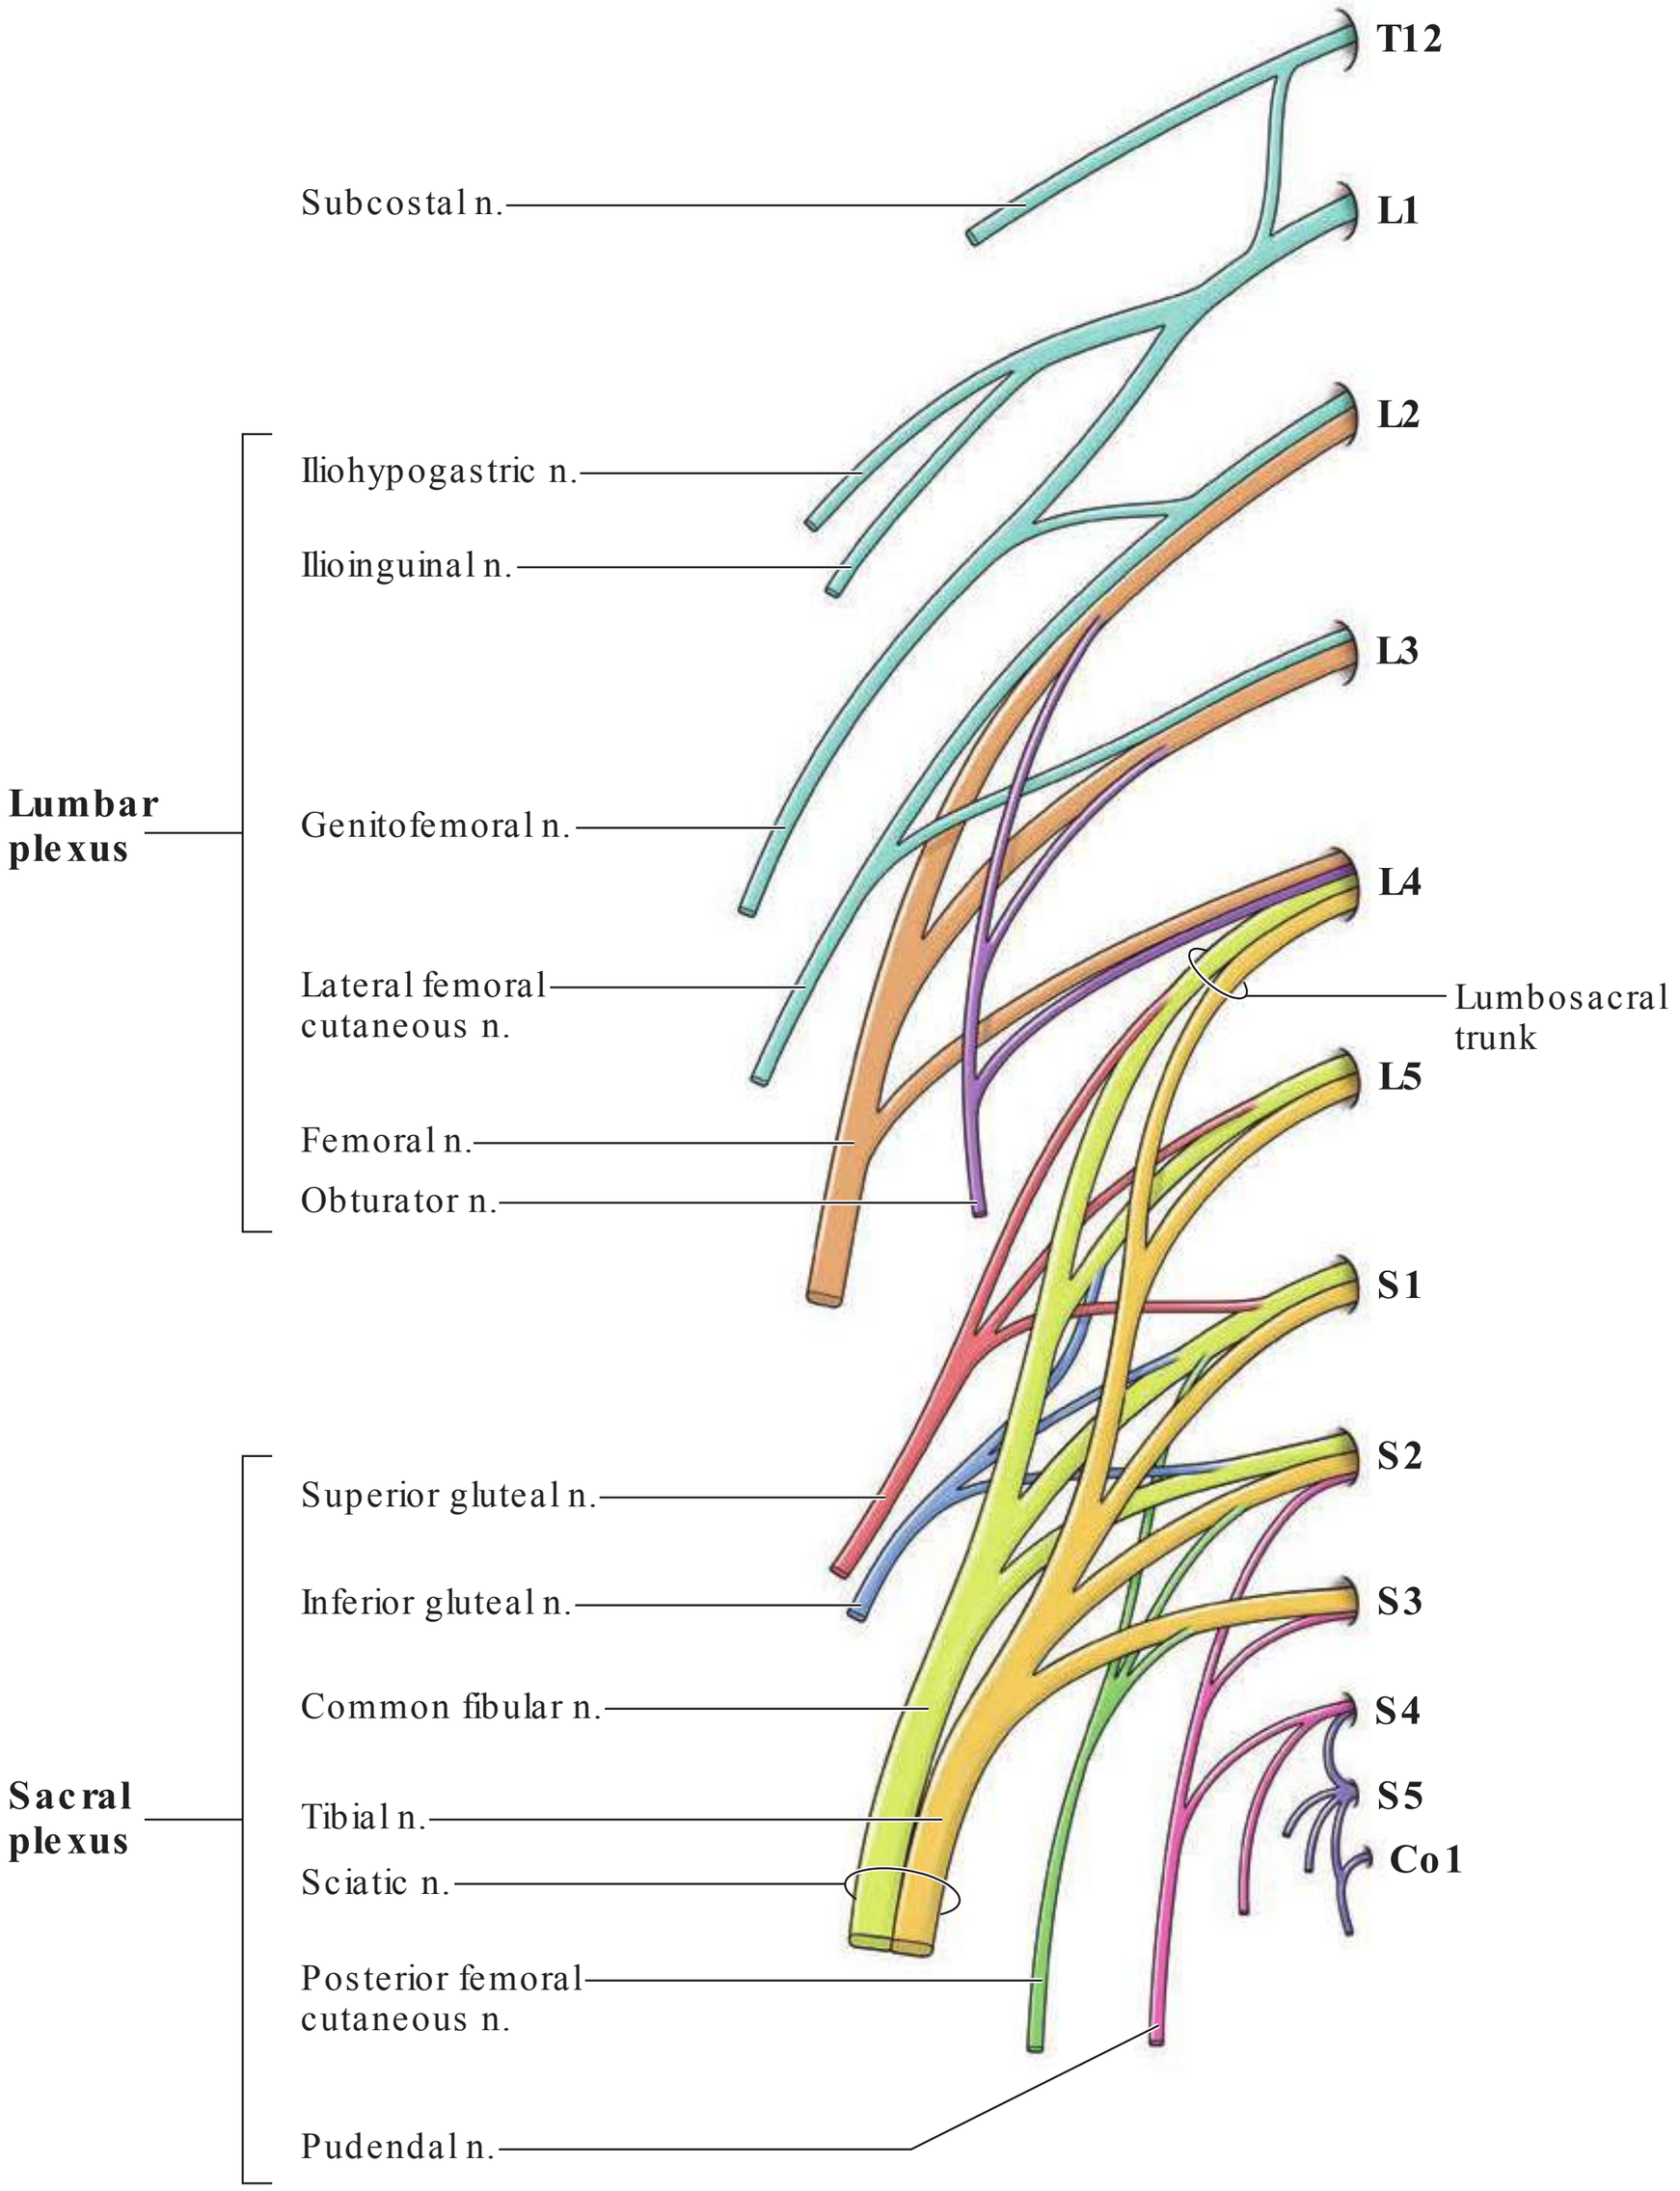

FIGURE 3-16 The lumbar plexus. (Reproduced, with permission, from Chapter 34. Overview of the Lower Limb. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

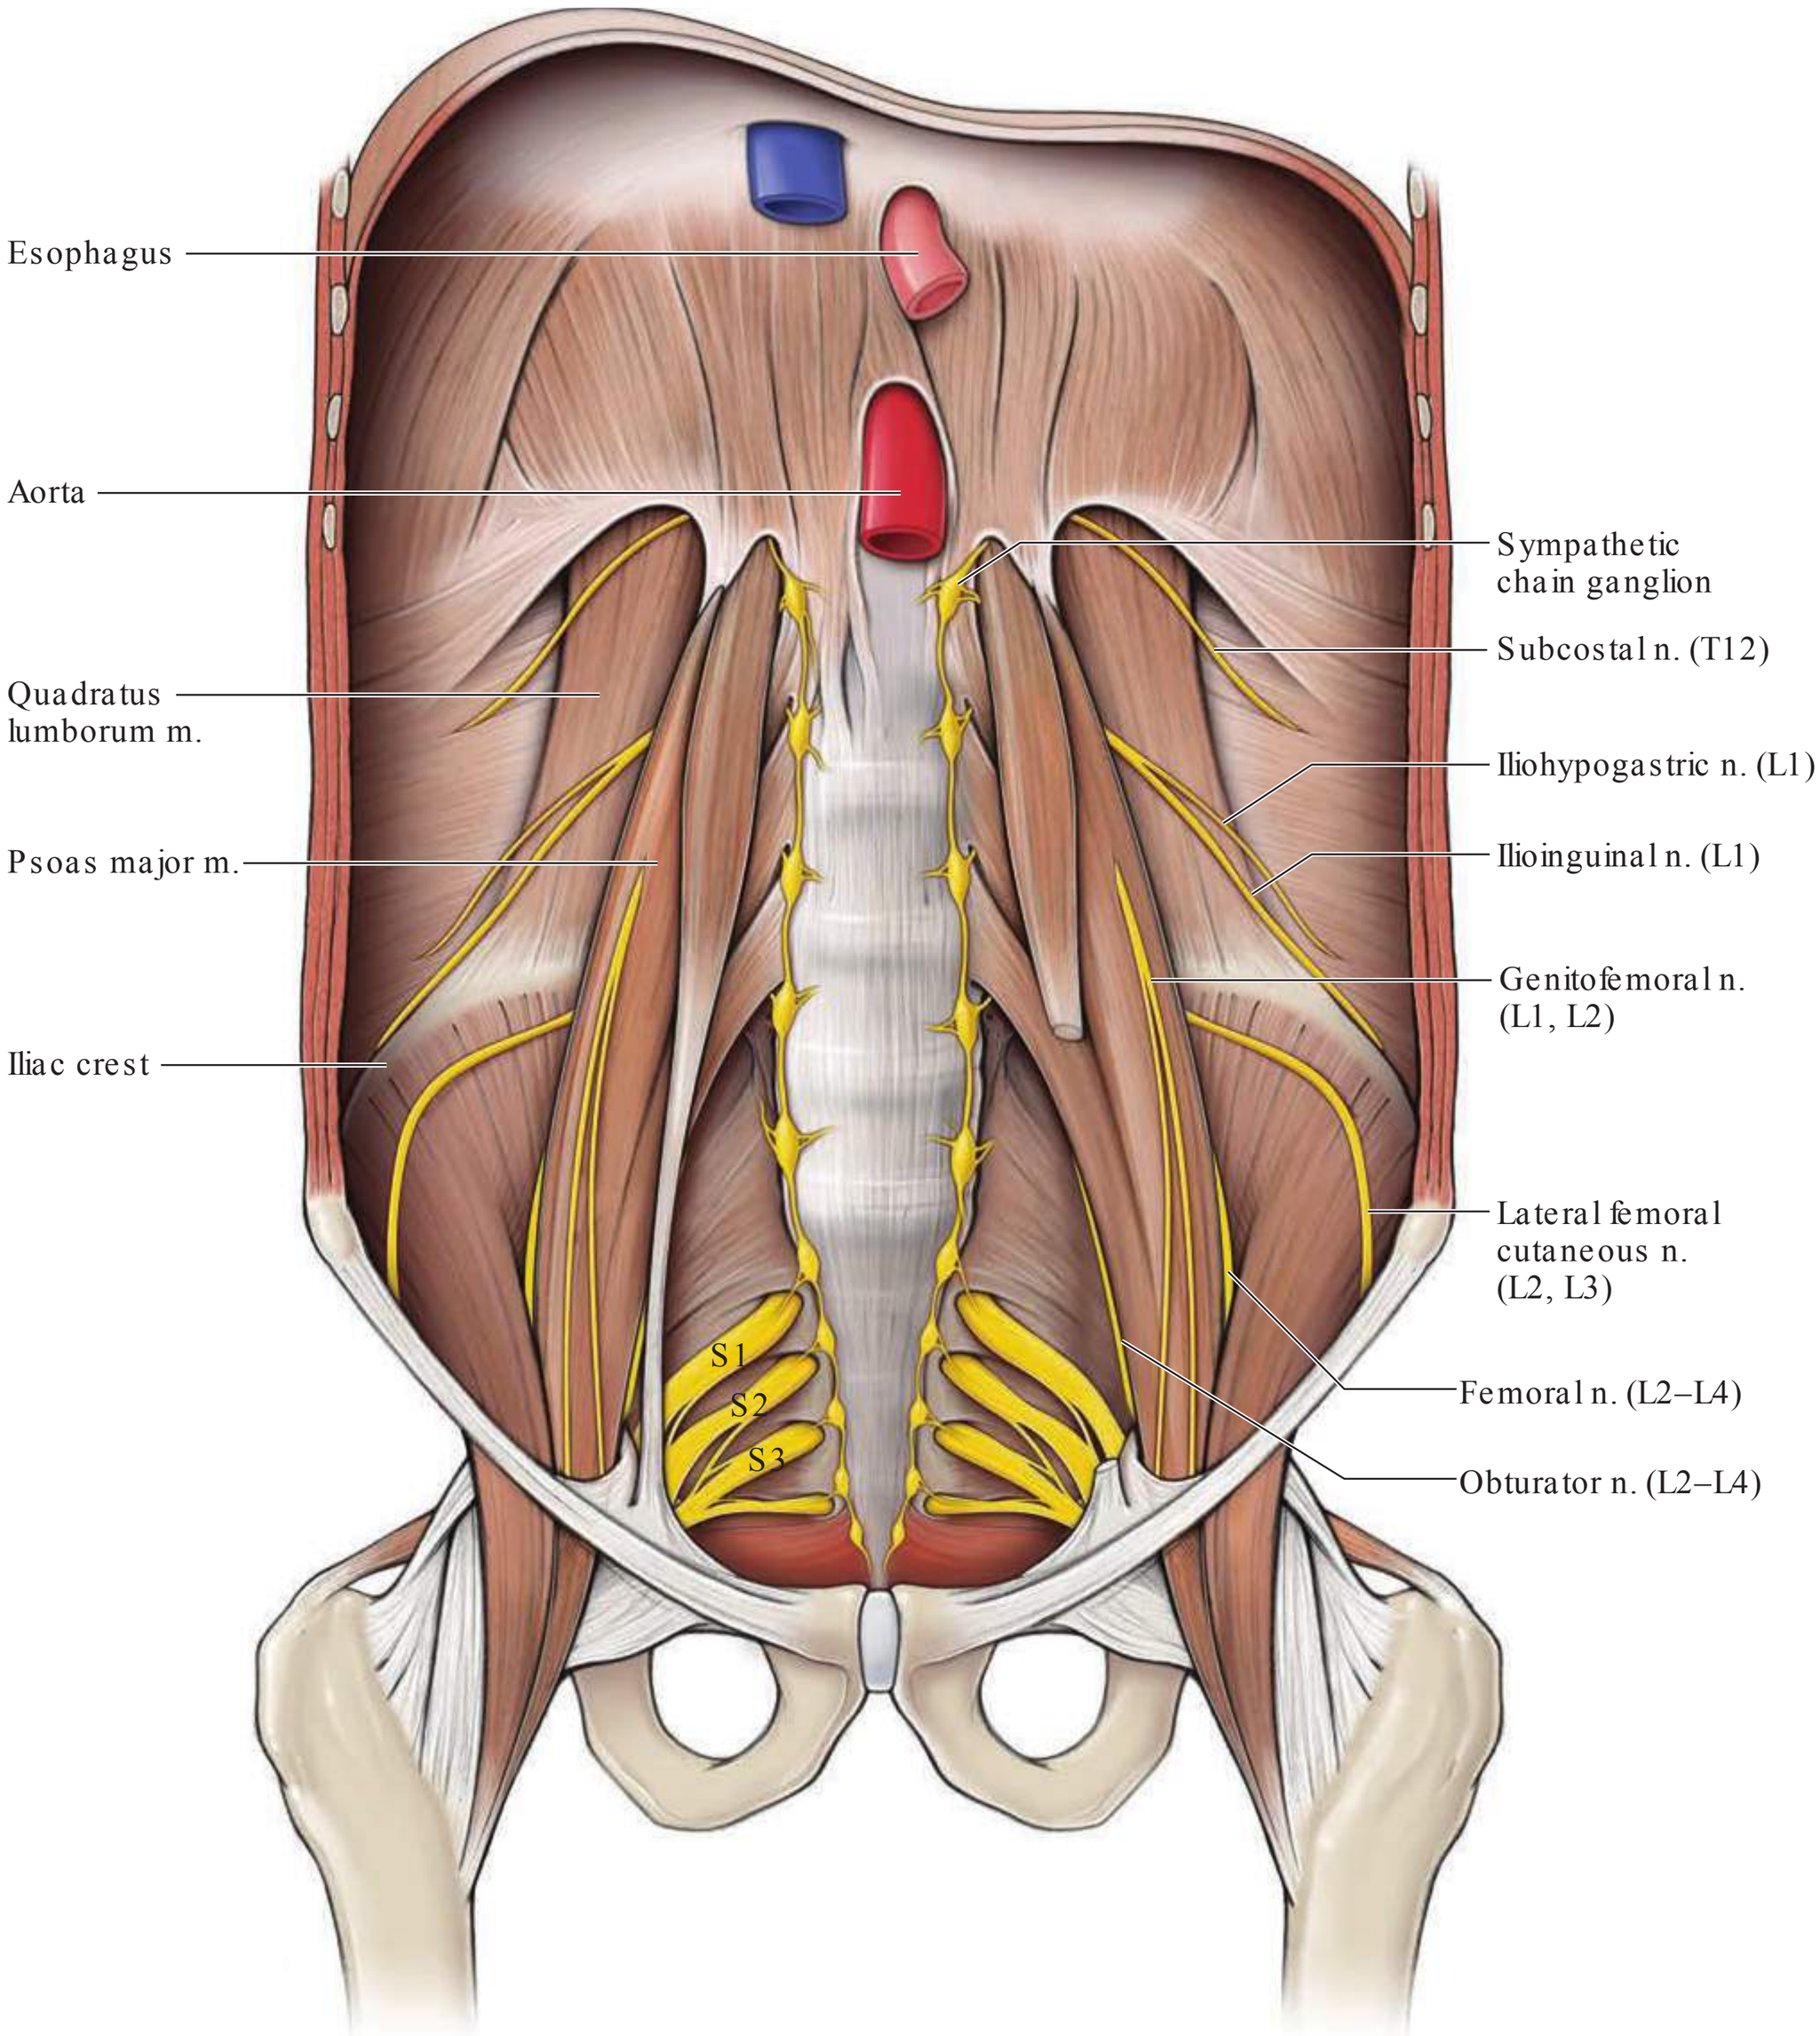
- Genitofemoral nerve (L1, 2) (see Fig. 3-17). This nerve descends obliquely and anteriorly through the psoas major before emerging from the anterior surface of the psoas and dividing into genital and femoral branches. The genital branch supplies the cremasteric muscle and the skin of the scrotum or labia, whereas the femoral branch supplies the skin of the upper middle part of the thigh and the femoral artery.

Collateral muscular branches supply the quadratus lumborum and intertransversarii from L1 and L4, and the psoas muscle from L2 and L3 (Fig. 3-17). The lower branch of L2, all of L3, and the upper branch of L4 split into a small anterior and a large posterior division (see Fig. 3-16). The three anterior divisions unite to form the obturator nerve; the three posterior divisions unite to form the femoral nerve, and the LCN of the thigh (see Fig. 3-16).

Peripheral nerves of the lumbar Plexus

The peripheral nerves of the lumbar plexus are subject to entrapment at various anatomical locations in the lower



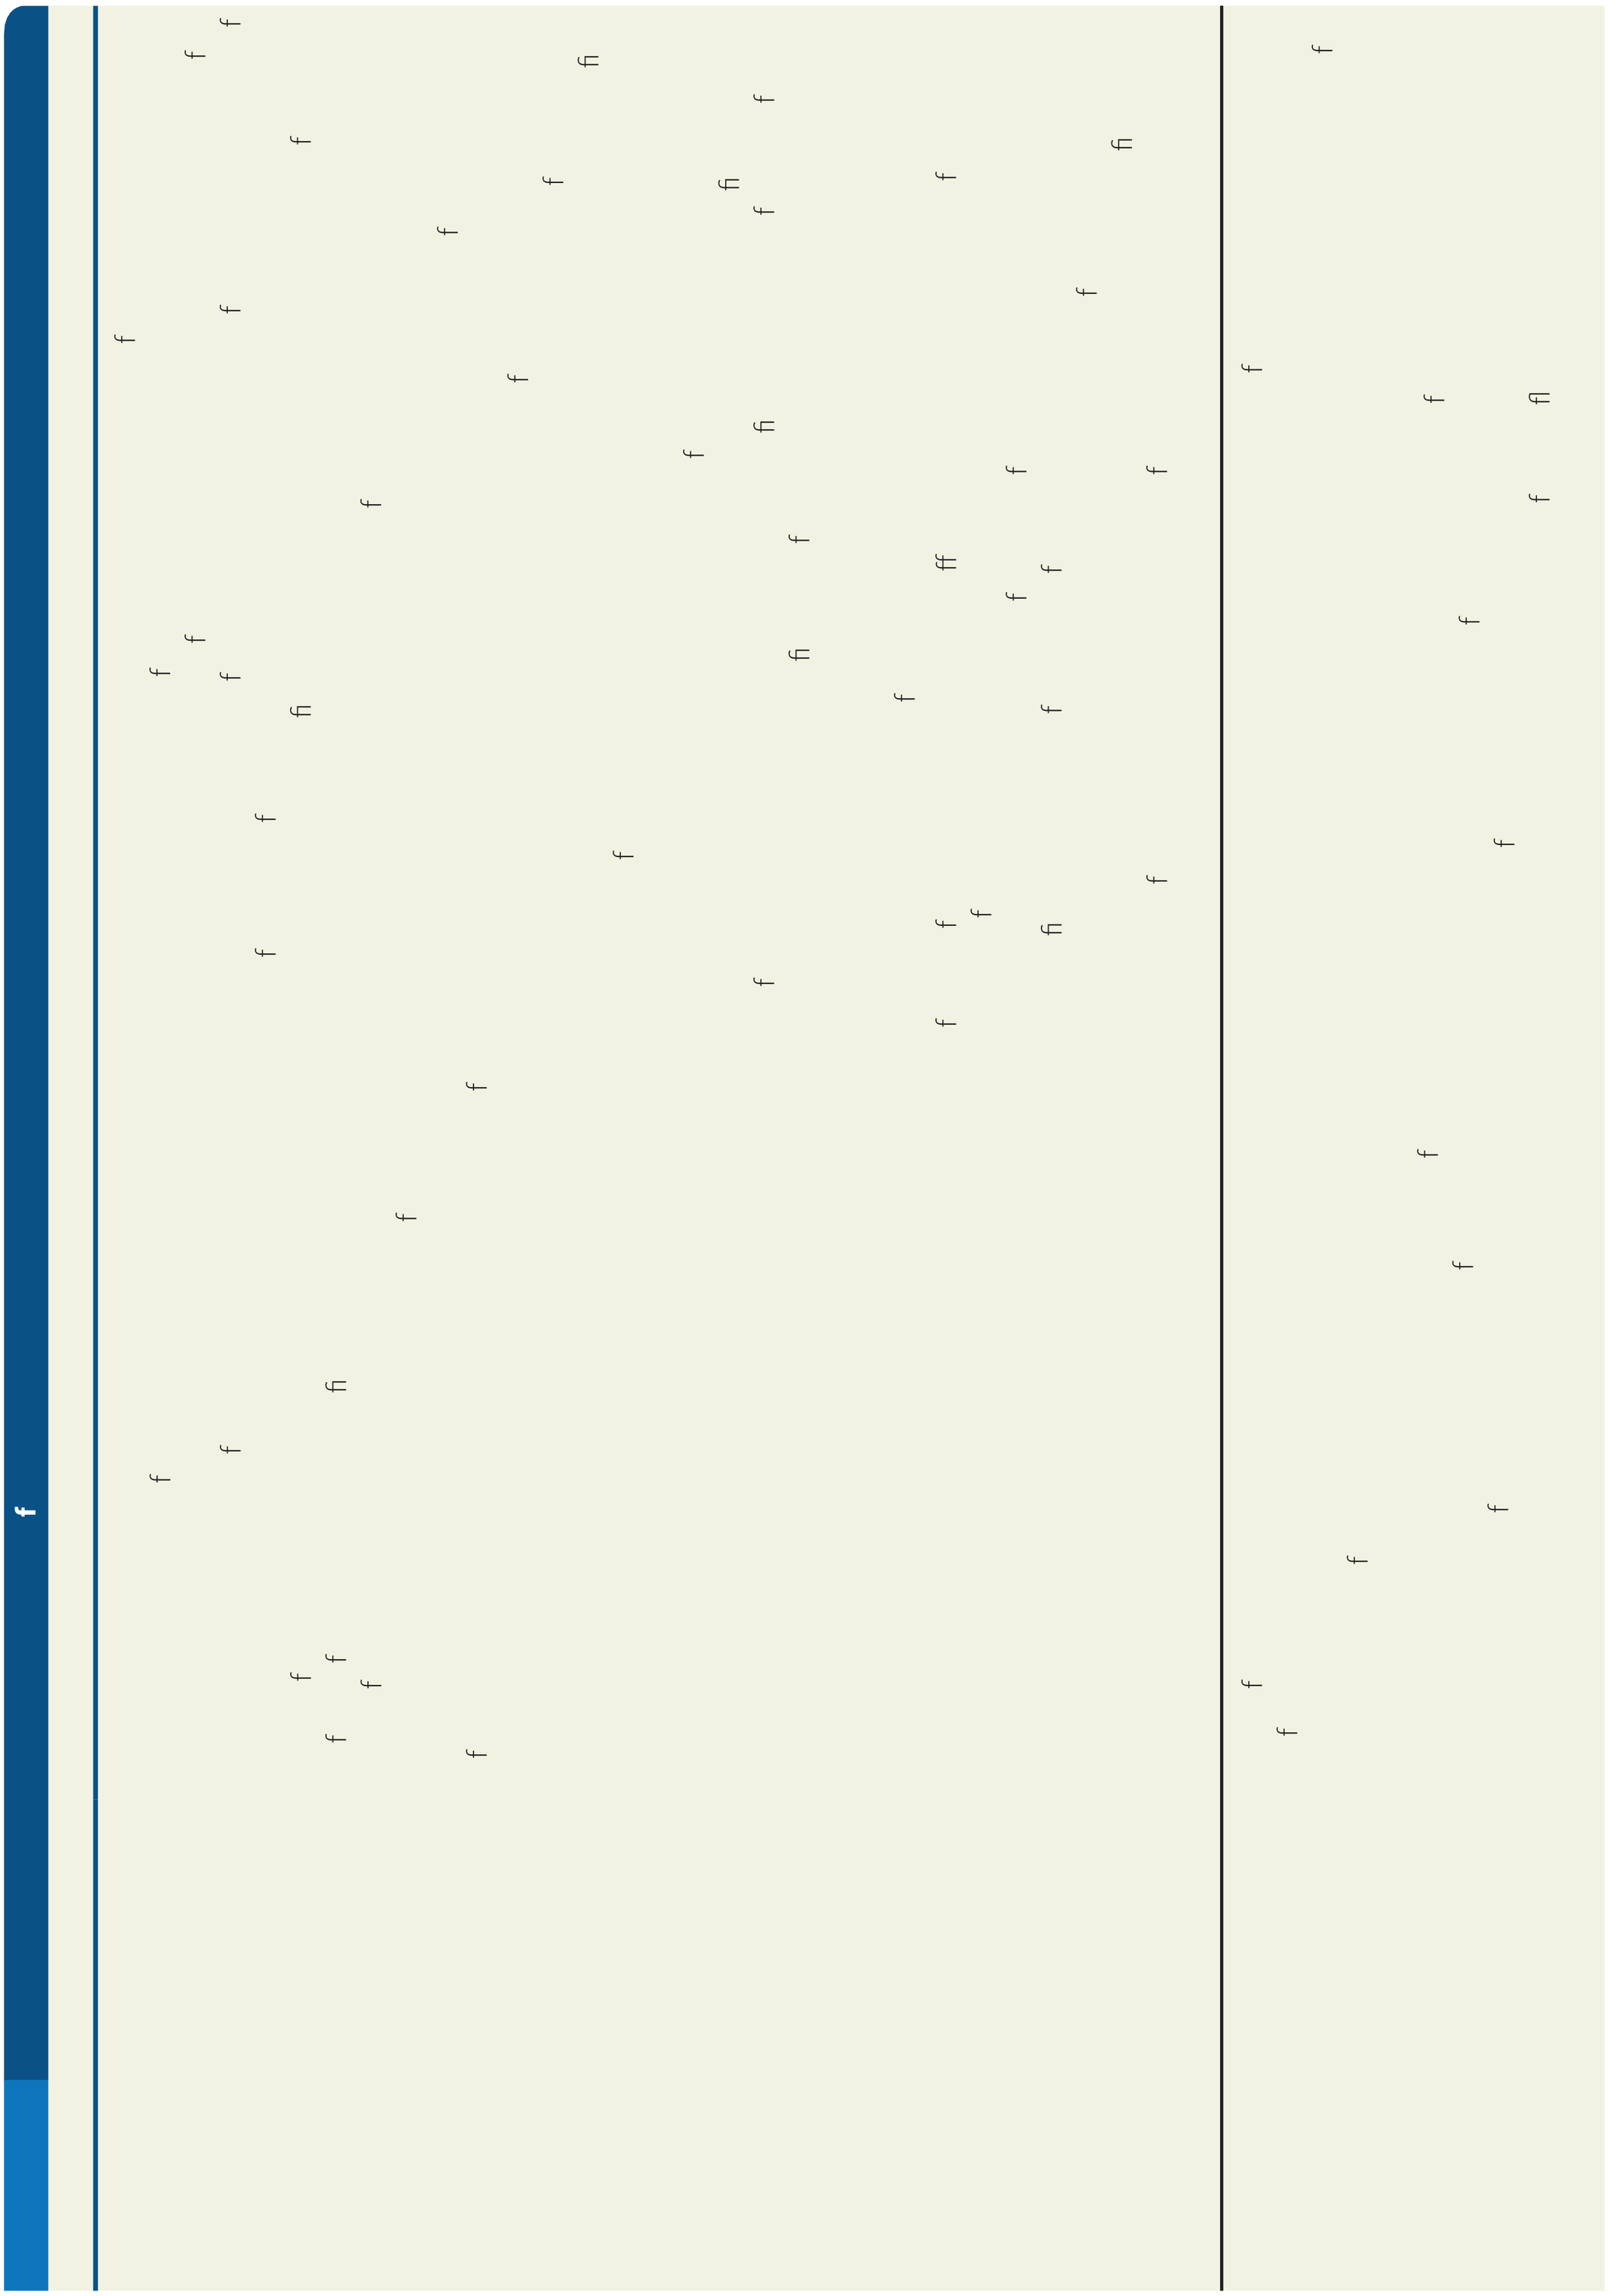


FIGURE 3-17 Branches of the lumbar plexus. (Reproduced, with permission, from Chapter 11. Posterior Abdominal Wall. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

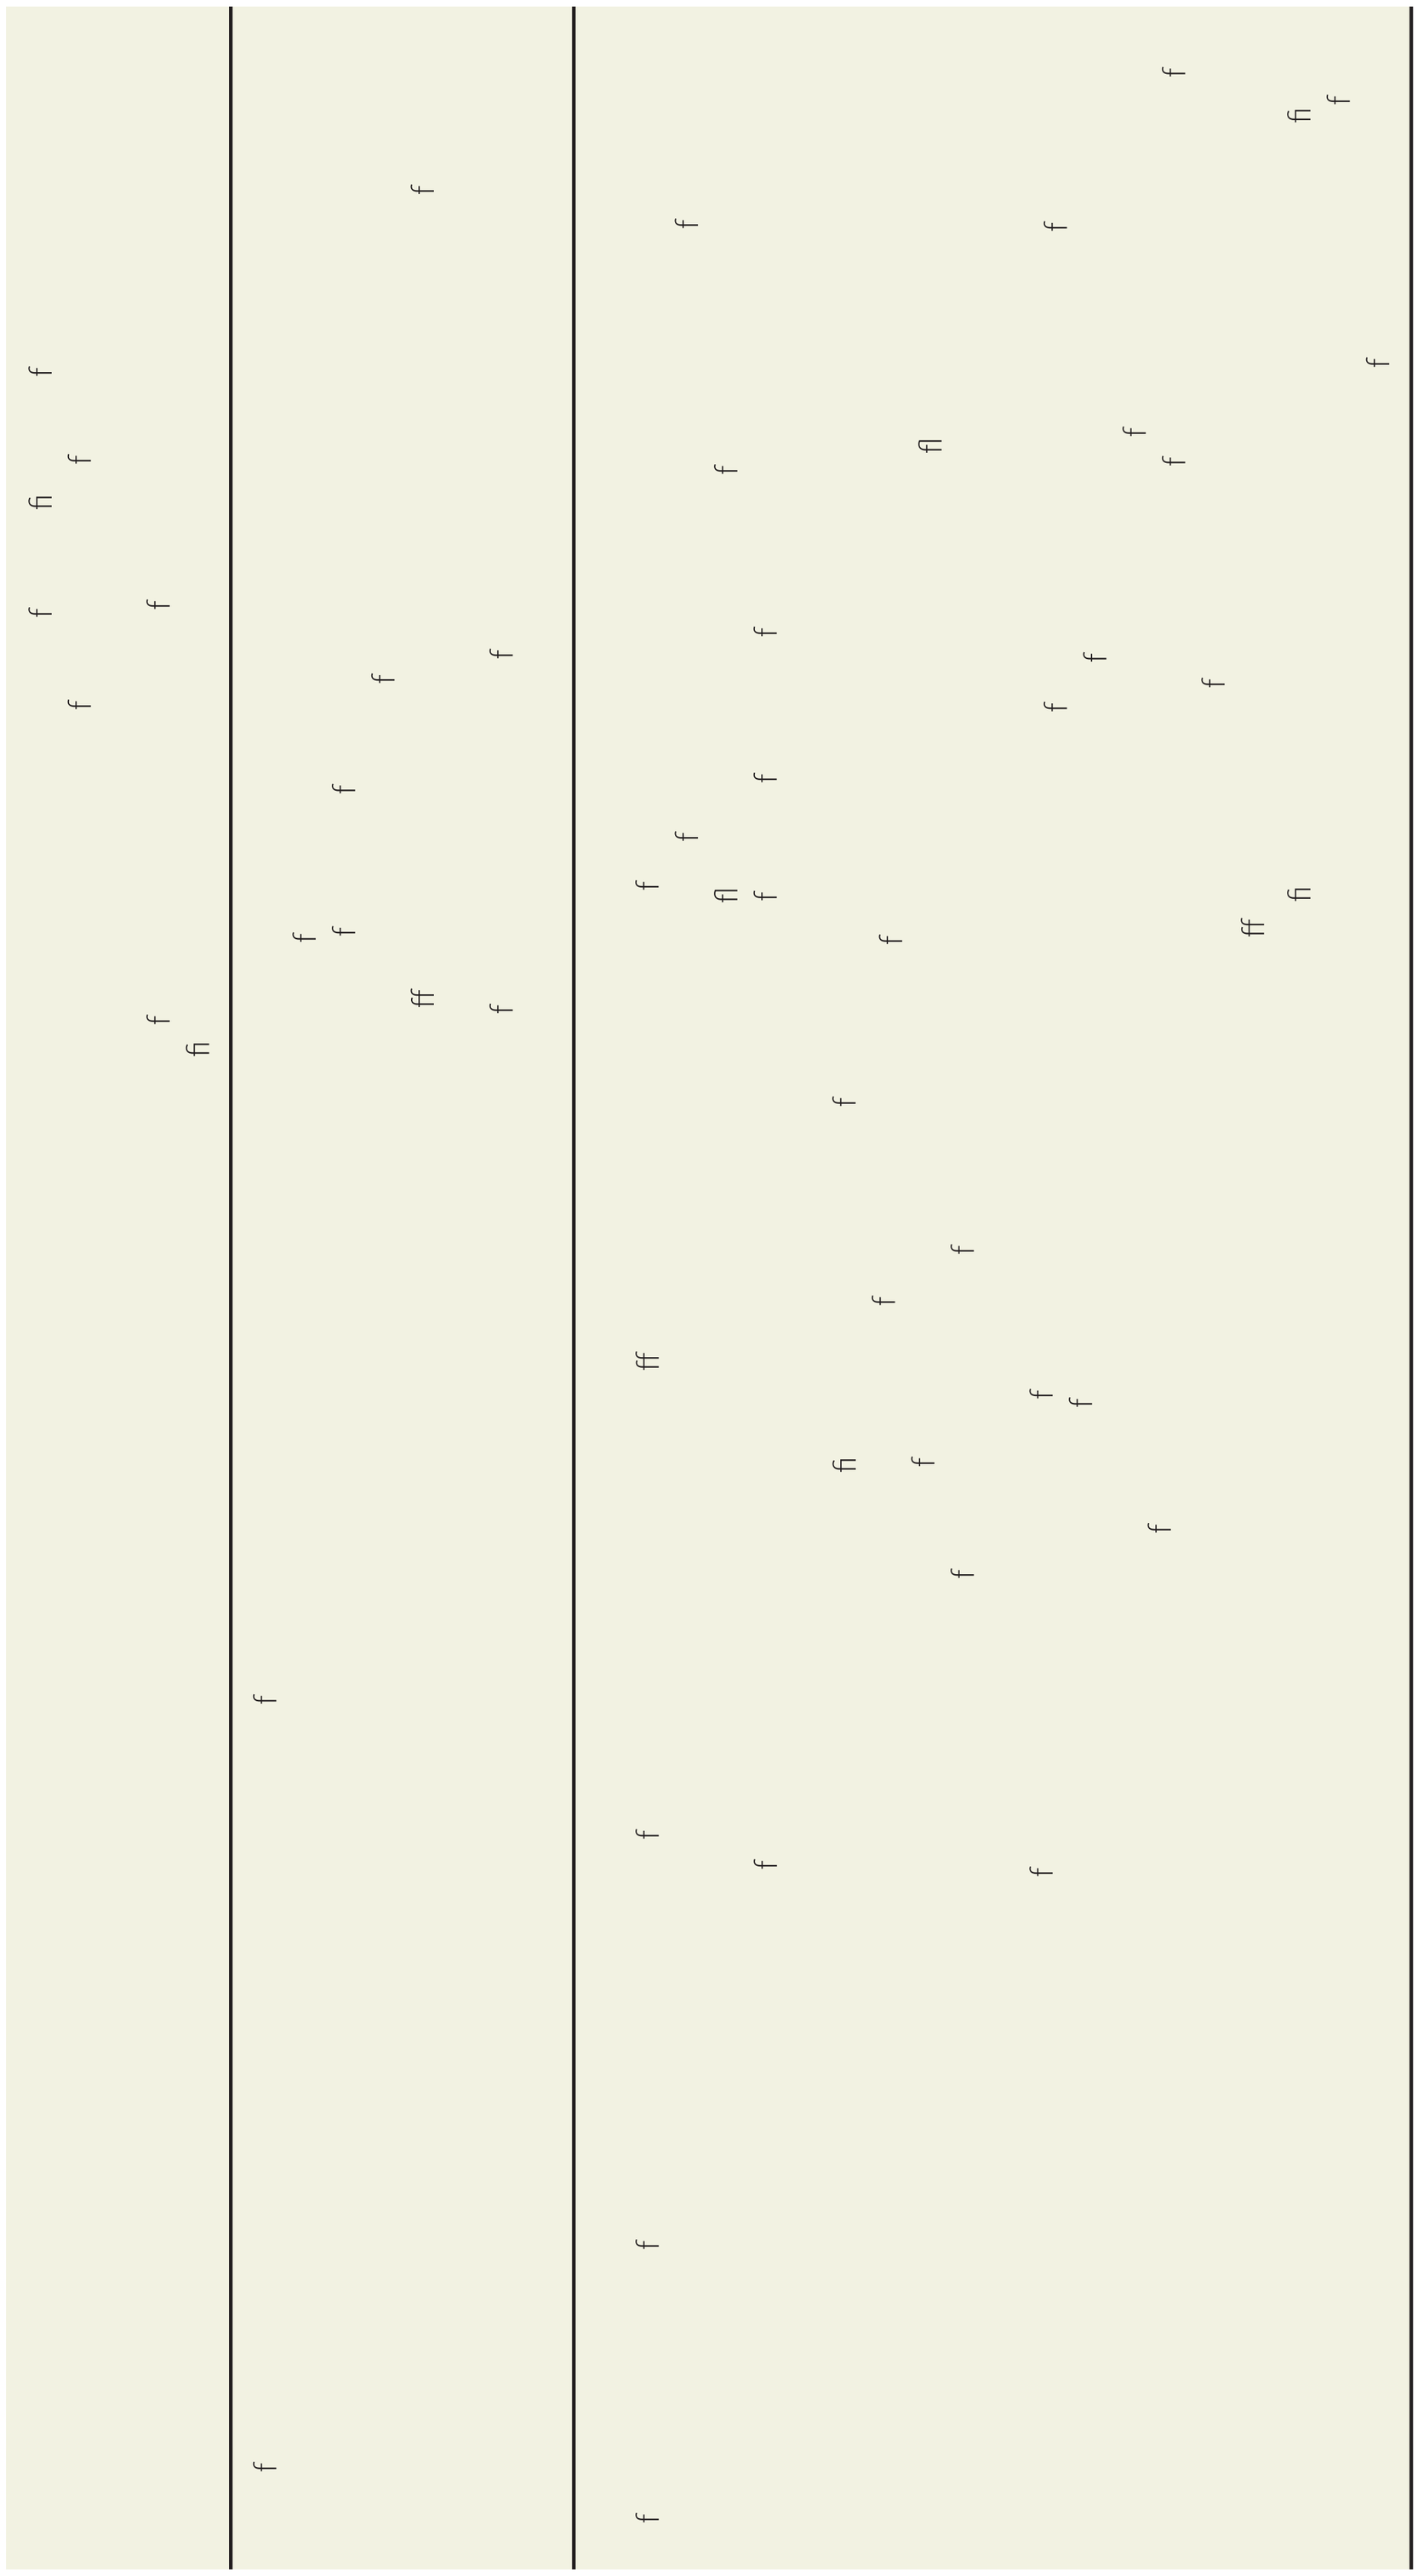
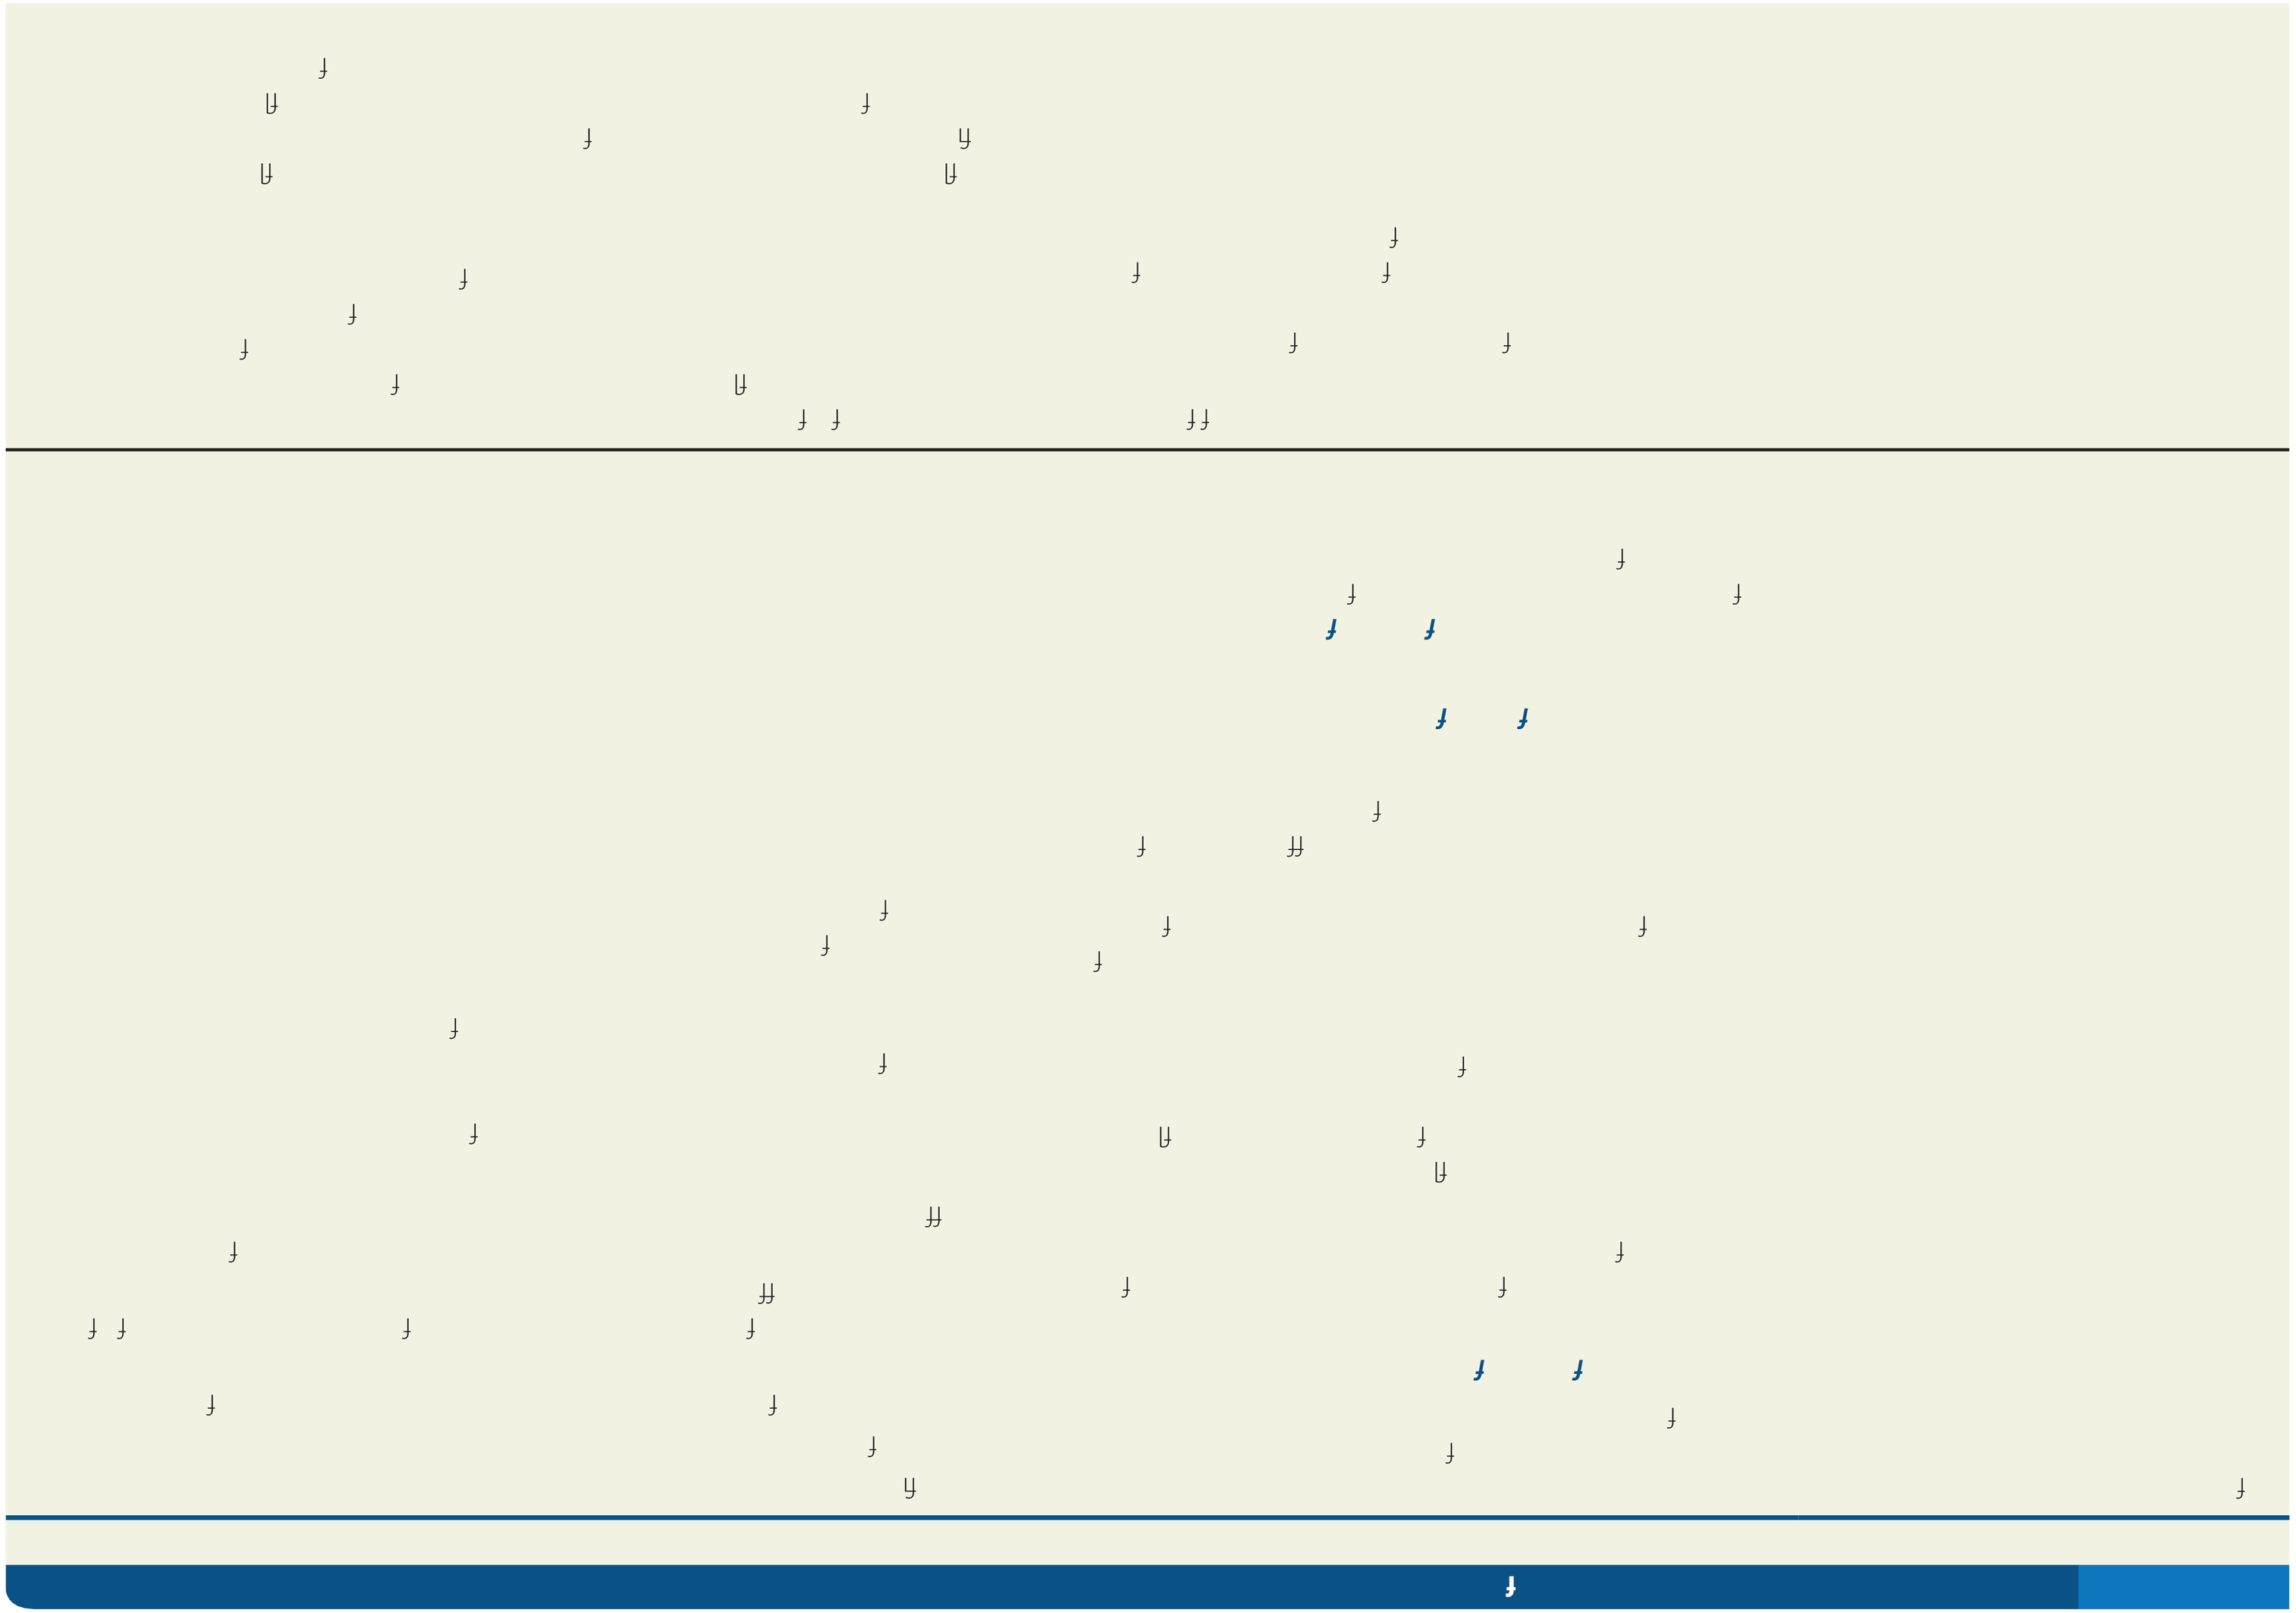
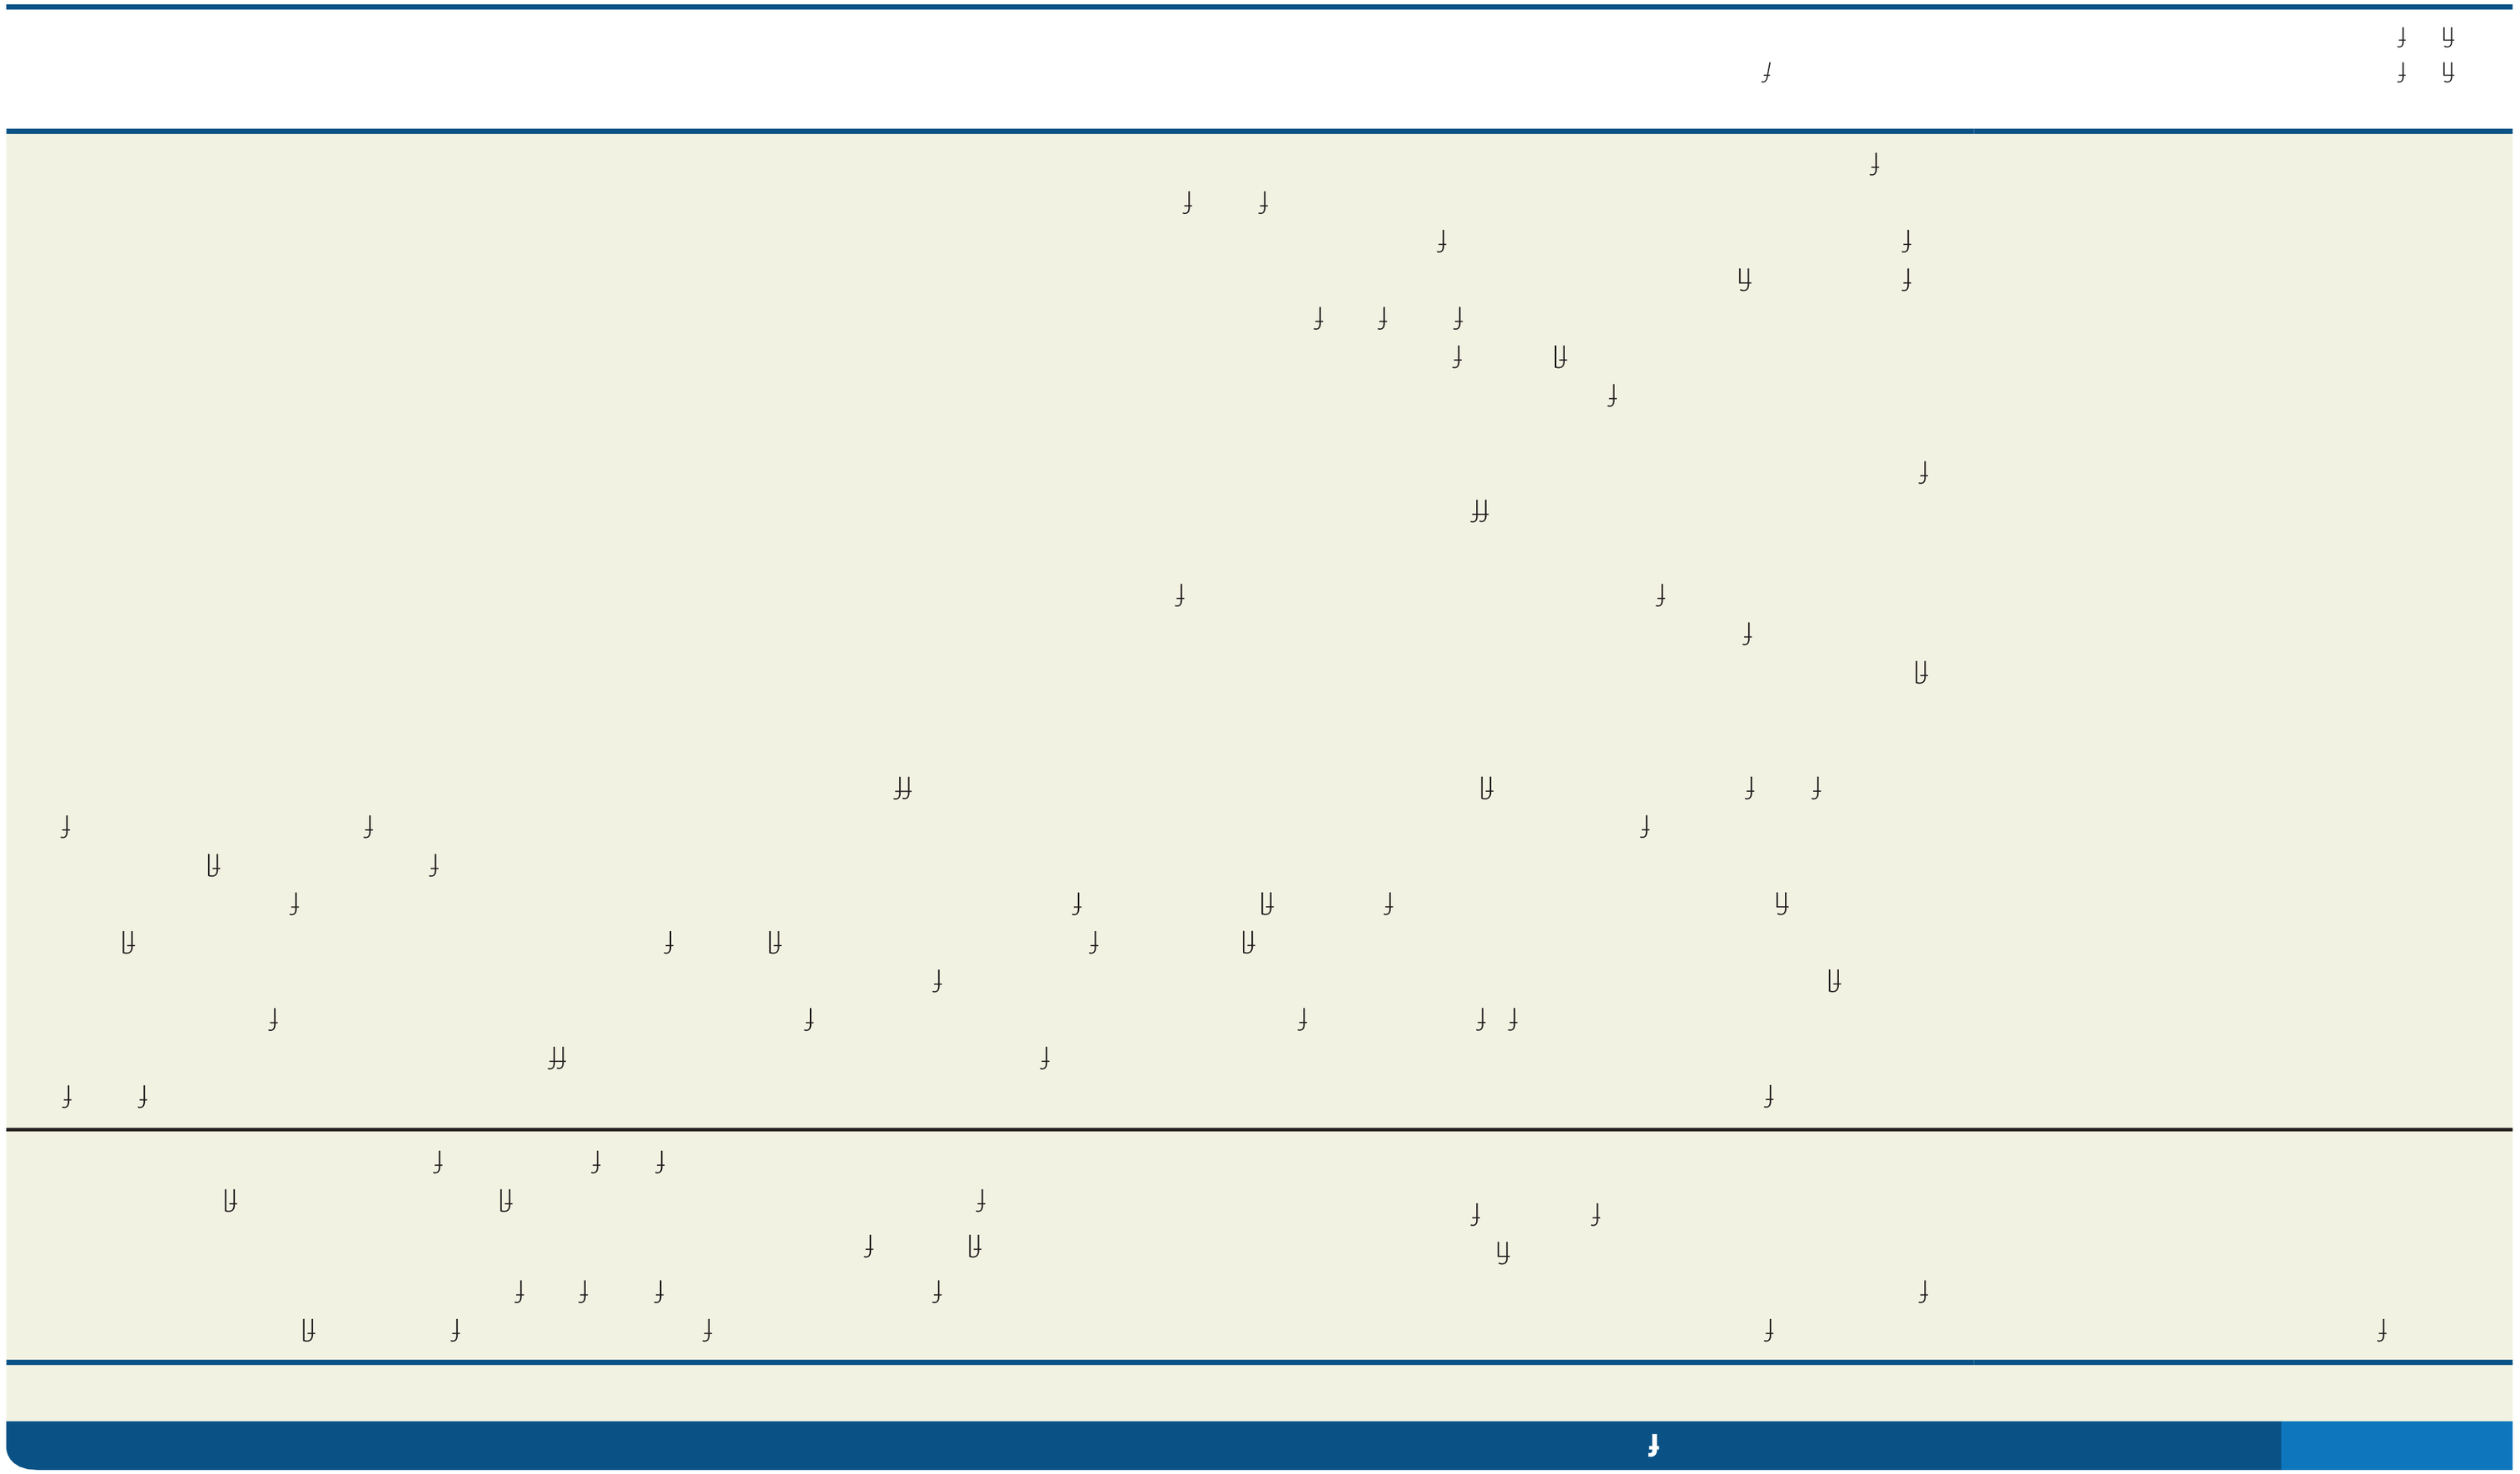


extremities. Peripheral nerve entrapment syndromes of the lower extremity are listed in Table 3-4.



Femoral nerve (L2–4)

The femoral nerve, the largest branch of the lumbar plexus, arises from the lateral border of the psoas just above the inguinal ligament. The nerve descends beneath this ligament to enter the femoral triangle on the lateral side of the femoral artery, where it divides into terminal branches. Above the inguinal ligament, the femoral nerve supplies the iliopsoas muscle, and, in the thigh, it supplies the sartorius, pectineus, and quadriceps femoris muscles.



The sensory distribution of the femoral nerve includes the anterior and medial surfaces of the thigh via the anterior femoral cutaneous nerve and the medial aspect of the knee, the proximal leg, and articular branches to the knee via the saphenous nerve (Fig. 3-18), the largest cutaneous branch of the femoral nerve. The saphenous nerve exits from the adductor (Hunter's, or subsartorial) canal, descends under the sartorius

f f f

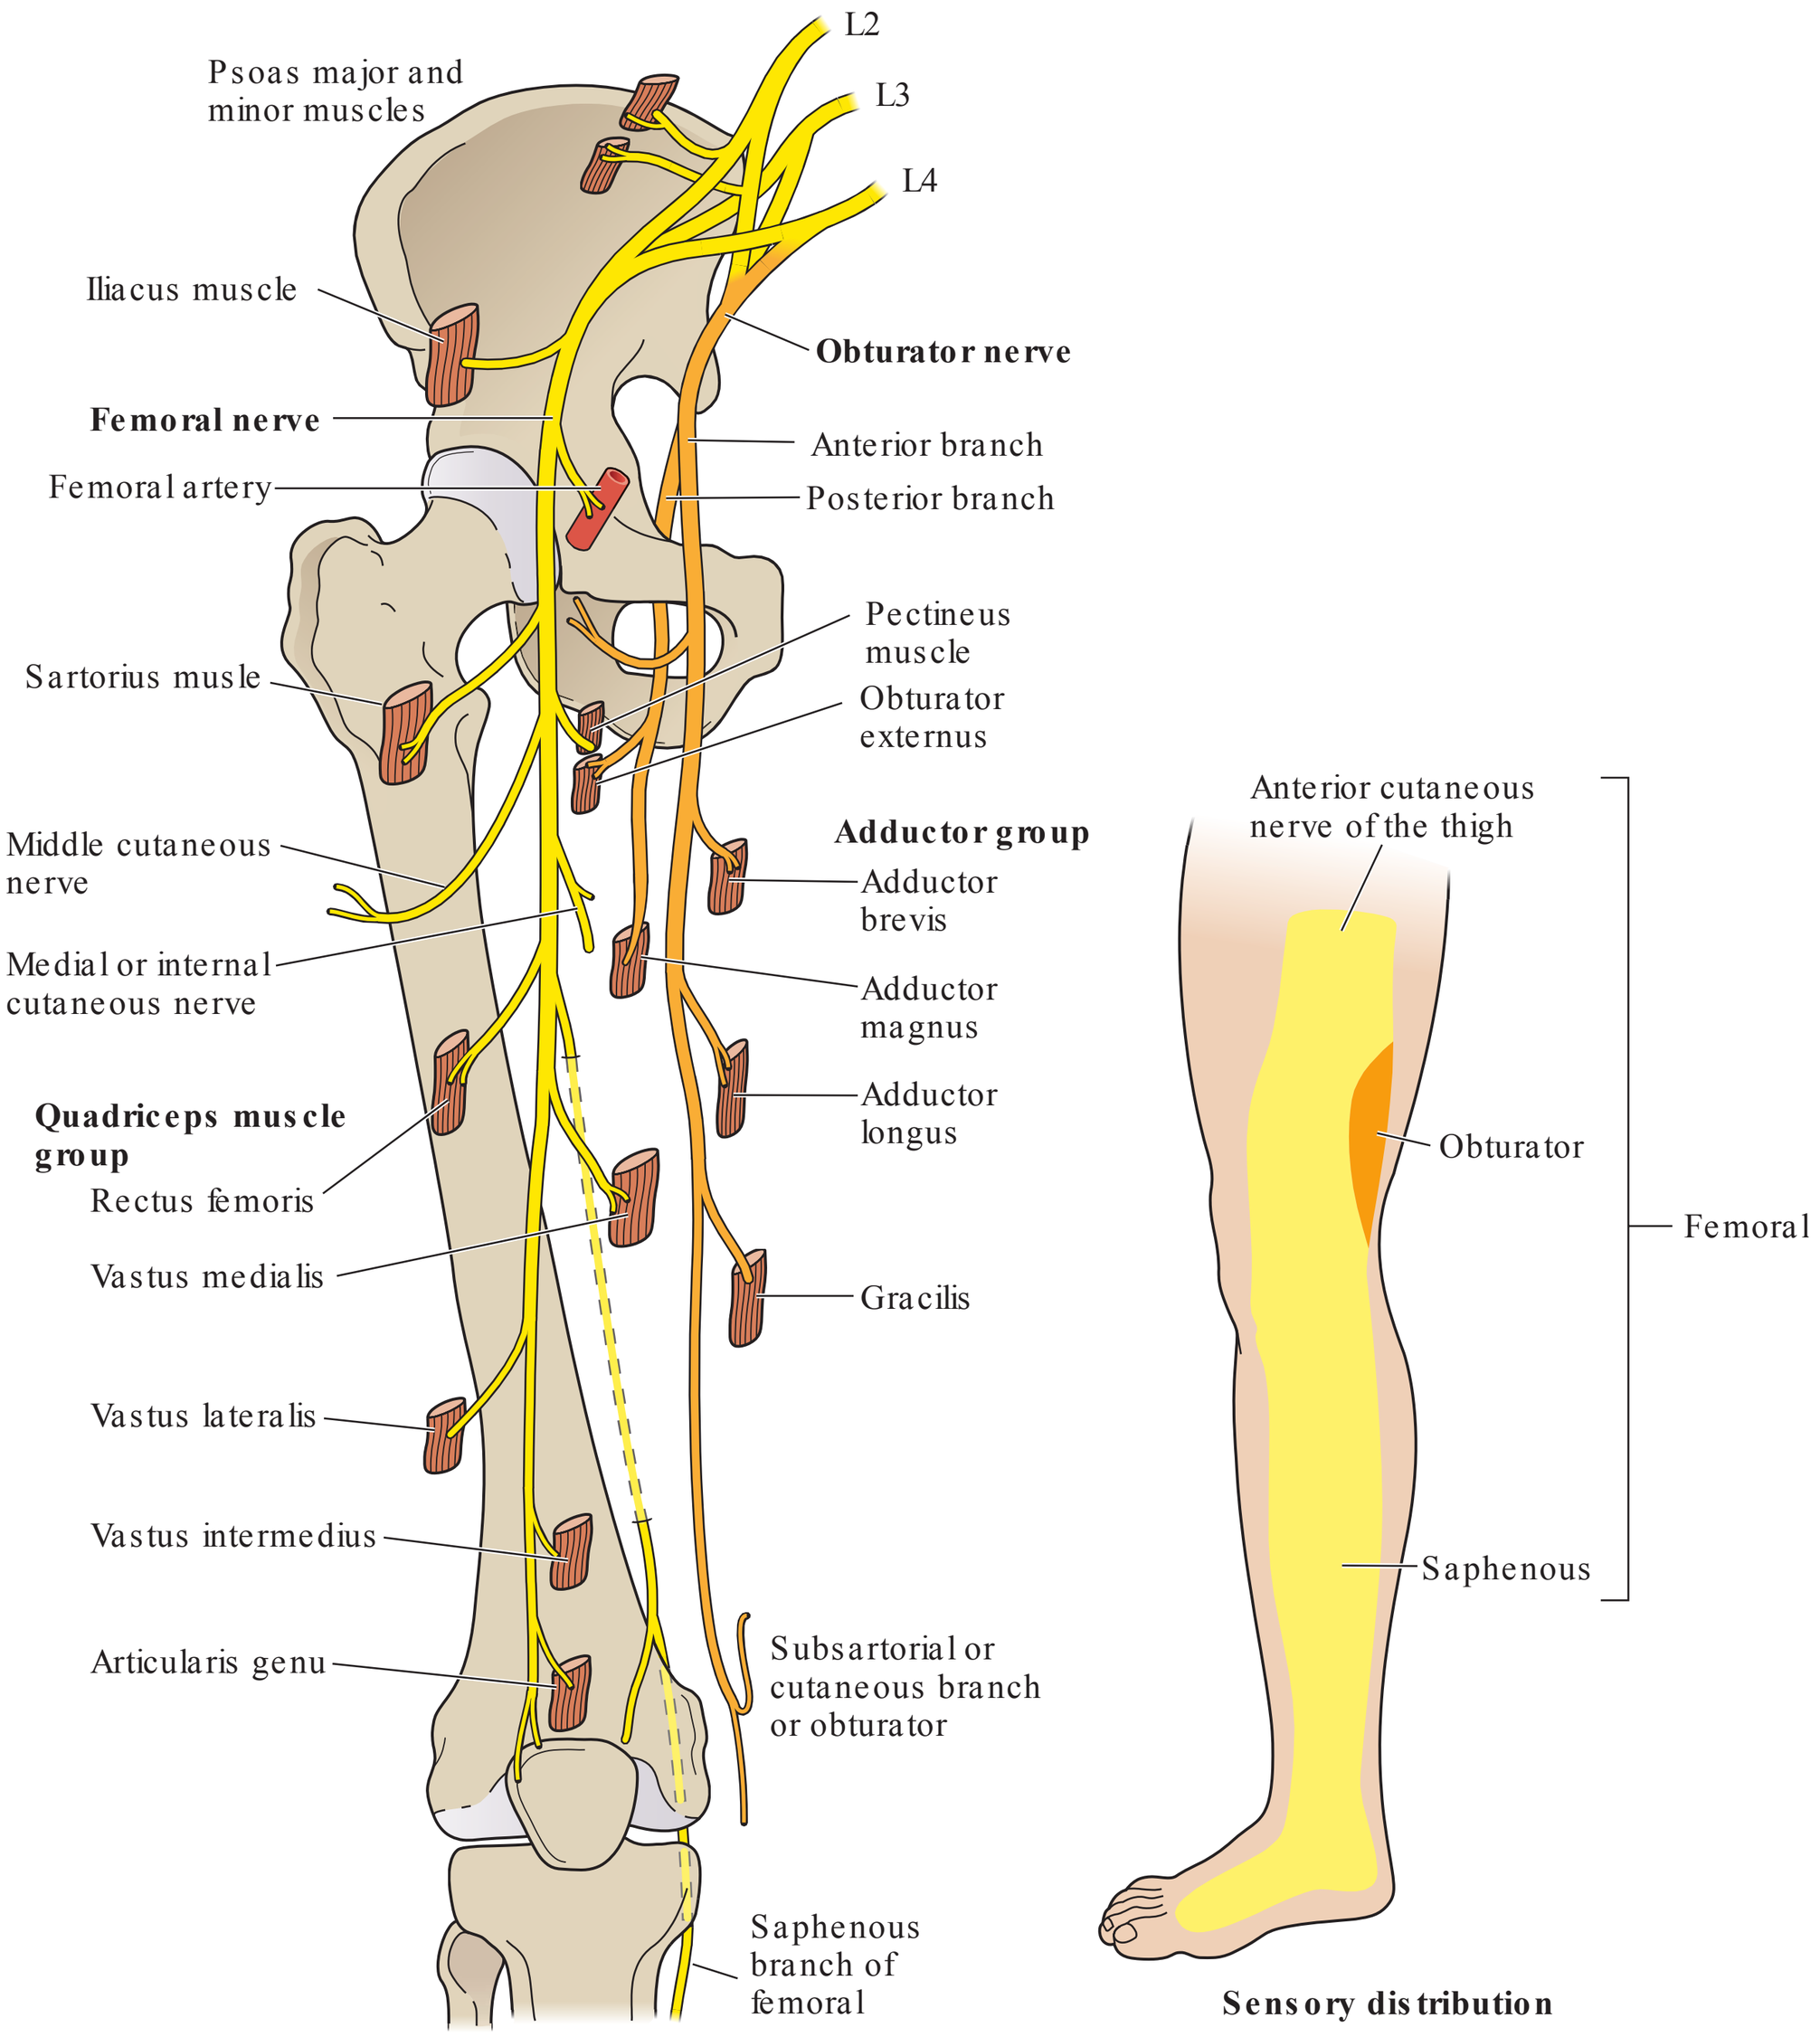


FIGURE 3-18 The femoral (L2–4) and obturator (L2–4) nerves. (Reproduced, with permission, from Appendix C. Spinal Nerves and Plexuses. In: Waxman SG. eds. Clinical Neuroanatomy, 27e. New York, NY: McGraw-Hill; 2013.)

muscle, and then winds around the posterior edge of the sartorius muscle at its tendon portion.

- The infrapatellar branch pierces the sartorius muscle and courses anteriorly to the infrapatellar region.
- The descending branch passes down the medial aspect of the leg and, at the lower third of the leg, divides into two branches. One of the branches of the descending portion of the saphenous nerve courses along the medial border of the tibia and ends at the ankle, while the other branch passes anterior to the ankle and is distributed to the medial aspect of the foot, sometimes reaching as far as the metatarsophalangeal joint of the great toe.

Entrapment of the saphenous nerve often results in marked pain at the medial aspect of the knee.

Femoral nerve palsy has been reported after acetabular fracture, cardiac catheterization, total hip arthroplasty, or anterior lumbar spinal fusion, and spontaneously in hemophilia.[106–108]

Clinical Pearl

An entrapment of the femoral nerve by an iliopsoas hematoma is the most likely cause of femoral nerve palsy.[109] Direct blows to the abdomen or a hyperextension moment at the hip that tears the iliacus muscle may produce an iliacus hematoma.

Obturator Nerve (L2–4)

The obturator nerve (see Fig. 3-18) arises from the second, third, and fourth lumbar anterior divisions of the lumbar plexus and emerges from the medial border of the psoas, near the brim of the pelvis. It then passes behind the common iliac vessels on the lateral side of the hypogastric vessels and the ureter, and descends through the obturator canal in the upper part of the obturator foramen to the medial side of the thigh. While in the foramen, the obturator nerve splits into anterior and posterior branches.

- The anterior division of the obturator nerve gives an articular branch to the hip joint near its origin. It descends anterior to the obturator externus and adductor brevis, deep to the pectineus and adductor longus and supplies muscular branches to the adductors longus and brevis, the gracilis, and, rarely, to the pectineus.[101] The anterior division divides into numerous named and unnamed branches, including the cutaneous branches to the subsartorial plexus and directly to a small area of skin on the middle internal part of the thigh, vascular branches to the femoral artery, and communicating branches to the femoral cutaneous and accessory obturator nerves.
- The posterior division of the obturator nerve pierces the anterior part of the obturator externus, which it supplies and descends deep to the adductor brevis. It also supplies the adductors magnus and brevis (if it has not received supply from the anterior division) and gives an articular branch to the knee joint (see Fig. 3-18).

The obturator nerve may be involved by the same pathologic processes that affect the femoral nerve. Disability is usually minimal, although external rotation and adduction of the thigh are impaired, and crossing of the legs is difficult. The patient may also complain of severe pain, which radiates from the groin down the inner aspect of the thigh (see Fig. 3-18).[110,111]

lCn of the Thigh

The LCN of the thigh (Fig. 3-7) is purely sensory and is derived primarily from the second and third lumbar nerve roots, with occasional contributions from the first lumbar nerve root.[112,113] Sympathetic afferent, and efferent fibers are also contained within the nerve.[114] The nerve leaves the lumbar plexus and normally appears at the lateral border of the psoas, just proximal to the crest of the ilium. From here, it courses laterally across the anterior surface of the iliacus (covered by iliac fascia) and approaches the lateral portion of the inguinal ligament posterior to the deep circumflex iliac artery. The nerve usually crosses beneath the inguinal ligament, just inferior–medial to the anterior superior iliac spine (ASIS).[115]

The site at which the LCN exits the pelvis varies. Meralgia paresthetica (see Table 3-4), the term used to describe LCN entrapment (see Chapter 5), has been reported with each of the five known variants as follows:[116]

- The split lateral attachment of the inguinal ligament. As the nerve curves medially and inferiorly around the ASIS, it may be subjected to repetitive trauma in this osteofibrous tunnel.[117]
- The nerve may pass posterior to the inguinal ligament and anterior to a sharp ridge of iliacus fascia, which can lead to a bowstring deformity of the nerve when the patient is supine.[118]
- Occasionally, the LCN enters the thigh within or beneath the substance of the sartorius muscle.[119]
- Several cases have been reported in which the LCN crosses over the iliac crest lateral and posterior to the ASIS. The nerve typically lies in a groove in the ilium and is subject to pressure from tight garments or belts.[118,119]
- The nerve may exit the pelvis in multiple branches, with entrapment of a single branch.[120]
- Alternatively, the nerve may be absent, with a branch from the femoral nerve arising below the inguinal ligament, or it may be replaced by the ilioinguinal nerve.[121]

Sacral Plexus

The lumbosacral trunk (L4–5) descends into the pelvis, where it enters the formation of the sacral plexus. The sacral plexus (Fig. 3-16) is formed by the anterior (ventral) rami of the L4 and L5 and the S1 through S4 nerves and lies on the posterior wall of the pelvis, anterior to the piriformis and posterior to the sigmoid colon, ureter, and hypogastric vessels in front. The L4 and L5 nerves join medial to the sacral promontory, becoming the lumbosacral trunk. The S1 through S4 nerves converge with the lumbosacral trunk in front of the piriformis muscle, forming the broad triangular band of the sacral plexus. The superior (upper) three nerves of the plexus divide into two sets of branches: the medial branches, which are distributed to the multifidi muscles, and the lateral branches, which become the medial cluneal nerves. The medial cluneal nerves supply the skin over the medial part of the gluteus maximus. The lower two posterior primary divisions, with the posterior division of the coccygeal nerve, supply the skin over the coccyx.

Collateral Branches of the Posterior Division

Superior Gluteal Nerve. The roots of the superior gluteal nerve (L4, 5; S1) arise within the pelvis from the sacral plexus (see Fig. 3-16) and enter the buttock through the greater sciatic foramen, above the piriformis. The nerve runs laterally between gluteus medius and gluteus minimus, which it innervates before terminating in the tensor fascia lata, which it also supplies. Because the nerve passes between the gluteal muscles, it is at risk during surgery on the hip.[122]

Inferior Gluteal Nerve. The inferior gluteal nerve (L5; S1, 2) passes below the piriformis muscle and through the greater sciatic foramen and travels to the gluteus maximus muscle (see Fig. 3-16), which it serves. Nerves to the piriformis consist of short smaller branches from S1 and S2.

Superior Cluneal Nerve. The medial branch of the superior cluneal nerve passes superficially over the iliac crest, where it is covered by two layers of dense fibrous fascia. When the medial branch of the superior cluneal nerve passes through the fascia against the posterior iliac crest and the osteofibrous tunnel consisting of the two layers of the fascia and the superior rim of the iliac crest, the possibility of irritation or trauma to the nerve is increased, making this a potential site of nerve compression or constriction.[123]

Posterior Cutaneous (Femoral) Nerve of the Thigh. The posterior cutaneous (femoral) nerve (PCN) of the thigh constitutes a collateral branch, with roots from both the anterior and the posterior divisions of S1 and S2 and the anterior divisions of S2 and S3 (Fig. 3-16). Perineal branches pass to the skin of the upper medial aspect of the thigh and the skin of the scrotum or labium majores. Despite its close proximity to the sciatic nerve, however, injury to the PCN of the thigh is quite rare.

Collateral Branches of the Anterior Division

Collateral branches from the anterior divisions extend to the quadratus femoris and gemellus inferior muscles (from L4, L5, and S1) and to the obturator internus and gemellus superior muscles (from L5, S1, and S2).

Sciatic Nerve. The sciatic nerve (Fig. 3-19) is the largest nerve in the body. It arises from the L4, L5, and S1 through

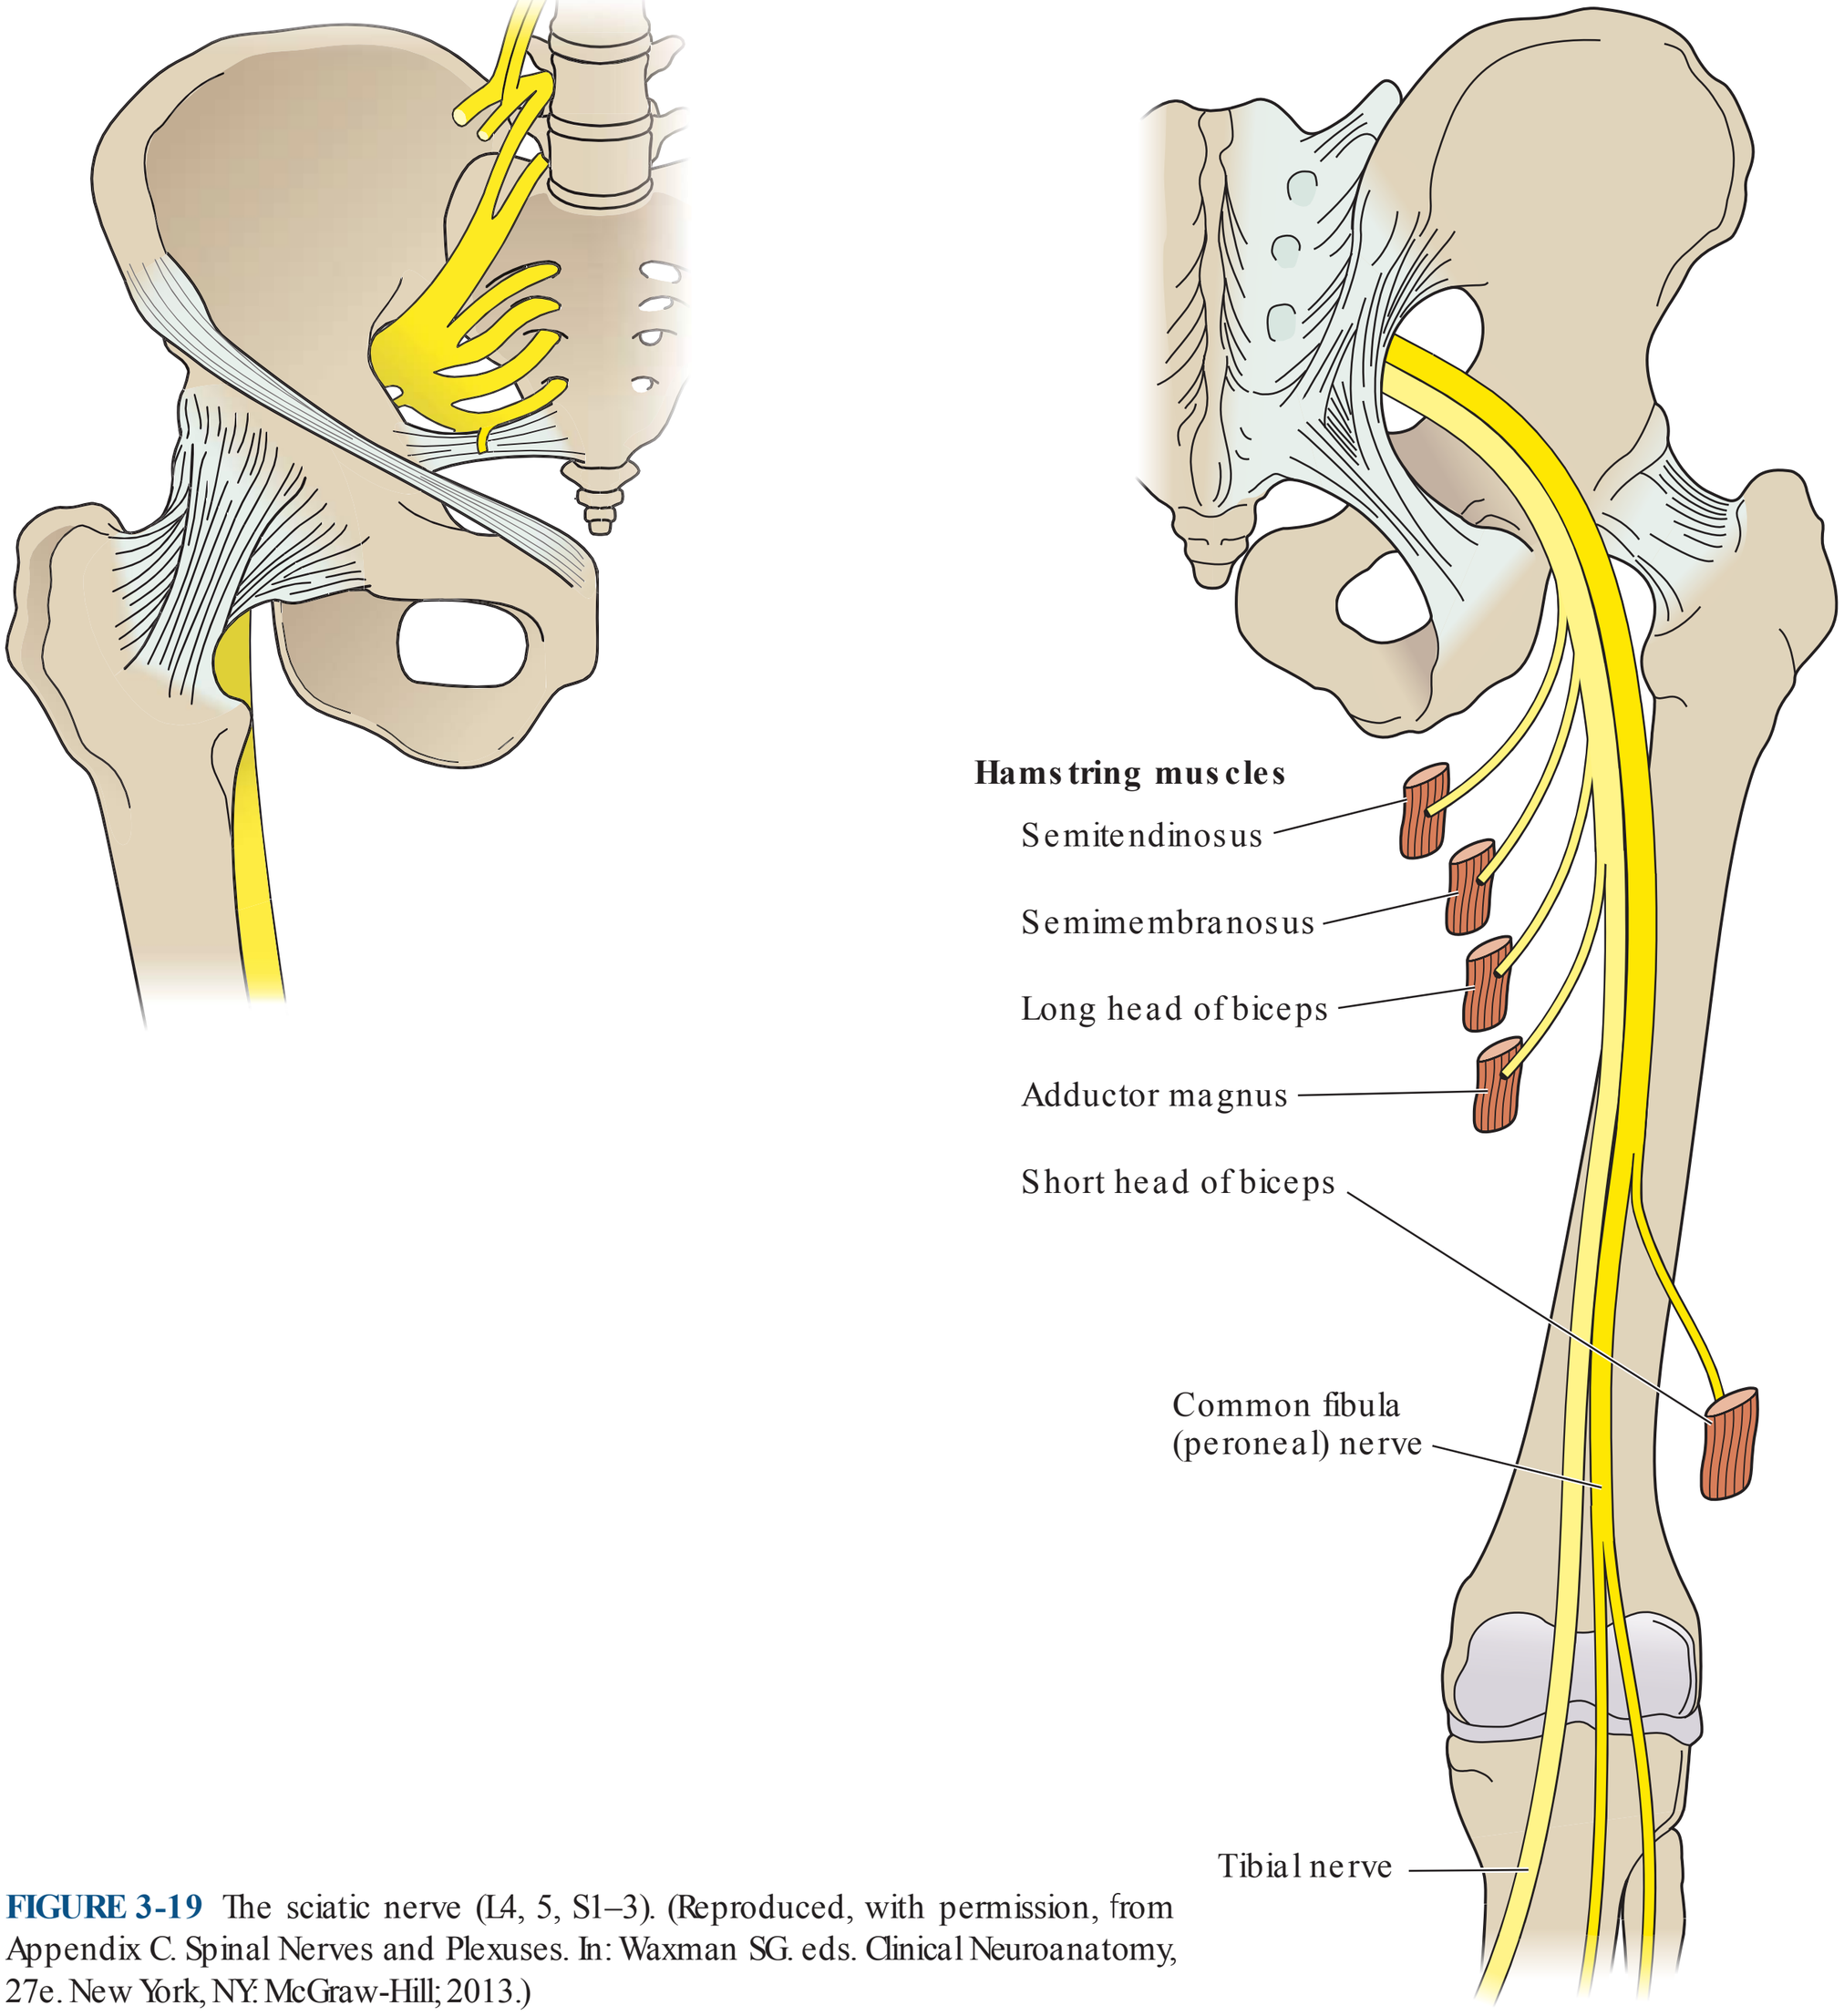

FIGURE 3-19 The sciatic nerve (L4, 5, S1–3). (Reproduced, with permission, from Appendix C. Spinal Nerves and Plexuses. In: Waxman SG. eds. Clinical Neuroanatomy, 27e. New York, NY: McGraw-Hill; 2013.)

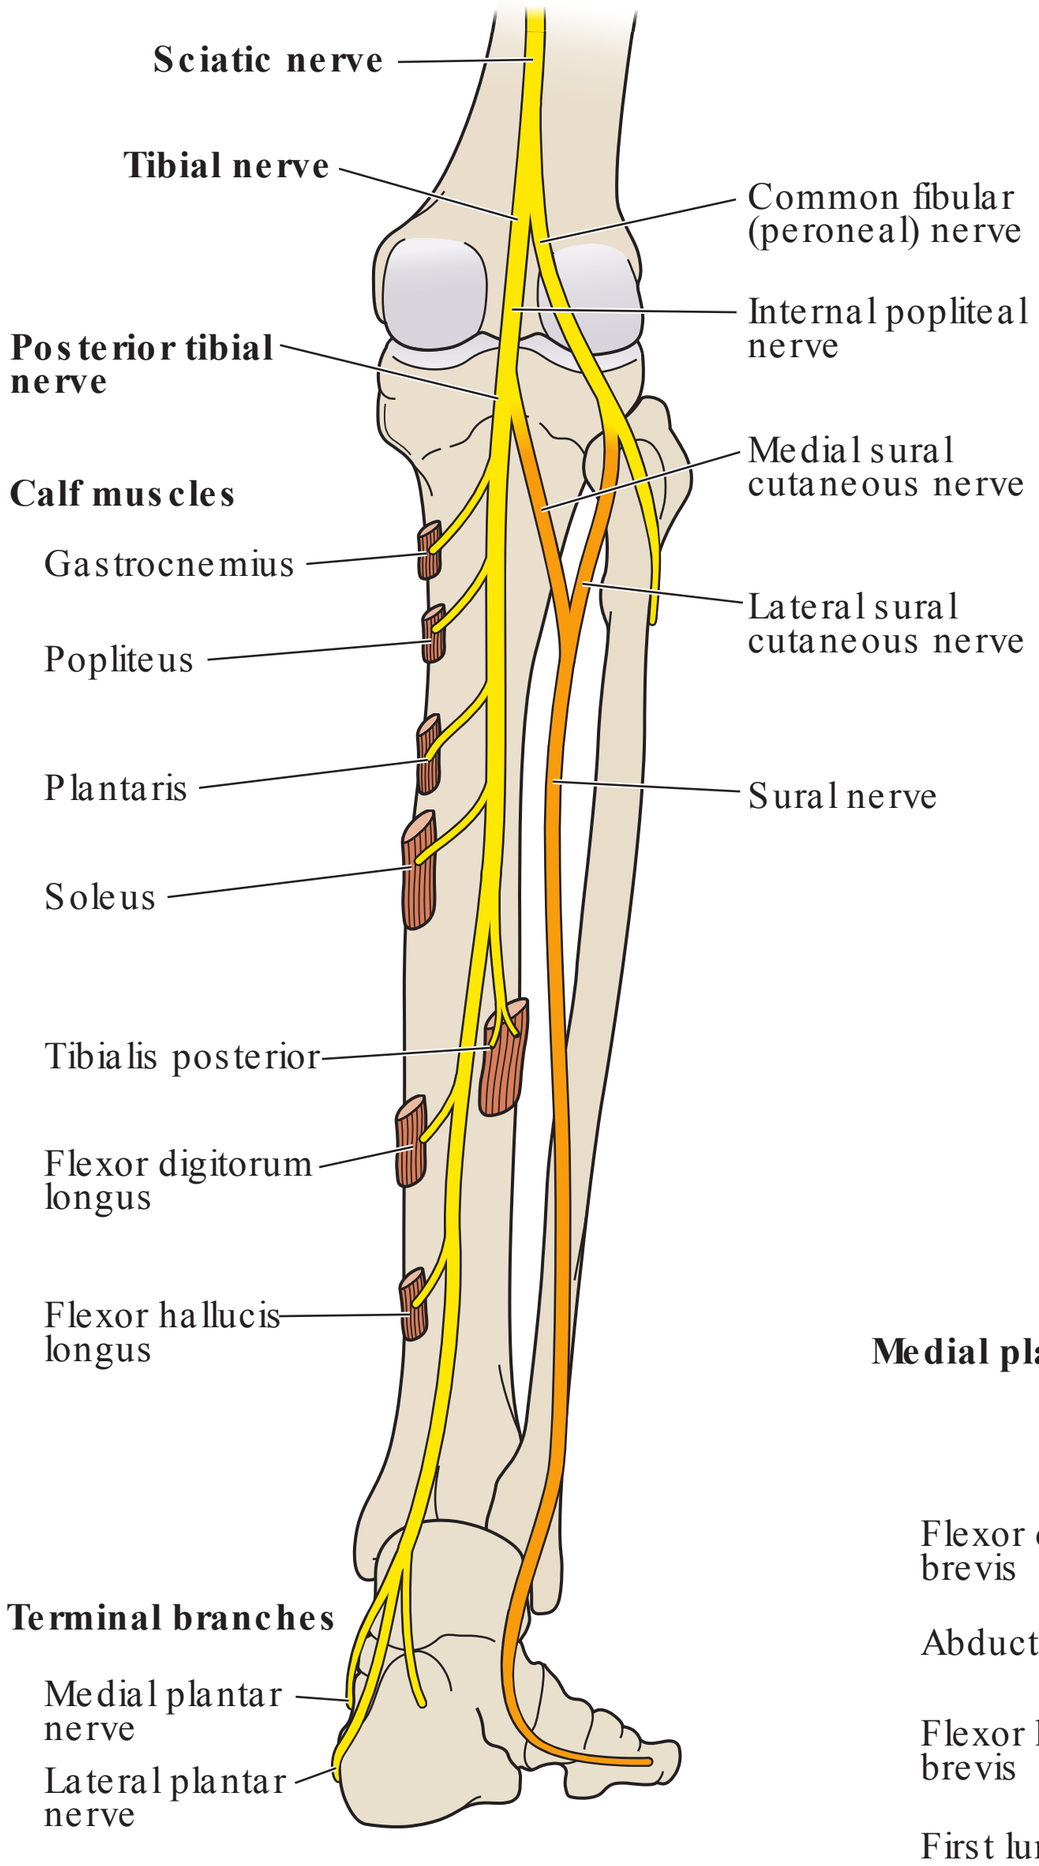
S3 nerve roots as a continuation of the lumbosacral plexus. The nerve is composed of the independent tibial (medial) and common fibular (peroneal) (lateral) divisions, which are usually united as a single nerve down to the lower portion of the thigh. The tibial division is the larger of the two divisions. Although grossly united, the funicular patterns of the tibial and common fibular (peroneal) divisions are distinct, and there is no exchange of bundles between them. The common fibular (peroneal) nerve is formed by the upper four posterior divisions (L4, 5; S1, 2) of the sacral plexus, and the tibial nerve is formed from all five anterior divisions (L4, 5; S1–3).

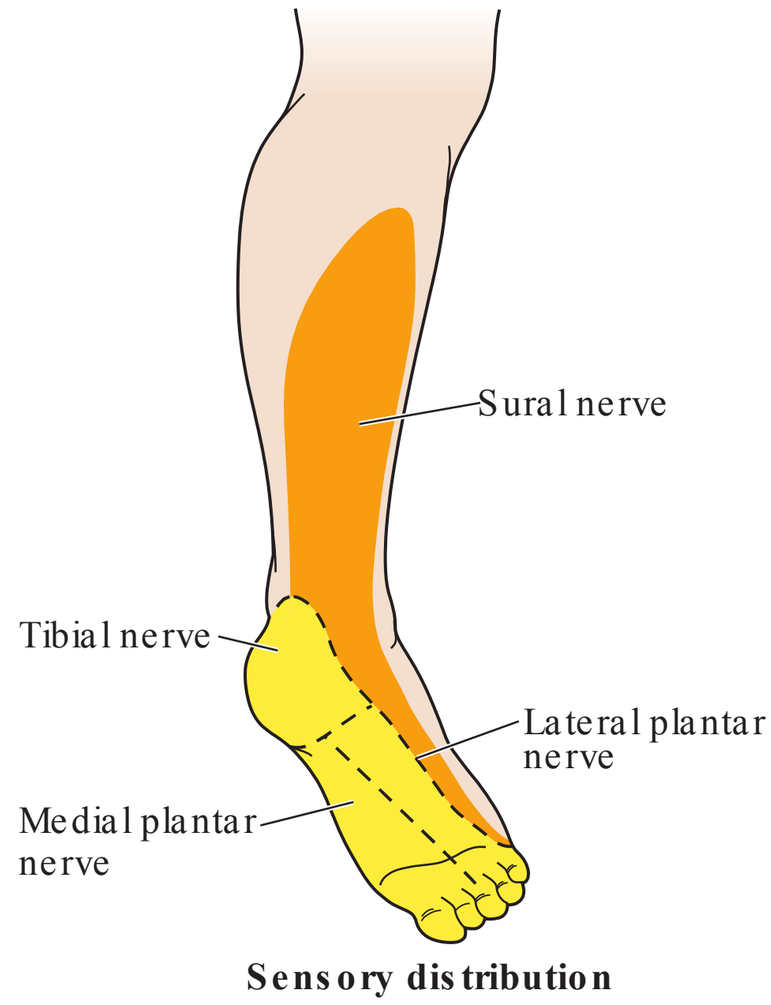
The sciatic nerve usually exits the pelvis through the anterior third of the greater sciatic foramen.[124] Also running through the greater sciatic foramen is the superior gluteal artery, the largest branch of the internal iliac artery, and its accompanying vein.

Numerous variations have been described for the course of the sciatic nerve, including cases in which the sciatic nerve passes through the piriformis, and cases in which the tibial division passes below the piriformis while the common fibular (peroneal) division passes above or through the muscle. It seems that the tibial division always enters the gluteal region below the piriformis, and the variability is in the course of the common fibular (peroneal) division. Typically, the sciatic nerve descends along the posterior surface of the thigh to the popliteal space, where it usually terminates by dividing into the tibial and common fibular (peroneal) nerves (see Fig. 3-19). Innervation of the short head of the biceps femoris comes from the common fibular (peroneal) division, the only muscle innervated by this division above the knee. Rami from the tibial trunk pass to the semitendinosus and the semimembranosus muscles, the long head of the biceps femoris, and the adductor magnus muscle.

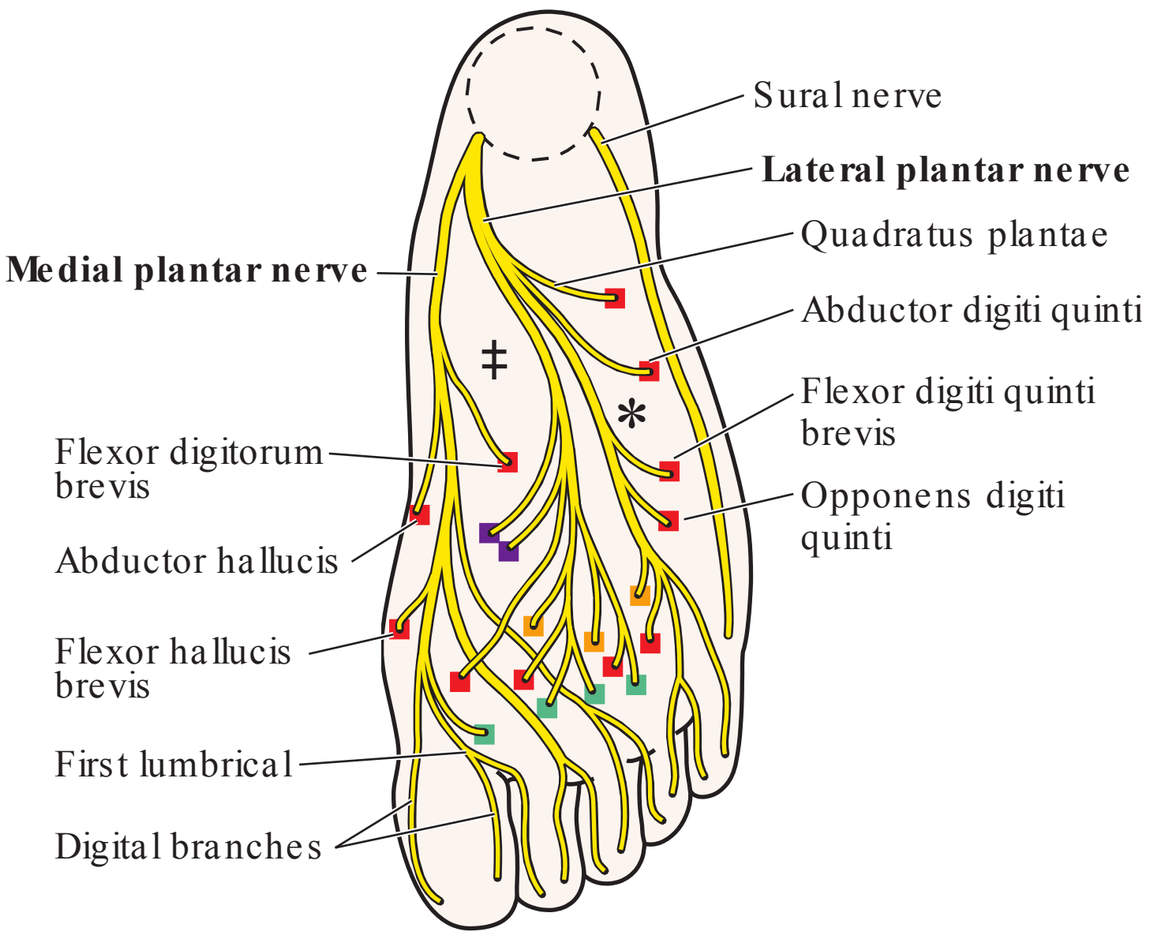
In most reports of sciatic nerve injury, regardless of the cause, the common fibular (peroneal) division is involved more frequently and often suffers a greater degree of damage than the tibial division; its susceptibility to injury being related to several anatomic features.



Injury to the sciatic nerve may result indirectly from a herniated intervertebral disk (protruded nucleus pulposus) or more directly from a hip dislocation, local aneurysm, or direct external trauma of the sciatic notch, the latter of which can be confused with a compressive radiculopathy of the lumbar or sacral nerve root.[125] Following are some useful clues to help distinguish the two conditions:



- Pain from an irritated lumbar spinal nerve root (radiculopathy) should not significantly change with the introduction of hip rotation during the straight-leg raise test (Chapter 11), whereas if there is a sciatic nerve entrapment by the piriformis muscle, pain is likely to be accentuated by introducing hip internal rotation to the straight-leg raise, which stretches the muscle fibers, and relieved by moving the hip into external rotation.
- Sciatic neuropathy produces sensory changes on the sole of the foot, whereas lumbosacral radiculopathy generally does not unless there is a predominant S1 involvement.
- Compressive radiculopathy below the L4 level causes palpable atrophy of the gluteal muscles, whereas a sciatic entrapment spares these muscles.
- The sciatic trunk is frequently tender from root compression at the foraminal level, whereas it is not normally tender in a sciatic nerve entrapment.[126]



Individual case reports of bone and soft tissue tumors along the course of the sciatic nerve have been described as a rare cause of sciatica.[127,128]

Tibial Nerve. The tibial nerve (L4, 5; S1–3) is formed by all five of the anterior divisions of the sacral plexus, thus receiving fibers from the lower two lumbar and the upper three sacral cord segments. Inferiorly, the nerve begins its own course in the upper part of the popliteal space, before descending vertically through this space, and passing between the heads of the gastrocnemius muscle, to the dorsum of the leg. The portion of the tibial trunk below the popliteal space is called the posterior tibial nerve; the portion within the space is called the internal popliteal nerve (Fig. 3-20). Entrapment of the posterior tibial nerve can occur within the fibro-osseous passageway posterior to the medial malleolus. This is entrapment is referred to as tarsal tunnel syndrome (see Chapter 21). The tibial nerve supplies the gastrocnemius, plantaris, soleus, popliteus, tibialis posterior, flexor digitorum longus, and flexor hallucis longus muscles (see Fig. 3-20).

- **Sural nerve.** The sural nerve (see Fig. 3-20) is a sensory branch of the tibial nerve. It is formed by the lateral sural cutaneous nerve from the common fibular (peroneal) nerve and the medial calcaneal nerve from the tibial nerve. The sural nerve supplies the skin on the posterior–lateral aspect of the lower one-third of the leg and the lateral side of the foot.
- **Terminal branches of the tibial nerve.** In the distal leg, the tibial nerve lies laterally to the posterior tibial vessels, and it supplies articular branches to the ankle joint and to the posteromedial aspect of the ankle. From this point, its terminal branches include the following:
  - Medial plantar nerve (comparable to the median nerve in the hand). This nerve supplies the flexor digitorum brevis, abductor hallucis, flexor hallucis brevis, and first lumbrical muscles and sensory branches to the medial side of the sole, the plantar surfaces of the medial 3½ toes, and the terminal ends of the same toes (see Fig. 3-20).
  - Lateral plantar nerve (comparable to the ulnar nerve in the hand). This nerve supplies the small muscles of the foot, except those innervated by the medial plantar nerve, and sensory branches to the lateral portions of the sole, the plantar surface of the lateral 1½ toes, and the distal phalanges of these toes (see Fig. 3-20). The interdigital nerves are most commonly entrapped between the second and third, and the third and fourth, web spaces, and the intermetatarsal ligaments as a result of a forced hyperextension of the toes, eventually resulting in an interdigital (Morton's) neuroma (see Chapter 21).
  - Medial calcaneal nerve. As it passes beneath the flexor retinaculum, the tibial nerve gives off medial calcaneal branches to the skin of the heel. An irritation of this nerve may result in heel pain.

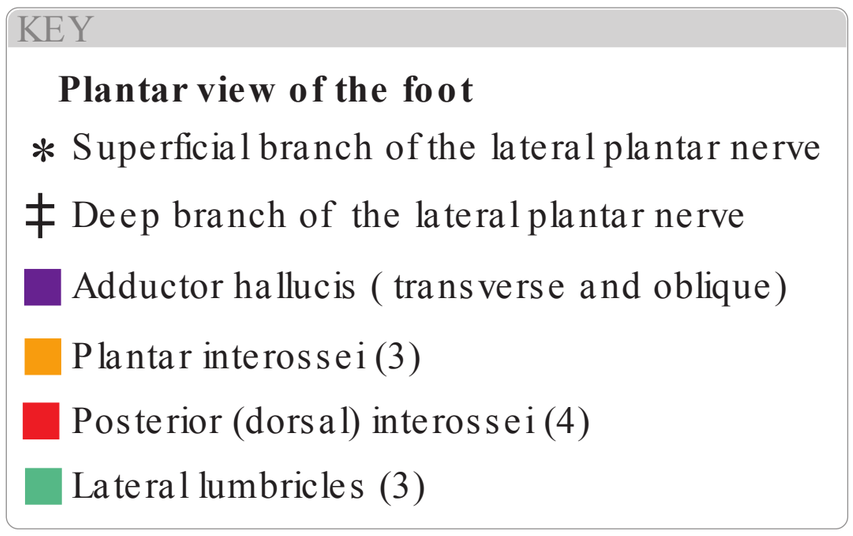


FIGURE 3-20 The tibial nerve (L4, 5, S1–3). (Reproduced, with permission, from Appendix C. Spinal Nerves and Plexuses. In: Waxman SG. eds. Clinical Neuroanatomy, 27e. New York, NY: McGraw-Hill; 2013.)

Common Fibular (Peroneal) Nerve

The common fibular (peroneal) nerve (L4, 5; S1–2) is formed by a fusion of the upper four posterior divisions of the sacral plexus, and thus derives its fibers from the lower two lumbar and the upper two sacral cord segments (see Fig. 3-21). In the thigh, it is a component of the sciatic nerve as far as the upper part of the popliteal space. The nerve gives off sensory branches in the popliteal space. These sensory branches include the superior and inferior articular branches to the knee joint and the lateral sural cutaneous nerve (see Figs. 3-20 and 3-21).

At the apex of the popliteal fossa, the common fibular (peroneal) nerve begins its independent descent along the posterior border of the biceps femoris and then crosses the dorsum of the knee joint to the upper external portion of the leg near the head of the fibula. The nerve curves around the lateral aspect of the fibula toward the anterior aspect of the bone, before passing deep to the two heads of the fibularis (peroneus) longus muscle, where it divides into three terminal rami: the recurrent articular, superficial, and deep fibular (peroneal) nerves.

- The recurrent articular nerve accompanies the anterior tibial recurrent artery, supplying the tibiofibular and knee joints, and a twig to the tibialis anterior muscle.
- The superficial fibular (peroneal) nerve arises deep to the fibularis (peroneus) longus (see Fig. 3-21). It then passes forward and downward between the peronei muscles and the extensor digitorum longus muscle, to supply the fibularis (peroneus) longus and brevis muscles, and provide sensory distribution to the lower front of the leg, the dorsum of the foot, part of the big toe, and adjacent sides of the second to fifth toes up to the second phalanges. Entrapment of this nerve is often confused with an intervertebral disk herniation involving the L5

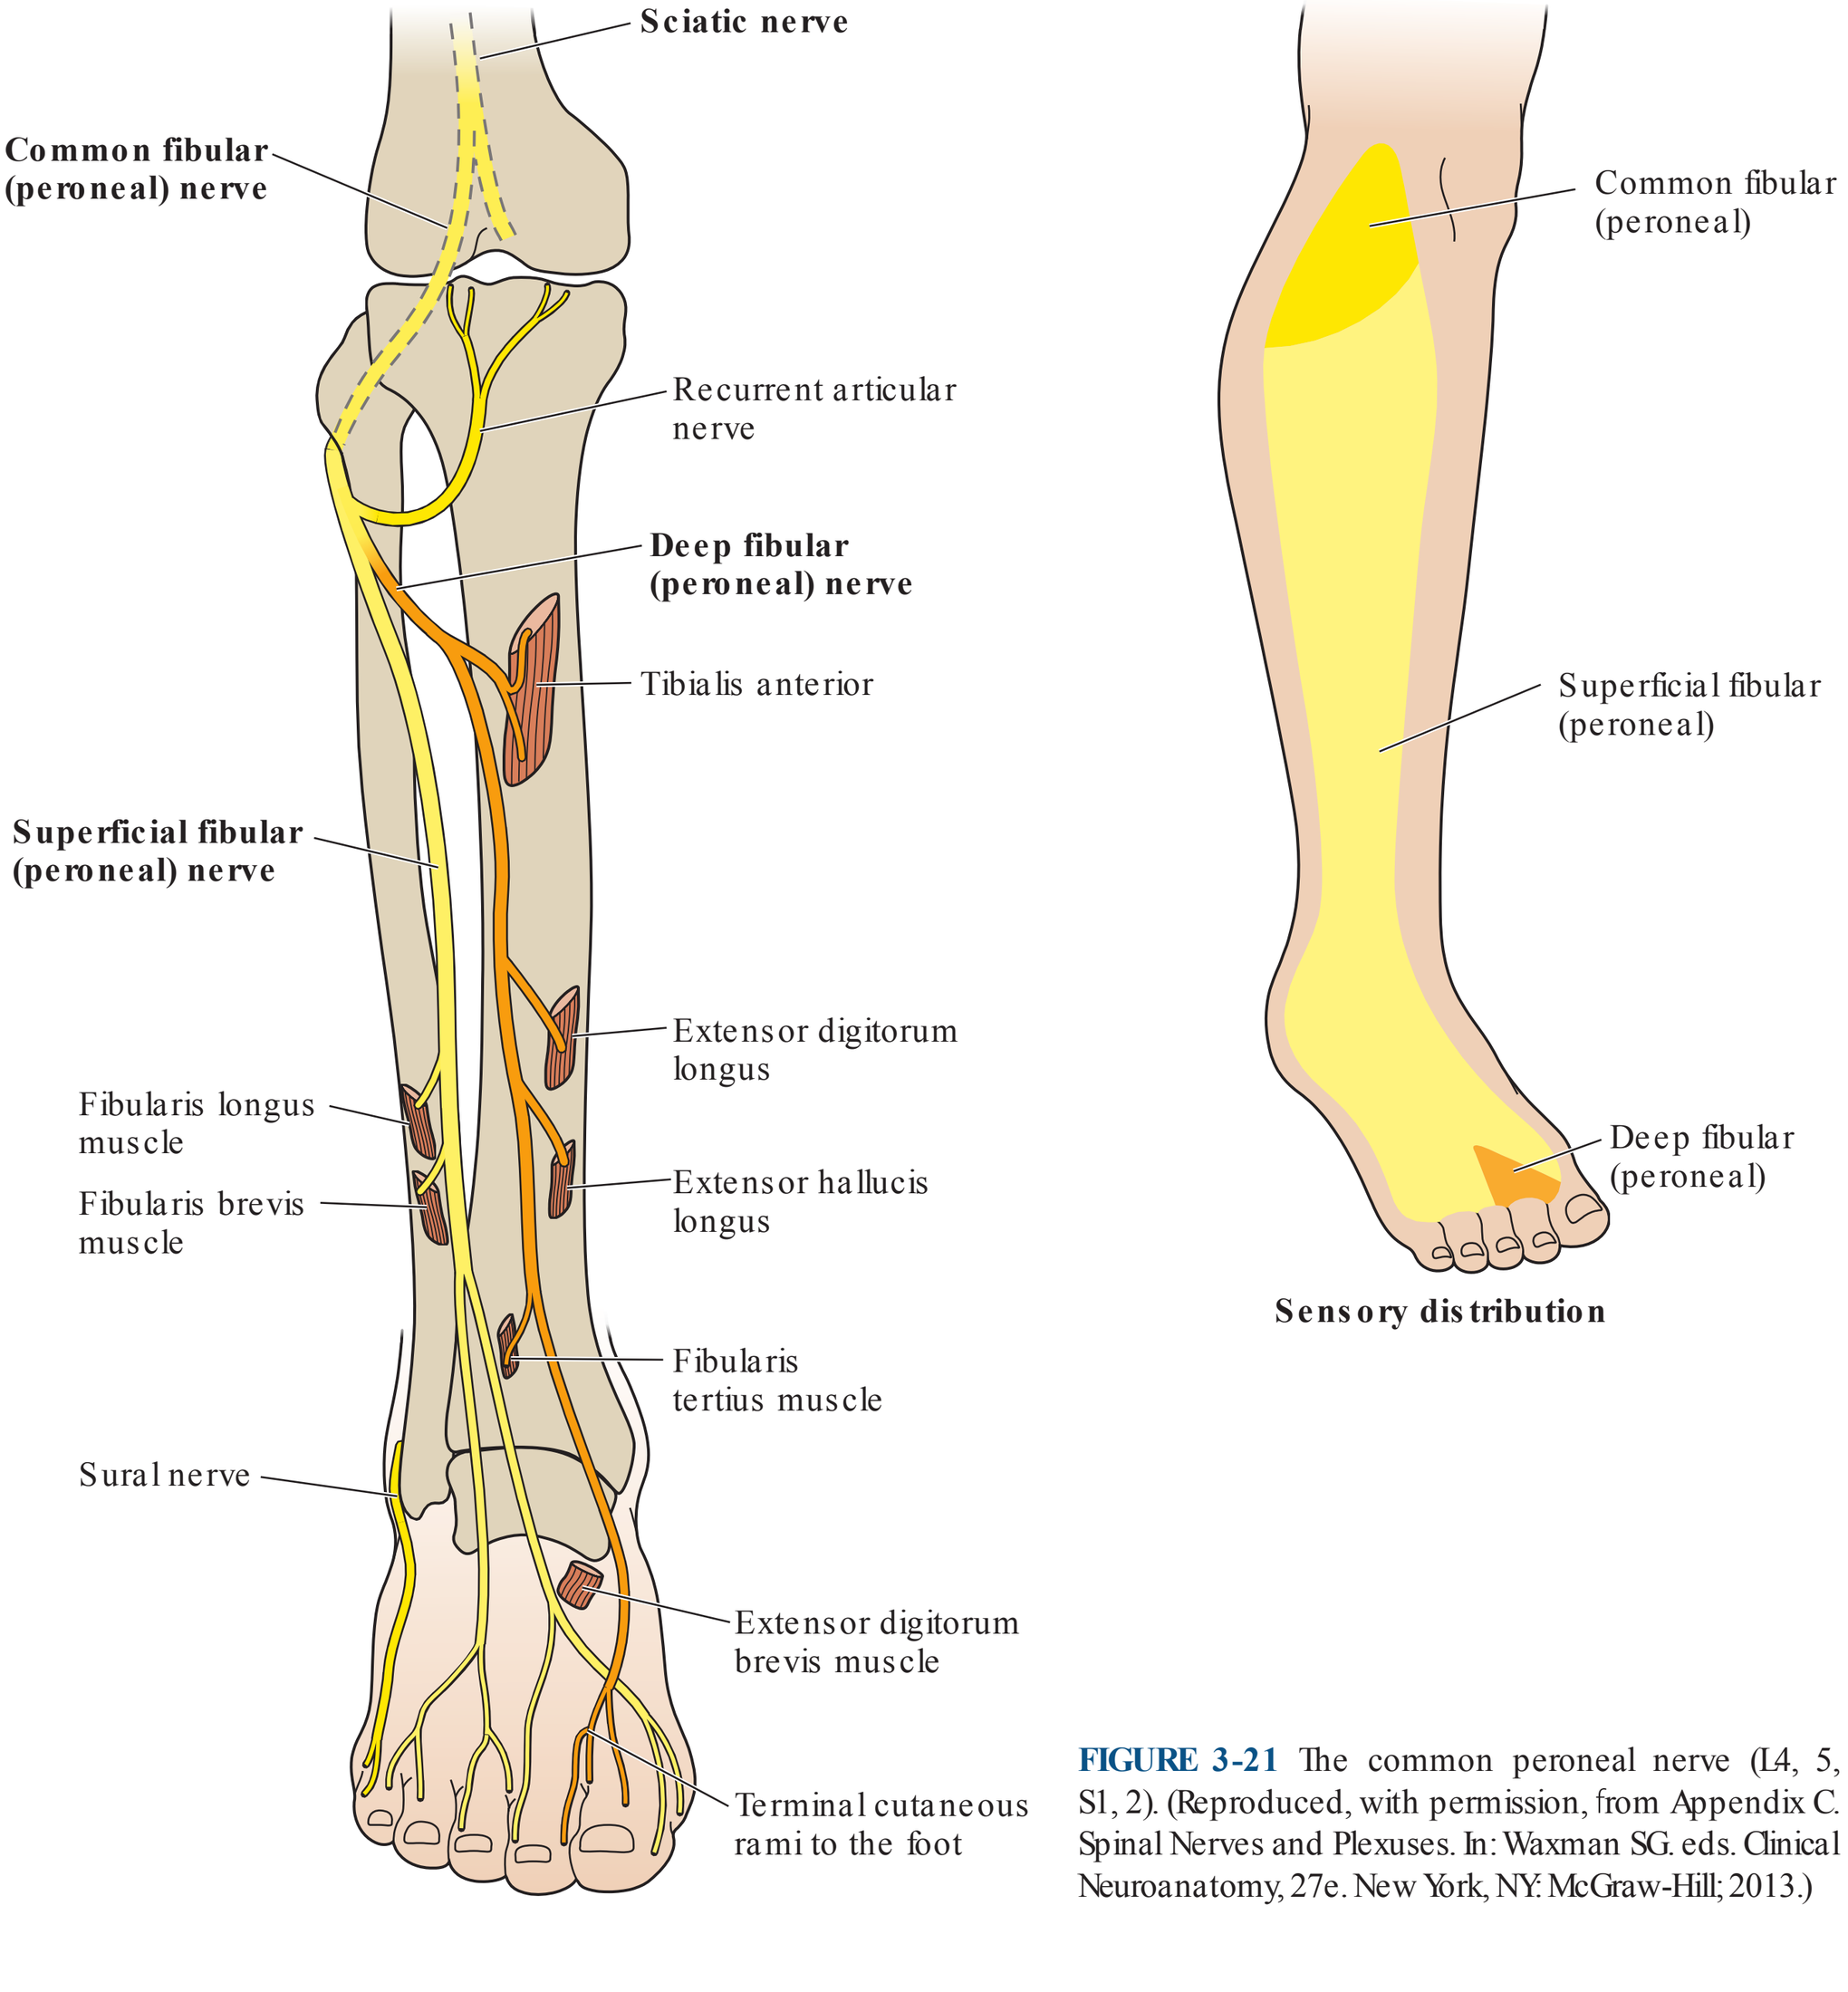

FIGURE 3-21 The common peroneal nerve (L4, 5, S1, 2). (Reproduced, with permission, from Appendix C. Spinal Nerves and Plexuses. In: Waxman SG. eds. Clinical Neuroanatomy, 27e. New York, NY: McGraw-Hill; 2013.)

nerve root because it causes pain over the distal lateral aspect of the leg and the ankle.

- The deep fibular (peroneal) nerve passes anterior and lateral to the tibialis anterior muscle, between the fibularis (peroneus) longus and the extensor digitorum longus muscles, and to the front of the interosseous membrane and supplies the tibialis anterior, extensor digitorum longus, extensor hallucis longus, and fibularis (peroneus) tertius muscles (see Fig. 3-21). At the level of the ankle joint, the deep fibular (peroneal) nerve passes behind the extensor hallucis longus tendon and lies between it and the extensor digitorum longus tendon. The deep fibular (peroneal) nerve divides into a medial and lateral branch approximately 1.5 cm above the ankle joint. These terminal branches extend to the skin of the adjacent sides of the medial two toes (medial branch), to the extensor digitorum brevis muscle (lateral branch), and the adjacent joints (see Fig. 3-21). When the deep fibular (peroneal) nerve is entrapped, there is a complaint of pain in the great toe, which can be confused with a posttraumatic, complex regional pain syndrome (formerly referred to as reflex sympathetic dystrophy).

Clinical Pearl

Compared with the tibial division, the common fibular (peroneal) division is relatively tethered at the sciatic notch and the neck of the fibula and may, therefore, be less able to tolerate or distribute tension, such as that occurs in acute stretching or with changes in limb position or length.

An insidious entrapment of the common fibular (peroneal) nerve (and it is very vulnerable, especially at the fibular neck) can be confused with symptoms of a herniated intervertebral disk, tendinopathy of the popliteus tendon, mononeuritis, idiopathic fibular (peroneal) palsy, intrinsic and extrinsic nerve tumors, and extraneural compression by a synovial cyst, ganglion cyst, soft tissue tumor, osseous mass, or a large fabella.[129] Traumatic injury of the nerve may occur secondary to a fracture, dislocation, surgical procedure, application of skeletal traction, or a tight cast.[129]

The pain from an entrapment of the common fibular (peroneal) nerve is typically on the lateral surface of the knee, the leg, and the foot. Lateral knee pain is a common problem among patients seeking medical attention, and entrapment of the common fibular (peroneal) nerve is frequently overlooked in the differential diagnostic considerations, especially in the absence of trauma or the presence of a palpable mass at the neck of the fibula.

Pudendal and Coccygeal nerves

The pudendal and coccygeal nerves are the most caudal portions of the lumbosacral plexus and supply the perineal structures (Fig. 3-22).

- The pudendal nerve supplies the coccygeus, levator ani, and sphincter ani externus muscles. The pudendal nerve is a mixed nerve, and a lesion that affects it or its ascending pathways can result in voiding and erectile dysfunctions.[130] A lesion in the afferent pathways of the pudendal nerve is often suspected clinically by suggestive patient histories, including organic neurologic disease or neurologic trauma. Lesions are also suspected when a neurologic physical examination to assess the function of signal segments S2, S3, and S4 is abnormal. The pudendal nerve divides into:
  - the inferior hemorrhoidal nerves to the external anal sphincter and adjacent skin;
  - the perineal nerve; and

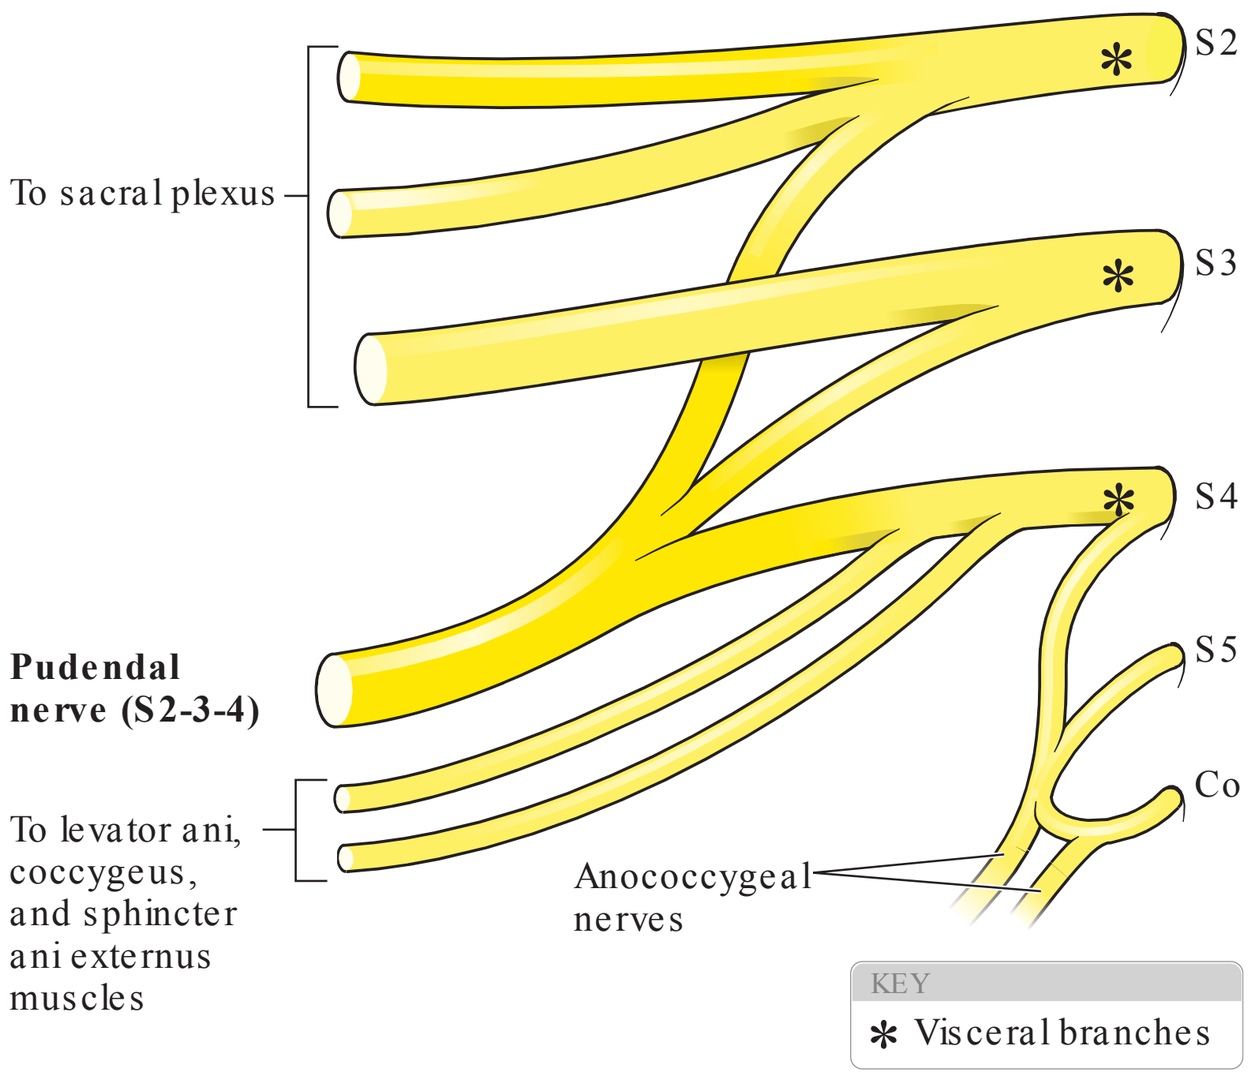

FIGURE 3-22 The pudendal and coccygeal plexuses. (Reproduced, with permission, from Appendix C. Spinal Nerves and Plexuses. In: Waxman SG. eds. Clinical Neuroanatomy, 27e. New York, NY: McGraw-Hill; 2013.)

- the posterior (dorsal) nerve of the penis.
- The coccygeal nerves are the small sensory anococcygeal nerves derived from the last three segments (S4, 5; C). They pierce the sacrotuberous ligament and supply the skin in the region of the coccyx.

Peripheral Nervous System: Autonomic Nervous System

The autonomic nervous system (ANS) is the division of the PNS that is responsible for the innervation of smooth muscle, cardiac muscle, and glands of the body that are not usually under voluntary control. Thus, it functions primarily at a subconscious level.

The ANS has two components, sympathetic (Fig. 3-23) and parasympathetic (Fig. 3-24), each of which is differentiated by its site of origin as well as the transmitters it releases.[131] In general, these two systems have antagonist effects on their end organs.

Neuromuscular Control

Neuromuscular control involves the integration of motor learning and motor control which is controlled by the

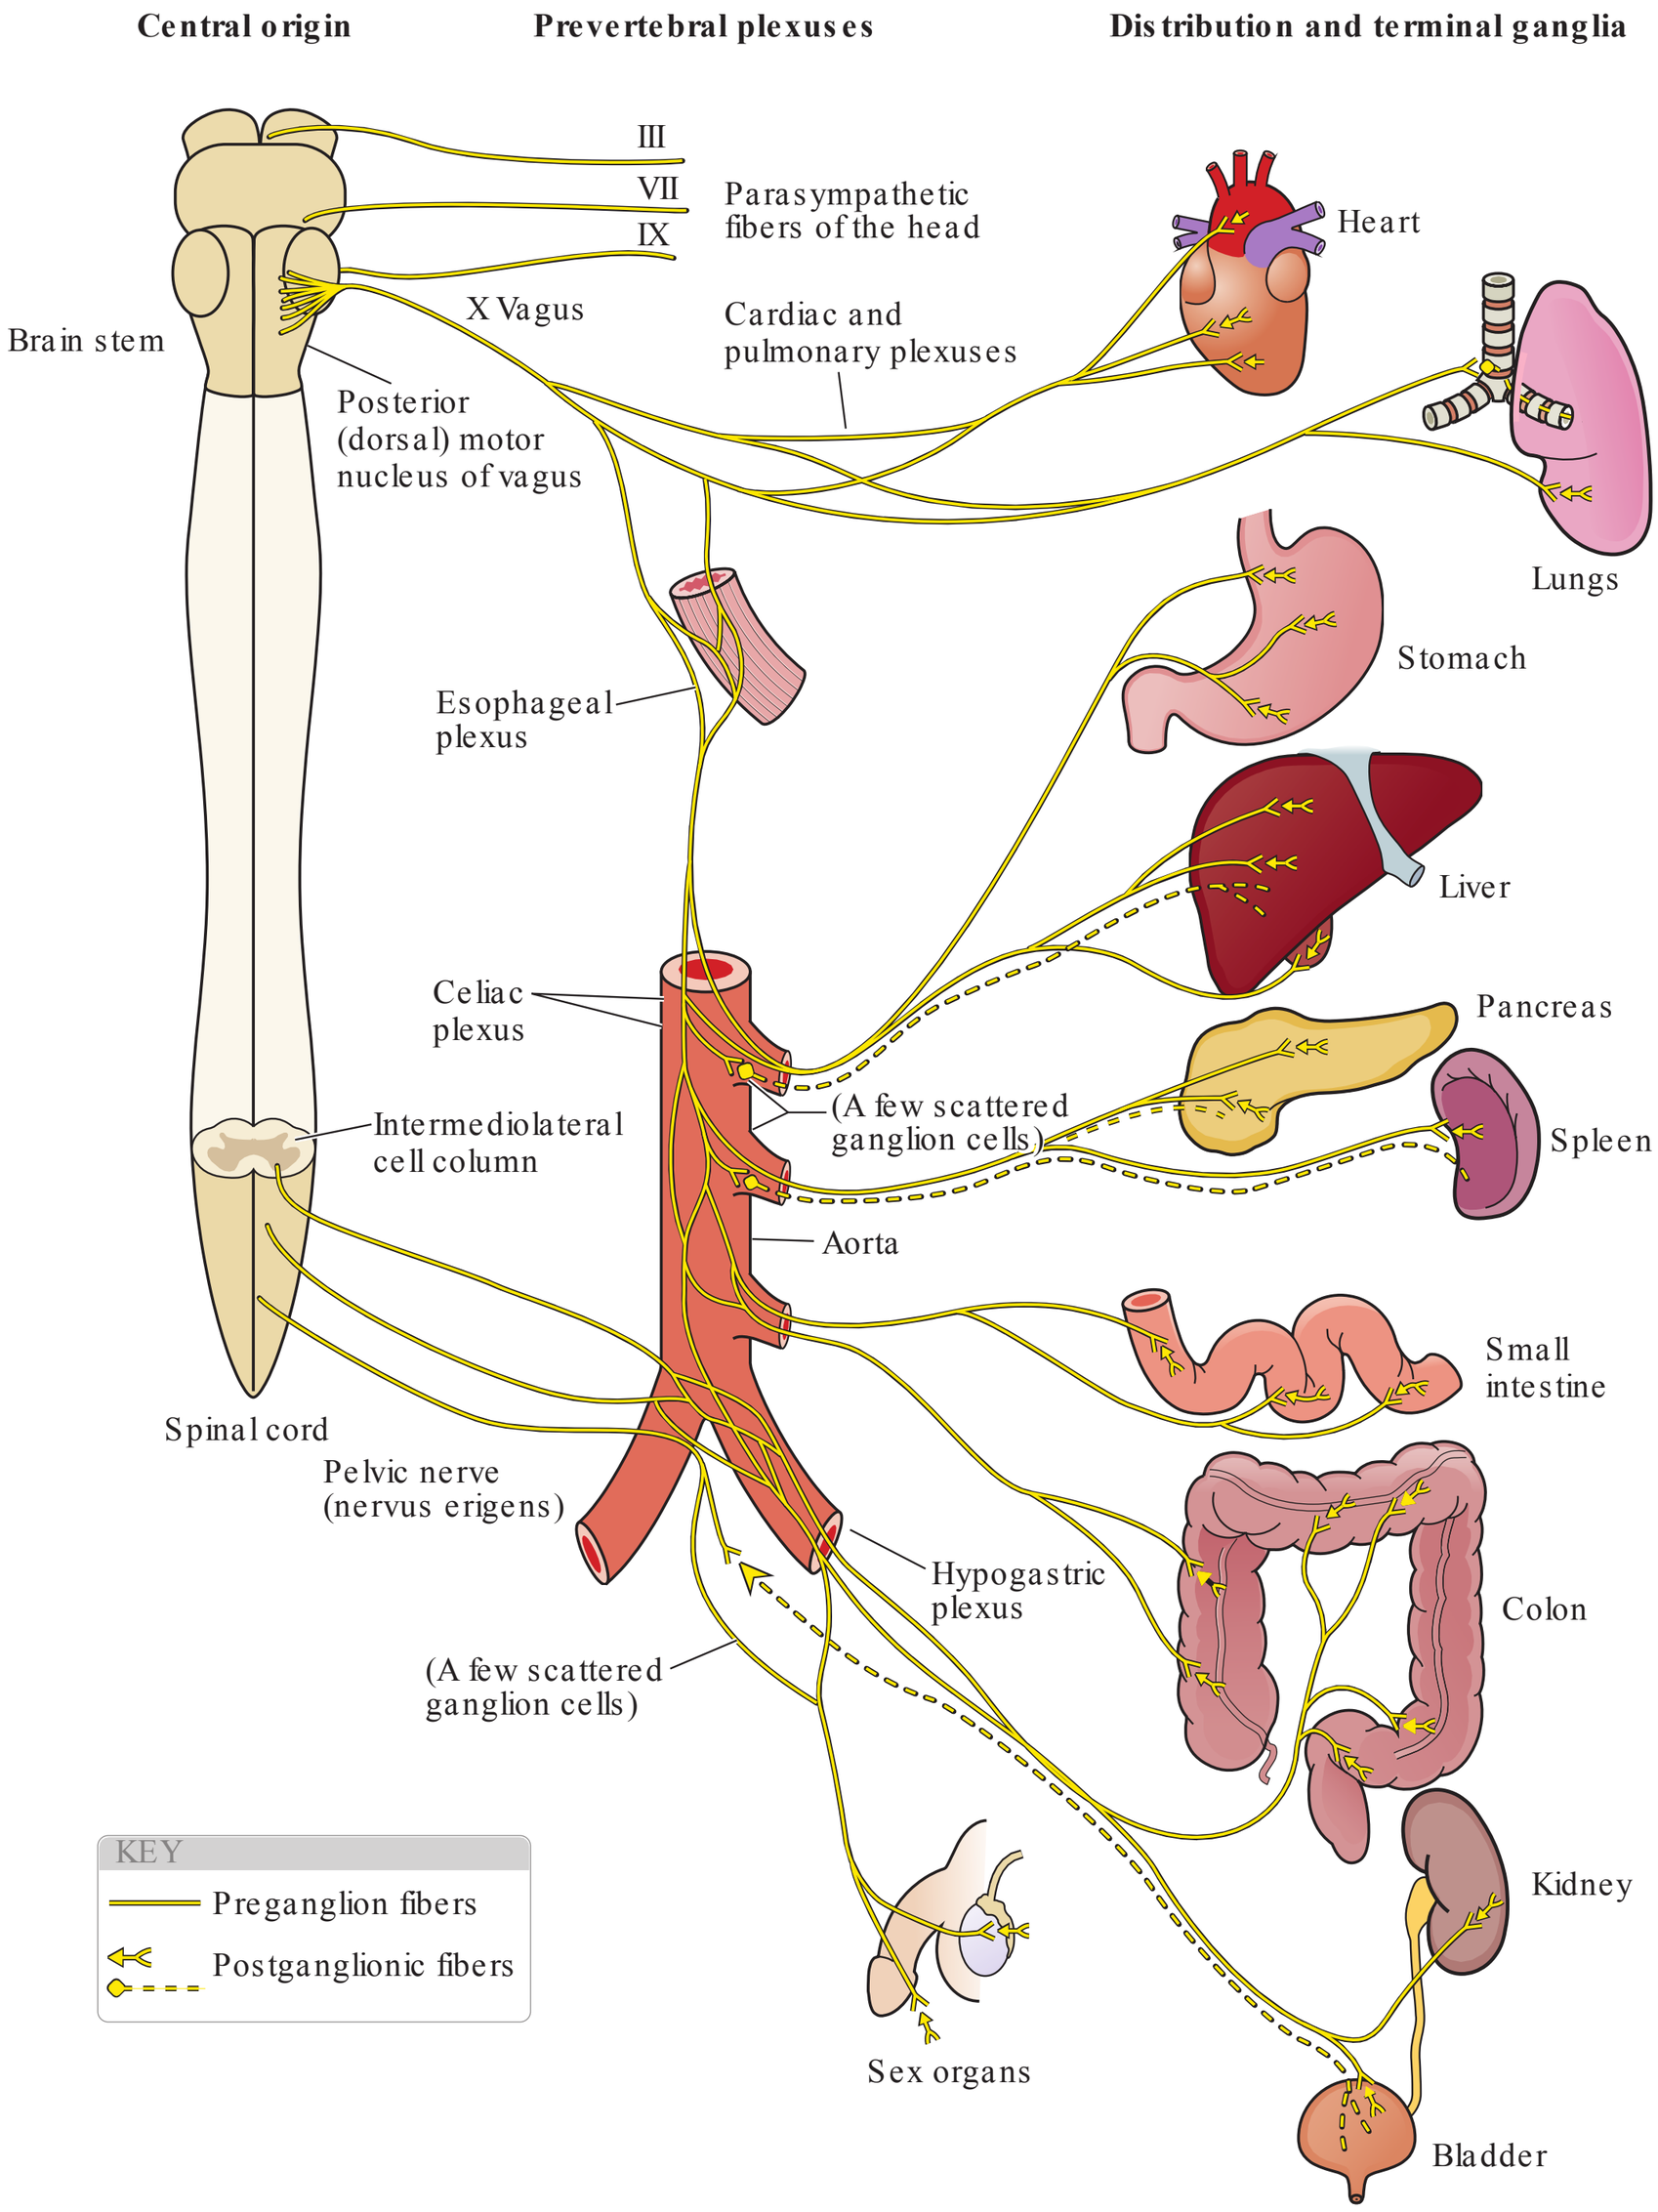

FIGURE 3-23 Sympathetic division of the autonomic nervous system (left half). (Reproduced, with permission, from Chapter 20. The Autonomic Nervous System. In: Waxman SG. eds. Clinical Neuroanatomy, 27e. New York, NY: McGraw-Hill; 2013.)

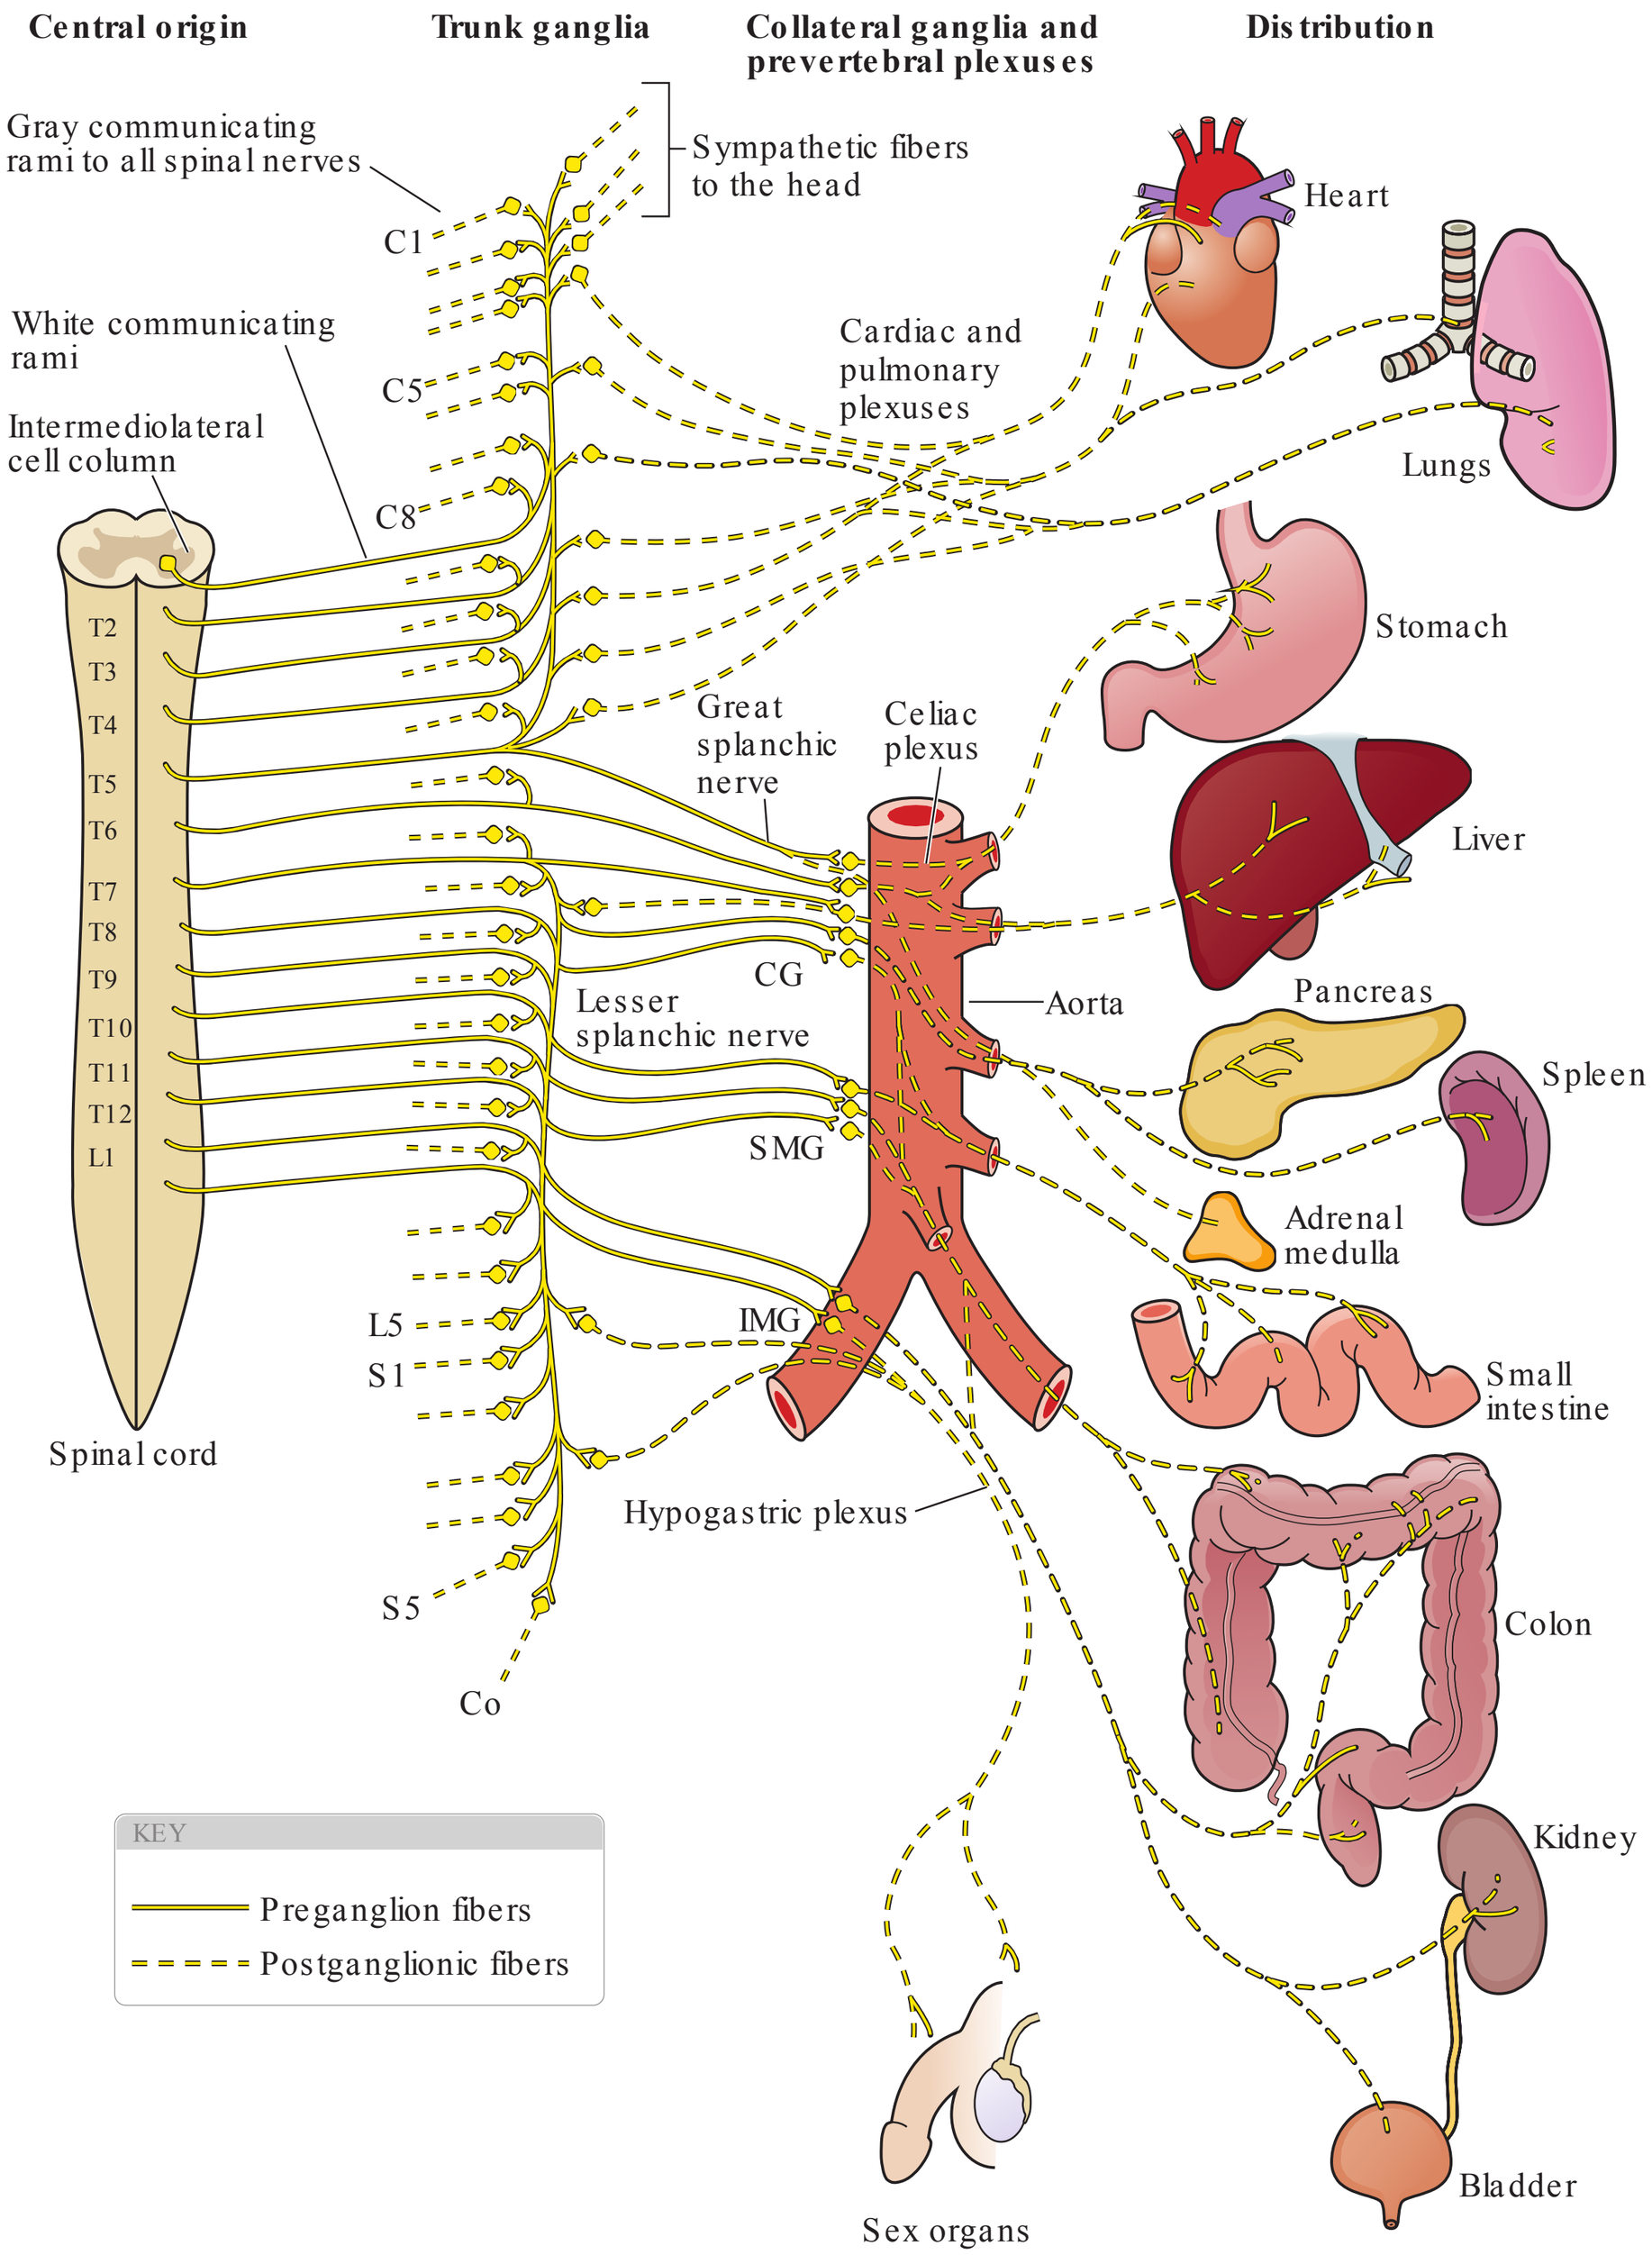

FIGURE 3-24 Parasympathetic division of the autonomic nervous system (left half). (Reproduced, with permission, from Chapter 20. The Autonomic Nervous System. In: Waxman SG. eds. Clinical Neuroanatomy, 27e. New York, NY: McGraw-Hill; 2013.)

descending motor systems. T ese systems include the corticospinal tracts, the rubrospinal tract, the vestibulospinal tracts, and the reticulospinal tracts:

- Corticospinal tract: critical for skilled voluntary movement throughout the body.[132,133] T ere are two main divisions of the corticospinal tract, the lateral corticospinal tract and ventral (anterior) corticospinal tract. Most of the corticospinal fibers (approximately 80%) cross over to the contralateral side in the medulla oblongata (pyramidal decussation) and travel in the lateral corticospinal tract. Ten percent enter the lateral corticospinal tract on the same side. T e remaining 10%

cross over at the level that they exit the spinal cord, and these travel in the anterior corticospinal tract.

- Rubrospinal tract: important for rapid, coordinated movement of the entire limb, especially when the reach involves adapting the hand or foot to the shape of an object.[134]
- Vestibulospinal tracts: involved with integrating information from the vestibular system to control eye movements, head-and-neck movements, and postural reactions for balance.
- Reticulospinal tracts: activated in the early stages of movement, including movement planning, to help initiate the proper state in the postural control system and the proximal limb to support the distal movement that is to occur.[135]

Mobility and stability rely upon the combination of musculoskeletal properties and neural control. It is believed that there are certain programs for movement patterns that are inherent in the CNS and that these naturally develop during the maturation process of the CNS. For example, gait on a level surface is controlled by a set of neural circuits known as a central pattern generator (CPG). The locomotion-initiating systems in the brain stem rely upon the reticulospinal tracts as the principal route for initiation and regulation of locomotion.[136] The parameters of gait (e.g., cadence) depend on the environmental demands. When walking must occur on unusual surfaces, the CPG continues to operate but with input from the lateral corticospinal and rubrospinal systems to translate the visual perception and allow accurate placement of the foot.[137,138]

In much the same way as there is a CPG for locomotion, the nervous system has a number of built-in corrections for postural stability—the ability to maintain a stable upright stance against internal and external perturbations—that can occur rapidly and automatically to counteract these perturbations (see Balance, later). Once a CPG is formed, the individual no longer has to concentrate on performing the activity, but can do so with very little cortical involvement. The motor program for each of these activities is saved in an engram (a hypothetical means by which a patterned response has been stabilized at the level of unconscious competence) within the cerebral cortex.[139–141] Thousands of repetitions (practice) are required to begin the engram formation, and millions are needed to perfect it.[141] Skilled performance is developed in proportion to the number of repetitions of an engram practiced just below the maximal level of ability to perform.[142,143]

The remaining motor responses rely on processing and planning at different levels: spinal cord, the brainstem and cerebellum, and the cerebral cortex. The complexity of the necessary processing affects the speed of motor responses, with spinal reflexes representing the shortest neuronal pathway and consequently the most rapid response to afferent stimuli. Certain actions, such as signing one's name, do not require sensory information for modification. These movements are said to be under open-loop control. Other movements, such as reflexively withdrawing the foot from painful stimuli, rely on feedback from the sensory system. This type of control is referred to as closed-loop control. In a feedback (reactionary) control system, parameters are monitored and compared to a reference set point. If monitored parameters fall outside the boundaries of the set point, the controller triggers a response that will correct the system (e.g., a thermostat system that regulates room temperature).[144] In contrast, feedforward (anticipatory) actions differ in that they anticipate pending disturbances and act to prepare the system (e.g., an individual anticipates the need for milk and buys some before the existing milk runs out).[144] Feedforward actions are based on knowledge or previous experience. Evidence suggests that both feedforward and feedback control mechanisms contribute to dynamic stability.[145] The sensorimotor system provides the direction that muscles require to achieve integrated multiplanar movements through various feedforward and feedback controls.[144]

Clinical Pearl

Motor programs are codes within the nervous system that when initiated, produce coordinated movement sequences.[146] These programs are usually under central control, the sensory input is used extensively in selecting the appropriate motor program, in monitoring whether or not movement is consistent with expectations, and in reflexively modulating the movement so that it is specific to environmental variables.[146,147]

When the CNS is successful at planning the best, or optimal, strategy:[148]

- all joints of the kinetic chain are controlled in both angular and translatoric motions, while allowing the necessary range of motion required for the task;
- spinal posture and orientation will be controlled both within and between regions and be appropriate for the task;
- postural equilibrium will be maintained;
- efficient movement (i.e., ability to adapt appropriately) will be available in the system to dampen and control multiple predictable and unpredictable challenges of varying loads and risk in potentially changing environments; and
- respiration, continence, and internal organ support and function will be maintained.

Failure to maintain any of the above features is an indication that the patient is using a nonoptimal strategy for the task.

A patient cannot succeed in functional and recreational activities if his or her neuromuscular system is not prepared to meet the demands of the specific activities.[149] Two key components involved in meeting the demands of neuromuscular control are proprioception and kinesthesia.

Proprioception

Proprioception is considered a specialized variation of the sensory modality of touch, which plays an important role in coordinating muscle activity and involves the integration of sensory input concerning static joint position (joint position sensibility), joint movement (kinesthetic sensibility), velocity of movement, and the force of muscular contraction (from the skin, muscles, and joints).[150,151] Proprioception can

be both conscious, as occurs in the accurate placement of a limb, and unconscious, as occurs in the modulation of muscle function.[151,152]

All synovial joints of the body are provided with an array of receptor endings (nociceptors, thermoreceptors, and mechanoreceptors) that are imbedded in articular, muscular, and cutaneous structures with varying characteristic behaviors and distributions (Table 3-1). T ese receptors provide information for the somatosensory system which mediates signals related to multiple sensory modalities (pain, temperature, and proprioception). T e nociceptors provide information with regard to pain while the thermoreceptors provide feedback related to temperature. T e mechanoreceptors, which are stimulated by mechanical forces (soft tissue elongation, relaxation, compression, and fluid tension), are usually classified into three groups based on receptor type: joint, muscle, or cutaneous. T ere are four primary types of joint receptors that include Pacinian corpuscles, Ruf ni endings, Golgi tendon organ (GTO)-like endings, and bare nerve endings.[19,153,154]

Cl In ICAl PEARl

The term musculotendinous kinesthesia refers to the capacity for musculotendinous structures to contribute proprioception information. Two types of muscle receptors are commonly described: muscle spindles and GTO (Box 3-1). It is most likely that the muscle and joint receptors work complementary to one another in this complex afferent system, with each modifying the function of the other.[155] The muscle spindle functions as a stretch receptor, whereas the GTO functions as a monitor for the degree of tension within a muscle and tendon. Based on the extensive work of Voss,[156] Peck et al.[157] proposed that in the extremities, smaller muscles with high muscle spindle concentrations, arranged in parallel with larger, less spindle-dense muscles, function primarily as kinesthetic monitors.[158]

- Ruffini endings. T ese slow-adapting, low-threshold stretch receptors are important postural mediators, signaling actual joint position or changes in joint positions.[159] T ey are primarily located on the *fl*exion side (detect the stretch that occurs with the extension of the joint) of the joint capsule, but are also found in ligaments, primarily near the origin and the insertion.[147,160] T ese receptors continue to discharge while the stimulus is present and contribute to the reflex regulation of postural tone, to coordination of muscle activity, and to a perceptional awareness of joint position. An increase in joint capsule tension by active or passive motion, posture, mobilization, or manipulation causes these receptors to discharge at a higher frequency.[154,161]
- Pacinian corpuscles. T ese are rapidly adapting, low-threshold receptors that function primarily in sensing joint compression and increased hydrostatic pressure in the joint.[162] T ey are primarily located in the subcapsular fibroadipose tissue, the cruciate ligaments, the annulus fibrosus, ligaments, and the fibrous capsule. T ese receptors are entirely inactive in immobile joints but become active for brief periods at the onset of movement and during rapid changes in tension. T ey also fire during active or passive motion of a joint, or with the application of traction. T is behavior suggests their role as a control mechanism to regulate the motor unit activity of the prime movers of the joint.
- G*T*O-like receptors. T ese receptors also referred to as Golgi ligament organs are found in the joint capsule, ligaments, and menisci.[163] T ese slow-adapting and high-threshold receptors function to detect large amounts of tension. T ey only become active at the extremes of motion such as when strong manual techniques are applied to the joint or when a joint reaches the end of its physiological range. T eir function is protective; to prevent further motion that would over displace the joint (a joint protective reflex), and their firing is inhibitory to those muscles that would contribute to excessive forces.
- Bare nerve endings. T ese high-threshold, nonadapting, free nerve ending receptors are inactive under normal circumstances but become active with marked mechanical deformation or tension.[164,165] T ey may also become active in response to direct mechanical or chemical irritation, and their sensitivity usually increases when a joint is inflamed or swollen.[166]

T us, the CNS is organized in a hierarchical and parallel fashion with the cortical centers of the brain being the location of the most complex processing, and the spinal cord being the location of the most basic processing.[147] At the upper end of the hierarchy, the motor cortex has a motor program, defined as an abstract plan of movement that, when initiated, results in the production of a coordinated movement sequence.[144,146] At the lower end of the hierarchy, specific motor units must act to accomplish the movement. Rapid motor responses to somatosensory feedback mediated in the spinal cord are referred to as spinal reflexes.[147] T ese reflex actions include preparatory postural adjustments[167] and reaction movements. T e former are preprogrammed neural mechanisms. T e latter occur too fast for the long loop feedback of the CNS, so they are automatic and occur subconsciously (see Supraspinal Reflexes later). Although the hierarchy is well established, research suggests these components also work in parallel so that any of the components may predominate in controlling some aspects of movement; the system is built for ef ciency and redundancy.[144]

Cl In ICAl PEARl

Proprioception can play a protective role in an acute injury through reflex muscle splinting via stimulation of the muscle spindles.[168]

Proprioceptive information is relayed to the cerebral cortex by one of the two major ascending systems, the dorsal column, and the spinothalamic tract. Once processed and evaluated, the proprioceptive information is capable of influencing muscle tone, motor execution programs, and cognitive, somatic perceptions or kinesthetic awareness.[155,169] All of this information helps generate a somatosensory image within the CNS.[155]

Box 3-1 Muscle Spindle and GTO

Muscle Spindle

Muscle spindles are encapsulated spindle-shaped structures lying in parallel with skeletal muscle fibers in the muscle belly. Essentially, the purpose of the muscle spindle is to compare the length of the spindle with the length of the muscle that surrounds the spindle. Spindles have three main components[1]:

- Intrafusal muscle fibers. 2–12 long, slender, and specialized skeletal muscle fibers. The central portion of the intrafusal fiber is devoid of actin or myosin and, thus, is incapable of contracting. As a result, these fibers are capable of putting tension on the spindle only. These intrafusal fibers are of two types: nuclear bag fibers and nuclear chain fibers. Nuclear bag fibers primarily serve as sensitivity meters for the changing lengths of the muscle.[2,3] Nuclear chain fibers each contain a single row or chain of nuclei and are attached at their ends to the bag fibers.
- Sensory neuron endings that wrap around the intrafusal fibers. The sensory neurons are afferents structures (groups Ia and II afferents) that send information regarding static muscle length and changes in muscle length to the dorsal root ganglia of the spinal cord. The group Ia afferents relay information regarding rates of change, whereas the group II afferents relay information regarding steady-state muscle length.
- Motor axons. While muscles are innervated by alpha motor neurons, muscle spindles have their own motor supply, namely gamma motor neurons.

The muscle spindle can be stimulated in two different ways:

- By stretching the whole muscle, which stretches the mid portion of the spindle and depolarize the Ia afferents. Ia afferent depolarization can trigger two separate responses[1]:
  - A monosynaptic or disynaptic spinal reflex
  - A long loop transcortical reflex
- By contracting only the end portion of the intrafusal fibers, exciting the receptor (even if muscle length does not change).

If the length of the muscles surrounding the spindle is less than that of the spindle, a decrease in intrafusal fiber afferent activity occurs. For example, a quick stretch applied to a muscle reflexively produces a quick contraction of the agonistic and synergistic muscle (extrafusal) fibers. This has the effect of producing a smooth contraction and relaxation of muscle and eliminating any jerkiness during movement. The firing of the type Ia phasic nerve fibers is influenced by the rate of stretch: the faster and greater the stimulus, the greater the effect of the associated extrafusal fibers.[3,4]

Golgi Tendon Organs

GTOs are small, encapsulated structures spaced in series along the musculotendinous junction that become activated by stretch.[1] In contrast to the muscle spindle, GTOs function to protect muscle attachments from strain or avulsion, by using a postsynaptic inhibitory synapse of the muscle in which they are located.[5] The signals from the GTO may go both to local areas within the spinal cord and through the spinocerebellar tracts to the cerebellum.[6] The local signals result in excitation of interneurons, which in turn inhibit the anterior α motor neurons of the GTO's own muscle and synergist, while facilitating the antagonists.[6] This is theorized to prevent overcontraction, or stretch, of a muscle.[5]

The ability of a joint to remain stable depends in part on its resistance to motion when subjected to external loads, referred to as its degree of stiffness. A joint's stiffness is the result of three components: passive factors associated with the material properties of the musculotendinous tissues; active intrinsic properties associated with the cross bridge attachment and length tension properties of the muscles that cross the joint (see Chapter 1); and reflexes associated with length feedback and force feedback from muscle spindles, tendon organs, and the influence of other somatosensory feedback on the fusimotor system.[147]

Following an injury, alterations occur with the stiffness of a joint and in the normal recruitment pattern and timing of muscular contractions.[170] These alterations are thought to result from an adjustment in the ratio of muscle spindles to GTO activity and a disruption of the proprioceptive pathway.[145,171,172] Any delay in response time to an unexpected load placed on the dynamic restraints can expose the static restraint structures

to excessive forces, increasing the potential for injury.[173] In addition, proprioceptive deficits have been implicated as contributing to balance impairments (see Balance) following lower extremity and trunk injuries or pathologies. Thus, the focus of neuromuscular rehabilitation must be directed toward creating an environment that promotes the restoration and development of motor responses and proprioception in the presence of altered sensory input (see Chapter 14).[174]

Fatigue may also play a part in injury, particularly if the fatigue produces a dominance of agonists or antagonists over the other.[172] Fatigue also reduces the capability of a muscle to absorb or dissipate loads. It seems plausible that some forms of muscle spindle desensitization, or perhaps ligament relaxation and Golgi tendon desensitization, occur with excessive fatigue.[175] This is may then lead to a decreased efferent muscle response and reduced ability to maintain balance.

Proprioceptive deficits can also be found with aging,[176] arthrosis,[177] and joint instability.[152,168,170,171,178–181]

Kinesthesia

Kinesthesia, a sub-modality of proprioception, refers to the sense of movement of the body or one of the segments. Although the articular receptors quite clearly play a very active role, the stretch reflex controlled by two other sensors, the muscle spindle, and the GTO, are also important. Information about movement sense travels up the spinocerebellar tract (Box 3-2).

Clinical Pearl

During a concentric muscle contraction, the muscle spindle output is reduced because the muscle fibers are either shortening or attempting to shorten, whereas during an eccentric contraction, the muscle stretch reflex generates more tension in the lengthening muscle.[158,182,183]

Box 3-2 Spinocerebellar Tract

The spinocerebellar tract conducts impulses related to the position and movement of muscles to the cerebellum. This information enables the cerebellum to add smoothness and precision to patterns of movement initiated in the cerebral hemispheres. Spinocerebellar impulses do not reach the cerebrum directly and, therefore, have no conscious representation. Four tracts constitute the spinocerebellar pathway; they are the posterior spinocerebellar, cuneocerebellar, anterior spinocerebellar, and rostral spinocerebellar tracts.

The posterior spinocerebellar tract conveys muscle spindle or tendon organ-related impulses from the lower half of the body (below the level of the T6 spinal cord segment); the cuneocerebellar tract is concerned with such impulses from the body above T6. The grain of information carried in these two tracts is fine, often involving single muscle cells or portions of a muscle–tendon complex. A much broader representation is carried by the individual fibers of the anterior and rostral spinocerebellar tracts.

The axons conducting impulses from muscle spindles, tendon organs, and skin in the lower half of the body are large type Ia, type Ib, and type II fibers, the cell bodies of which are in the spinal ganglia of spinal nerves T6 and below.

Motor learning and Skill Acquisition

Motor learning is a complex set of internal processes that involves the relatively permanent acquisition and retention of a skill or task through practice.[184–186] Though motor skills vary widely in type and complexity, the learning process that individuals utilize to acquire these skills is similar.[187]

Clinical Pearl

Learning, unlike performance, is not something that can be directly measured. Rather, we measure behavior and infer learning when the change in behavior seems relatively permanent.[188] However, learning can be measured indirectly using retention tests or transfer tests.

- Retention test: involves allowing sufficient time between practice and testing to assess whether a relatively permanent change has occurred.
- Transfer tests: involves the ability to transfer a skill used in one task to other situations.

- Performance involves the acquisition of a skill. A change in performance is dependent upon practice or experience.
- Learning involves both the acquisition and retention of a skill. Two main types of learning are recognized:[188]
  - Declarative—the learning of facts.
  - Procedural—learning that is dependent on practice, association (associating a particular stimulus with another stimulus, or certain stimulus with a certain response, or certain response with a certain result), and adaptation (making adjustments based on previous results), habituation (filtering out irrelevant stimuli), and sensitization (integration of relevant stimuli).

For learning to occur there must be a goal. Inherent in the idea of the goal is motivation.[188]

- Motor task. There are three basic types of motor tasks or skills:[146,189]
  - Discrete: involves a movement with a recognizable beginning and end. For example, throwing a ball, or opening a door.
  - Serial: involves a series of discrete movements that are combined in a particular sequence. For example, the sequence of tasks that are involved in getting out of a chair when using crutches.
  - Continuous: involves repetitive, uninterrupted movements that have no distinct beginning and ending. Examples include walking and cycling.

Stages of Motor learning

Fitts and Posner[190] proposed three stages of motor learning:[191]

- Cognitive. This is stage, which is characterized by the learner's conscious attempt to determine what exactly needs to be done in a step-by-step manner, begins when the patient is first introduced to the motor task. This is stage requires great concentration and attentional capacity. During this phase there are variable performances

filled with errors because the learner must determine the objective of the skill as well as the relational and environmental cues to control and regulate the movement. During this stage, since the learner is more concerned with what to do and how to do it, the clinician should provide frequent and explicit positive feedback using various forms of feedback (verbal, tactile, visual), and allow trial and error to occur within safe limits.

- Associative. T is stage commences when the learner has acquired the basic movement pattern and is less concerned about every detail and is more concerned with performing and refining the skills. By this stage, the important stimuli have been identified, and their meaning is known. Conscious decisions about what to do become more automatic and the patient concentrates more on the task and appears less rushed. During this phase, the clinician should begin to increase the complexity of the task, emphasize problem solving, avoid manual guidance, and vary the sequence of tasks.
- Autonomous. T is stage, which requires extensive practice to reach, is characterized by an ef cient and nearly automatic kind of performance. Movements are accurate, very consistent, and ef ciently produced.[187] For example, when walking occurs automatically without conscious thought. During this phase, the clinician should set up a series of progressively more dif cult activities the patient can do independently, such as increasing the speed, the distance, and the complexity of the task.

Cl In ICAl PEARl

Most patients in rehabilitation are often in the associated stage because they are familiar with the skills they need to perform, the movement for a particular skill may be altered and need to be learned because of neuromuscular dysfunction.[174]

Practice

Practice, repeatedly performing a movement or series of movements in a task, is probably the single most important variable in learning a motor skill.[189,191] T e various types of practice for motor learning are as follows:[189]

- Part versus whole.
  - Part. A task is broken down into separate components, and the individual components (usually the more dif cult ones) are practiced. After mastery of the individual components, the components are combined in a sequence so that the whole task can be practiced.
  - Whole. T e entire task is performed from beginning to end and is not practiced in separate components.
- Blocked, random, and random blocked.
  - Blocked. T e same task or series of tasks is repeatedly performed under the same conditions and in a predictable order. For example, consistently practicing walking in a straight line on a flat surface.
  - Random. Slight variations of the same task are carried out in an unpredictable order. For example, a patient could practice walking on various walking surfaces and in different directions.
  - Random blocked. Variations of the same task are performed in random order, but each variation of the task is performed more than once. For example, the patient walks on a particular surface and then repeats the same task a second time before moving on to a different surface.
- Massed versus distributed.
  - Massed. Involves participation in a long bout of practice, where substantially less time is spent in rest compared to the time spent practicing during the practice period. T e disadvantages of this type of practice are that the patient is not able to reflect on his or her performance between practices, and there is more potential for fatigue and an increased likelihood of a slight detriment for learning.[146]
  - Distributed. T is type of practice involves participation in a series of practices throughout the day. T e advantage of this type of practice is that the patient is able to reflect on his or her performance between practices and, therefore, correct previous mistakes.
- Physical versus mental.
  - Physical. T e movements of a task are actually performed.
  - Mental. A cognitive rehearsal of how a motor task is to be performed occurs prior to actually doing the task.
- Constant versus varied.
  - Constant. Occurs when the skill is repeatedly practiced without changing anything. For example, shooting hoops from only the foul line.
  - Varied. Occurs when a parameter is changed throughout the practice session. For example, shooting hoops from various areas of the court. Contrary to popular belief, repetition of the same movement pattern may be a suboptimal method of learning a skill compared to utilizing variations, the latter of which can stimulate the brain to find optimal solutions to unanticipated events more effectively.[192]

Feedback

Second only to practice, feedback is considered the next most important variable that influences learning. T e various types of feedback associated with motor learning are as follows:[189]

- Intrinsic versus extrinsic (augmented).
  - Intrinsic. Intrinsic feedback, or internal focus, is a natural part of the task.[146] It can take the form of a sensory cue (proprioceptive, kinesthetic, tactile, visual, or auditory), or set of cues, inherent in the execution of the motor task. For example, the feedback can consist of directions about body movements (e.g., "Land with your feet shoulder width apart").[193] T e feedback can also arise from within the learner and be derived from the performance of the task.
  - Extrinsic. Extrinsic feedback, or external focus, is supplemental feedback that is not normally an inherent part of the task but is directed toward the outcome or

effects of the movement (e.g., "Imagine sitting down on a chair when landing").[194] T is type of feedback can include sensory cues (verbal, visual, or auditory). It is thought that an external focus of attention enhances the production of effective and ef cient movement patterns.[195] T is is because when a skill is learned, important brain resources are not being used to memorize movements during an activity and can therefore be focused more on movement control and other factors (i.e., environmental conditions, position of other people, etc.).[187]

- Knowledge of results (KR) versus knowledge of performance (KP).
  - KR: immediate, post task, extrinsic feedback about the outcome of a motor task. T is type of feedback is primarily reserved for instances when individuals are unable to generate this type of information for themselves, or when the information may serve as a motivational tool.[146]
  - KP: feedback given about the nature or quality of the performance of the motor task. T is type of feedback better facilitates motor skill learning than KR.

Feedback about performance can be provided at various times:

- Continuous versus Intermittent.
  - Continuous is ongoing. T is type of feedback improves skill acquisition more quickly during the initial stage of learning than intermittent feedback.
  - Intermittent occurs irregularly, randomly. Intermittent feedback has been shown to promote learning more effectively than continuous feedback.
- Immediate, delayed, and summary.
  - Immediate is given directly after a task is completed. T is type of feedback is used most frequently during the cognitive (initial) stage of learning.
  - Delayed is given after an interval of time elapses, allowing the learner to reflect on how well or poorly a task was done. T is type of feedback promotes retention and generalizability of the learned skills.
  - Summary is given about the average performance of several repetitions of the movement or task. T is type of feedback is used most frequently during the associative stage of learning.

Skill Acquisition

Patla[196] describes several locomotor control systems that act on and interact with the musculoskeletal system to influence the expression of skilled locomotor behavior. T ese systems include core locomotor pattern, dynamic equilibrium, active propulsion, weight support, maintaining structural integrity, minimization of energy expenditure, steering and accommodation, and cognitive spatial mapping.[196] Steering and accommodation and cognitive spatial mapping require the individual to adjust to changes in the physical environment (e.g., unlevel terrain, obstacles, and slippery conditions) or other contextual demands (e.g., crowds, being in a hurry) that require the ability to navigate and adjust to changes in direction, path, or speed. A number of theories of skill acquisition have been proposed with respect to the ability to adjust to the environment:

- Open versus closed skills. Open (temporal and spatial factors in an unpredictable environment) and closed skills (spatial factors only in a predictable environment), exist along a continuum. Using a sport as an example, a closed skill could include shooting a foul shot in basketball. An everyday example of a closed skill is drinking from a cup. An example of an open skill in everyday life would be stepping onto a moving walkway, whereas in sport an open skill would involve throwing a touchdown pass. While closed skills allow an individual to evaluate the environment and perform the movement without much modification, open skills require more cognitive processing and decision making in choosing and adjusting the movement.[174] Open and closed skills can be viewed as a continuum, where the perceptual and habitual nature of a task determines whether the task is open or closed.
- Gentile taxonomy of motor tasks.[197] T is is a two-dimensional classification system for teaching motor skills. Using the concept that motor skills range from simple to complex, Gentile expanded the popular one-dimensional classification system of open and closed skills to combine the environmental context together with the function of the action:[189,191]
  - T e environmental (closed or open) context in which the task is performed. Regulatory conditions (other people, objects) in the environment may be either stationary (closed skills) or in motion (open skills).
  - T e intertrial variability (absent or present) of the environment that is imposed on the task. When the environment in which a task is set is unchanging from one performance of a task to the next, intertrial variability is absent—the environmental conditions are predictable. For example, walking on a flat surface. Intertrial variability is present when the demands change from one attempt or repetition of the task to the next. For example, walking over varying terrain.
  - T e need for a person's body to remain stationary (stable) or to move (transport) during the task. Skills that require body transport are more complex than skills that require no body transport as there are more variables to consider. For example, a body transport task could include walking in a crowded shopping mall.
  - T e presence or absence of manipulation of objects during the task. When a person must manipulate an object, the skill increases in complexity because the person must do two things at once—manipulate the object correctly and adjust the body posture to fit the ef cient movement of the object.

Balance

Balance, or postural control, is a complex motor control task involving the detection and integration of sensory information to assess the position and motion of the body in space and the execution of appropriate musculoskeletal responses

to control body position within its stability limits, and within the context of the environment and task, whether stationary or moving.[198] Posture is the relative position of the various parts of the body with respect to one another, to the environment, and to gravity (see Chapter 6).[199]

Balance results from an integration of three components:[199]

- The nervous system, which provides sensory processing for the perception of body orientation in space, which is provided largely by the visual, vestibular, and somatosensory systems. The sensory motor integration provides motor strategies for the planning, the programming, and the execution of balance responses.[200]
  - Visual system. The visual system, which involves CNII, III, IV, and VI, assists in balance control by providing input about the position of the head or the body in space (see Supraspinal Reflexes later) the direction and speed of head movements, the position of the head relative to the environment, and the orientation of the head to maintain a level gaze. Through the vestibulo-ocular input, signals from the muscle spindles in the extraocular muscles, the position of the eyeball is controlled so that a visual image is maintained on the fovea. The coordination of eye movements during gaze is a complex affair and is controlled by efferent signals from the trochlear, the abducens, and the oculomotor nuclei via the fourth, the sixth, and the third CNs, respectively (refer to the discussion of cervico-ocular and vestibular reflexes later in this chapter).[12] Coordination of these nuclei is achieved by gaze centers in the reticular formation, the midbrain, and the cortex, and by the cerebellum, which have fibers that project into the three eye muscle nuclei and control the orbital movements concerned with slow and rapid eye movements.[12] Visual loss or specific deficits in acuity, depth perception, contrast sensitivity, and peripheral vision can impair balance and lead to falls.[201–204]
  - Vestibular system. The vestibular system, with contributions from the inner ear (see Cranial Nerves), provides information about movement and spatial orientation. Vestibular dysfunction, which can have a myriad of causes running the gamut from a viral infection to a traumatic brain injury, is a common cause of falls.[205] Vestibular rehabilitation is discussed in Chapter 23.
  - Somatosensory system. This system provides information about proprioception and kinesthesia, which has already been discussed. Reduced somatosensation in the lower extremities caused by peripheral neuropathy, the aged, and individuals with diabetes have been associated with balance deficits and an increased risk of falls.[206,207]
- Musculoskeletal contributions including postural alignment, flexibility, joint integrity, muscle performance, and mechanoreceptor sensation.
- Contextual effects that interact with the nervous and the musculoskeletal systems. These effects include whether the environment is closed (predictable with no distractions) or open (unpredictable and with distractions), the support surface, the amount of lighting, the effects of gravity and inertial forces on the body, and the characteristics of the task (new vs. well learned, predictable vs. unpredictable, single vs. multiple).

The visual, vestibular, and somatosensory information is subconsciously combined to produce the brain's sense of orientation and movement. Somatosensory information has the fastest processing time for rapid responses, followed by visual and vestibular inputs.[188] It is the role of the CNS to suppress any inaccurate input from one system and to combine the appropriate sensory inputs from the other two systems, a process called the sensory organization.

Impaired balance can be caused by injury or disease to any of the structures involved in the stages of information processing. Even if the three components mentioned are working effectively, a loss of balance control will occur if these internal mechanisms are overwhelmed.

Clinical Pearl

Proprioception and balance are not synonymous. Proprioception can be conscious or unconscious whereas balance is typically conscious.

An individual's balance is greatest when the body's center of mass (COM) is maintained over its base of support (BOS). Functional tasks require different types of balance control, including:[198]

- Static balance control: involves maintaining a stable antigravity position while at rest, such as when standing and sitting.
- Dynamic balance control: the ability to stabilize the body when the support surface is moving, or when the body is moving on a stable surface, such as during sit to stand transfers or walking.
- Automatic postural reactions: the ability to maintain balance in response to unexpected external perturbations, such as standing on a bus that suddenly decelerates.

Anticipatory and Compensatory Postural Adjustments

Anticipatory postural adjustments occur in response to internal perturbations such as voluntary movements of the body by activating muscle synergies of the postural muscles in advance of the actual perturbation. Research has shown that anticipatory postural adjustments are highly adaptable and vary according to the task demands.[208] For example, postural muscles in standing humans are activated prior to (and during) voluntary movement of an upper limb and are specific to this movement—a person pulling on the handle when standing. Anticipatory postural adjustments have also been studied during leg movements,[209,210] trunk movements,[211,212] arm movements in standing subjects,[213,214] and during load release from extended arms.[215–217]

While anticipatory reactions are initiated by the subject, compensatory reactions, which occur later, are initiated by sensory feedback triggering signals. With anticipatory reactions, the CNS tries to predict postural perturbations associated with a planned movement and minimize them with

anticipatory corrections in a feedforward manner, while compensatory reactions deal with actual perturbations of balance that occur because of the suboptimal ef cacy of the anticipatory components. Feedforward (open loop motor control) is utilized for movements that occur too fast to rely on sensory feedback, or for the anticipatory aspects of postural control to be initiated. In contrast, closed-loop control is utilized during precision movements that require sensory feedback such as when standing on an unsteady surface.

Automatic Postural Responses

To maintain balance, the body must continually adjust its position in space to keep its COM over its BOS. A certain amount of anteroposterior and lateral sway normally occur while maintaining balance. For example, normal anteroposterior sway in adults is 12 degrees from the most posterior to the most anterior position.[218] If the sway exceeds the limits of stability, some strategy must be employed to regain balance. Horak and Nashner[219] describe several different feedforward control strategies used to maintain balance. T e feedforward control is produced by motor programs that are preprogrammed collections of motor signals with the goal of achieving a specific task. T e goal of the automatic postural responses, including the ankle, the hip, and the stepping strategies, are designed to adjust the body's COM so that the body is maintained within the BOS to prevent the loss of balance or falling.

- T e ankle strategy, in which muscles around the ankles are used to provide postural stability in the anteroposterior plane, is employed with small perturbations. T e ankle strategy is utilized to maintain the body's COM safely within the BOS during quiet stance by automatically activating the various ankle muscles to counteract body sway in different directions.
- T e hip strategy, in which muscles around the hip and the trunk (gluteus medius, iliopsoas, thoracic paraspinals, and tensor fasciae latae) are recruited, is employed with larger perturbations during quiet stance.
- T e weight-shift strategy is a movement strategy utilized to control medial–lateral perturbations involving shifting the bodyweight laterally from one leg to the other.
- T e suspension strategy, which involves lowering the body's COM by flexing the knees, causing associated flexion of the ankles and the hips or a slight squatting motion.
- T e stepping strategy, in which a step is taken to maintain postural control, is employed if the two previous strategies are insuf cient.

Most healthy individuals use combinations of the above strategies to maintain balance depending on the control demands.[199]

Balance Control during Activities *of* Daily Living (ADLs). During all ADLs, sensory information with regard to balance is transmitted centrally, processed, and a response is then selected for execution. Complex tasks take longer to process and program than simple tasks. One of the most common ways in which balance is challenged during ADLs is when lifting a heavy object. To prevent a loss of balance during the lift, the body adjusts the position of the COM. For example, when a load is lifted in front of the body, the COM is shifted forward in anticipation of the magnitude of the expected load. T is displacement of the body is based on an estimate made by the CNS, which uses previous experience with the load, or with other objects of similar physical properties.[220] As the lift begins, a backward horizontal linear momentum is generated to allow the person lifting the load to move toward an upright posture. By making subtle adjustments to these compensations, a different load can be lifted using different postures. For example, individuals tend to flex the hips and knees more and shift their weight back when lifting a heavy load than when lifting a light load.[220]

The neurophysiology of Pain

A 2011 report by the Institute of Medicine indicated that attention to individual patient differences to pain is of paramount importance.[221] Pain is considered an emotional experience that is highly individualized and extremely dif cult to evaluate. It is well established that health status and concomitant conditions, such as psychological factors, can influence the pain experience.[222,223] Intrinsic biological factors, including genetics, age, and sex, are also known to influence how an individual experiences pain.[223,224]

Cl In ICAl PEARl

Patients' attitudes, beliefs, and personalities may strongly affect their immediate experience of acute pain.

Types of Pain

Pain, which is the most common determinant for a patient to seek intervention, is a broad and significant symptom that can be described using many descriptors. In addition, the pain perception and the response to the painful experience can be influenced by various cognitive processes, including anxiety, tension, depression, past pain experiences, and cultural influences.[225] Perhaps, the simplest descriptors for pain are acute and chronic.

Acute pain can be defined as "the normal, predicted physiological response to an adverse chemical, thermal, or mechanical stimulus…associated with surgery, trauma, and acute illness."[226] T is type of pain usually precipitates a visit to a physician, because it has one or more of the following characteristics:[227]

- It is new and has not been experienced before.
- It is severe and disabling.
- It is continuous, lasting for more than several minutes, or recurs very frequently.
- T e site of the pain may cause alarm (e.g., chest and eye).
- In addition to the sensory and affective components, acute pain is typically characterized by anxiety. T is may produce a fight-or-flight autonomic response, which is normally used for survival needs. T is autonomic reaction is also associated with an increase in systolic and diastolic blood pressure, a decrease in gut motility and salivary flow, increased muscle tension, and pupillary dilation.[19,228]

Clinical Pearl

- Hyperalgesia is an increased response to a noxious stimulus. Primary hyperalgesia occurs at the site of injury, whereas secondary hyperalgesia occurs outside the site of injury.
- Allodynia is defined as pain in response to a previously innocuous stimulus.
- Referred pain is a site adjacent to, or at a distance from, the site of an injury's origin. Referred pain can occur from muscle, joint, and viscera. For example, the pain felt during a myocardial infarction is often felt in the neck, shoulders, and back rather than in the chest, the site of the injury.

Acute pain following trauma, or the insidious onset of a musculoskeletal condition, is typically chemical in nature. Although motions aggravate the pain, they cannot be used to alleviate the symptoms. In contrast, cessation of movement (absolute rest) tends to alleviate the pain, although not necessarily immediately. The structures most sensitive to chemical irritation in order of sensitivity are:

- The periosteum and joint capsule
- Subchondral bone, tendon, and ligament
- Muscle and cortical bone
- The synovium and articular cartilage

Clinical Pearl

The aching type of pain, associated with degenerative arthritis and muscle disorders, is often accentuated by activity and lessened by rest. Pain that is not alleviated by rest, and that is not associated with acute trauma, may indicate the presence of a serious disorder such as a tumor or an aneurysm. This pain is often described as deep, constant, and boring and is apt to be more noticeable and more intense at night.[229]

Chronic pain is typically more aggravating than worrying, lasts for more than 6 months, and has the following characteristics:[227]

- It has been experienced before and has remitted spontaneously, or after simple measures.
- It is usually mild to moderate in intensity.
- It is usually of limited duration, although it can persist for long periods (persistent pain).
- The pain site does not cause alarm (e.g., knee and ankle).
- There are no alarming associated symptoms.

However, patients with chronic pain may be more prone to depression and disrupted interpersonal relationships.[230–233]

The symptoms of chronic pain typically behave in a mechanical fashion, in that they are provoked by activity or repeated movements and reduced with rest or a movement in the opposite direction.

Clinical Pearl

Referred pain, which can be either acute or chronic, is pain perceived to be in an area that seems to have little or no relation to the existing pathology.

The Guide to Physical Therapist Practice[234] has suggested that categorization of pain based on signs and symptoms should be a primary goal of the diagnostic process. In contrast, some researchers have suggested that a pain-mechanism–based pain diagnosis be made to assist in directing treatment.[235,236]

Transmission of Pain

A nociceptive neuron is one that transmits pain signals. The nociceptive system is normally a quiescent system requiring strong, intense, potentially damaging stimulation before it becomes activated.[182] Any tissue that contains free nerve endings involved with nociception is capable of being a source of pain. Pain receptors (nociceptors), unlike other receptors, are nonadapting in nature; that is, they will continue to fire for as long as the stimulus is present. It is apparent that many peripheral nociceptors are polymodal. Nociceptor stimulation can only occur in one of the following three ways:[183]

- Mechanical deformation resulting in the application of sufficient mechanical forces to stress, deform, or damage a structure.
- Excessive heat or cold.
- The presence of chemical irritants in sufficient quantities or concentrations. Key mediators that have been identified include bradykinin, serotonin, histamine, potassium ions, adenosine triphosphate, protons, prostaglandins, nitric oxide, leukotrienes, cytokines, and growth factors.[226] The effects of these mediators involve binding to specific receptors, activation of ion channels for depolarization, activation of intracellular second messenger systems, and release of a range of neuropeptides to promote neurogenic inflammation, and alteration of neuronal properties by modifying gene transcription.[182,226]

One of the most fundamental influences on nociceptor sensitivity is the pH of the surrounding tissue.[182] High local proton concentrations are known to occur in many inflammatory states, and the consequent reduction in pH can contribute to sensitization and activation of polymodal nociceptors.[182,237]

The transmission of pain to the CNS occurs via two distinct pathways, which correspond to the two different types of pain: fast-conducting A delta and slow-conducting C fibers (Table 3-1), although not all of the fibers are necessarily nociceptors. Each of these types of fibers has different pain characteristics: A delta fibers evoke a rapid, sharp, lancinating pain reaction; C fibers cause a slow, dull, crawling pain.

Rapid Pain

T e fast, or dermatomal, pain signals are transmitted in the peripheral nerves by small, myelinated A fibers at velocities between 6 and 30 m (20 and 98 ft) per second. T e fast pain impulse is a signal telling the subject that a threat is present and provoking an almost instantaneous and often reflexive response. T is signal often is followed a second or more later by a duller pain that tells of either tissue damage or continuing stimulation.

Slow Pain

Slow, or sclerotomal, pain is transmitted in even smaller and unmyelinated C nerve fibers at much slower velocities, between 0.5 and 2 m (1.6 and 6.6 ft) per second. On entering the posterior (dorsal) horn of the spinal cord, the pain signals from both visceral and somatic tissues do one of the following three things:

- Synapse with interneurons that synapse directly with motor nerves and produce reflex movements.
- Synapse with autonomic fibers from the sympathetic and parasympathetic systems and produce autonomic reflexes.
- Synapse with interneurons that travel to the higher centers in the brain.
  - T e fast signals of the C fibers terminate in laminae I and V of the posterior (dorsal) horn (Fig. 3-25). Here they excite neurons (internuncial neurons, segmental motor neurons, and flexor reflex afferents) that send long fibers to the opposite side of the cord and then upward to the brain in the lateral division of the anterior–lateral sensory pathway (lateral spinothalamic tract (Box 3-3).
  - T e slow signals of the C fibers terminate in laminae II and III of the posterior (dorsal) horn (Fig. 3-25). Most of the signal then passes through another short fiber neuron to terminate in lamina V. Here, the neuron gives off a long axon, most of which joins with the fast signal axons to cross the spinal cord and continue upward in the brain in the same spinal tract. Approximately, 75–90% of all pain fibers terminate in the reticular formation of the medulla, pons, and mesencephalon. From here, other neurons transmit the signal to the thalamus, hypothalamus (pituitary), limbic system, and the cerebral cortex.

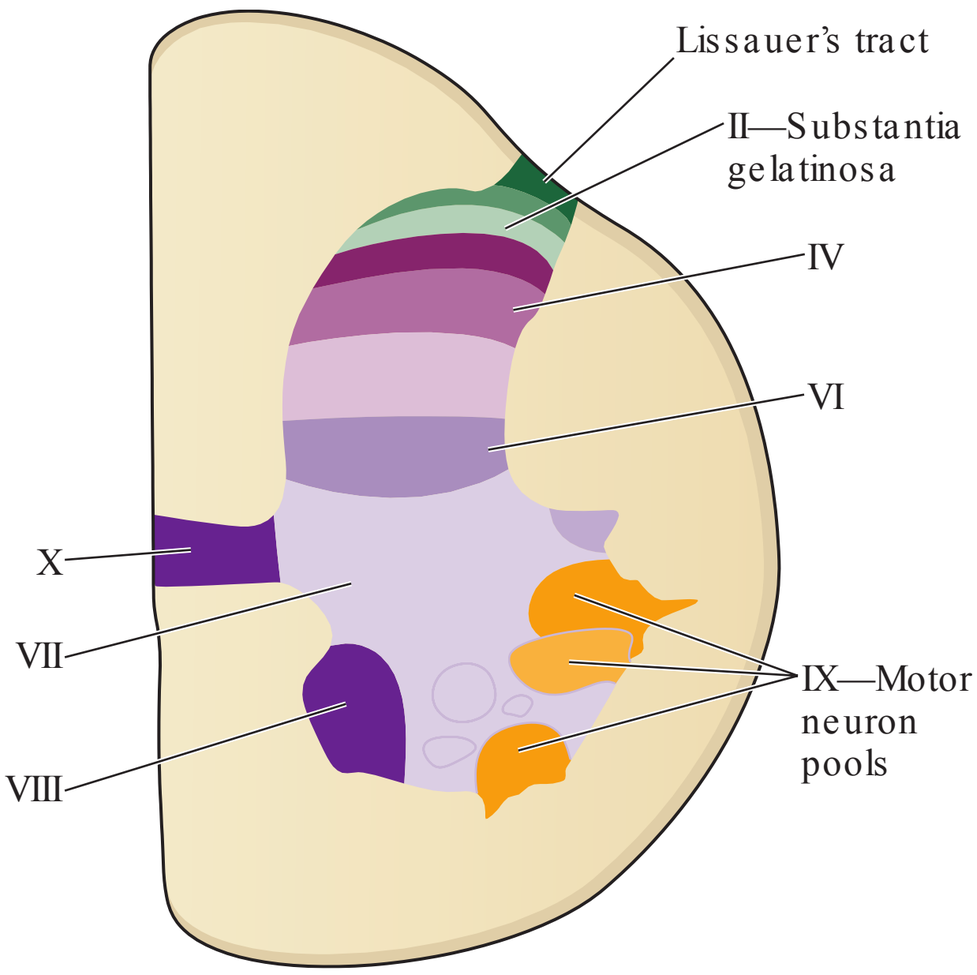

FIGURE 3-25 Laminas of the gray matter of the spinal cord. (Reproduced, with permission, from Waxman SG: Clinical Neuroanatomy, 26th ed, McGraw-Hill, 2010.)

Cl In ICAl PEARl

Pain and nociceptive input can exert a strong influence on motor function and emotional state.[182]

T e central pathways for processing nociceptive information begin at the level of the spinal cord (and medullary) posterior (dorsal) horn. As with the periphery, the posterior (dorsal) horn of the spinal cord contains many transmitters and receptors, both identified and accepted, including several neuroactive peptides (substance P, calcitonin gene-related peptide, somatostatin, neuropeptide Y, and galanin), excitatory amino acids (aspartate and glutamate), inhibitory amino acids (γ-aminobutyric acid and glycine), nitric oxide, the arachidonic acid metabolites, the endogenous opioids, adenosine, and the monoamines (serotonin and noradrenaline).[238] T is list indicates that there are diverse therapeutic possibilities for the control of the transmission of nociceptive information to the brain.

Cl In ICAl PEARl

Several compounds, classified as biogenic amine transmitters or neuroactive peptides, exist that can facilitate or inhibit synaptic activity.

Interneuronal networks in the posterior (dorsal) horn are responsible not only for the transmission of nociceptive information to neurons that project to the brain, but also for the modulation of that information. T e information is passed to other spinal cord neurons, including the flexor motor neurons and the nociceptive projection neurons (e.g., certain patterns of stimulation can lead to enhanced reflex actions and the sensitization of projection neurons and increased nociceptive transmission). Other inputs result in the inhibition of projection neurons.

A small number of fast fibers are passed directly to the thalamus, and then to the cerebral cortex, bypassing the brain stem. It is believed that these signals are important for recognizing and localizing pain, but not for analyzing it. Of the slow signals, none, or at least very few, avoid the reticular system. Because most of the fast, and all of the slow, pain signals go through the reticular formation, they can have wide-ranging effects on almost the entire nervous system.

Box 3-3 Spinothalamic Tract

The spinothalamic tract helps mediate the sensations of pain, cold, warmth, and touch from receptors throughout the body (except the face) to the brain.[1–4] Laterally projecting spinothalamic neurons are more likely to be situated in laminae I and V. Medially projecting cells are more likely to be situated in the deep posterior (dorsal) horn and in the anterior (ventral) horn. Most of the cells project to the contralateral thalamus, although a small fraction projects ipsilaterally.[5] Spinothalamic axons in the anterior–lateral quadrant of the spinal cord are arranged somatotopically. At cervical levels, spinothalamic axons representing the lower extremity and caudal body are placed more laterally, and those representing the upper extremity and rostral body, more anterior medially.[6,7]

Most of the neurons show their best responses when the skin is stimulated mechanically at a noxious intensity. However, many spinothalamic tract cells also respond, although less effectively, to innocuous mechanical stimuli, and some respond best to innocuous mechanical stimuli.[8] A large fraction of spinothalamic tract cells also respond to a noxious heating of the skin, while others respond to stimulation of the receptors in muscle,[9] joints, or viscera.[10]

Spinothalamic tract cells can be inhibited effectively by repetitive electrical stimulation of peripheral nerves,[11] with the inhibition outlasting the stimulation by 20–30 minutes. Some inhibition can be evoked by stimulation of the large myelinated axons of a peripheral nerve, but the inhibition is much more powerful if small myelinated or unmyelinated afferents are included in the volleys.[12] The best inhibition is produced by stimulation of a peripheral nerve in the same limb as the excitatory receptive field, but some inhibition occurs when nerves in other limbs are stimulated. A similar inhibition results when high-intensity stimuli are applied to the skin, with a clinical transcutaneous electrical nerve stimulator (TENS) unit in place of direct stimulation of a peripheral nerve.[13]

As the spinothalamic tract ascends, it migrates from a lateral position to a posterior–lateral position. In the midbrain, the tract lies adjacent to the medial lemniscus. The axons of the secondary neurons terminate in one of a number of centers in the thalamus.

Lamina V (Fig. 3-25) is the area for convergence, summation, and projection. The response of the cells in lamina V depends largely on the intensity of the stimulus. High-intensity stimulation leads to facilitation of the cell, and relatively easy transmission across the cord to the other side and, from here, upward. More gentle stimulation inhibits this transmission. This inhibition is, according to theory, the result of pre- and postsynaptic effects produced by the cells of laminae II and III. Thus, the net effect at lamina V will determine whether the pain signal is relayed upward. If mild mechanoreceptor input dominates, the pain signal is stopped at this point. If, however, pain input dominates, or if the mechanoreceptor input is too strong, transmission of the pain signal occurs.

The neurophysiological mechanisms responsible for the generation and maintenance of pain can be divided into separate categories[239]:

- Nociceptive: pain that is predominantly driven by activation of peripheral nociceptive sensory fibers. The pattern of pain associated with this type is localized to the area of injury/dysfunction, mechanical/anatomic in nature, intermittent and sharp with movement/mechanical provocation, and dull or throbbing at rest. This type of pain responds well to posture education, muscle stretching, joint mobilization, motor control exercises, and muscle strengthening.

- Peripheral neuropathic: pain attributed to a lesion or dysfunction in the dorsal horn or cervicotrigeminal nucleus or peripheral nerve. This type of pain is typically referred in a dermatomal or cutaneous distribution and is associated with a history of nerve injury, pathology, or mechanical compromise. Pain/symptom provocation

occurs with mechanical/movement tests that move/load/compress neural tissue.

- Central sensitization: application of neural signaling in the CNS that elicits pain hypersensitivity. Central sensitization results when repetitive nociceptive input causes an increase in the excitability of the spinal cord neurons receiving the noxious input and adjacent spinal cord neurons receiving non-noxious input. T e result is amplification of pain information in the brain, resulting in what has been termed a windup in both central and PNS processes, which causes pain and normal central inhibitory mechanisms that help to balance activation of pain centers.[240] Increase facilitation and reduced inhibition of central system pain processing centers can cause muscle pain through a combination of altered central pain perception and possible antidromic effects.[241] Central sensitization can also result in referred pain located outside the local tissue causing the pain.[242] Muscles with sustained nociceptive input or with prolonged muscle guarding may develop trigger points that, when palpated, result in regional, dull, achy pain distal from the muscle itself.[243] T is type of pain, which has a disproportionate and unpredictable pattern, responds well to cognitive behavior treatment, aerobic exercise, strength training, and manual therapy.

Over the last decade, researchers have begun to investigate the influence of pain on patterns of neuromuscular activation and control.[182] It has been suggested that the presence of pain leads to inhibition or delayed activation of muscles or muscle groups that perform key synergistic functions to limit unwanted motion.[244] T is inhibition usually occurs in deep muscles, local to the involved joint, that perform a synergistic function in order to control joint stability.[245–247] It is now also becoming apparent that in addition to being influenced by pain, motor activity, and emotional state can, in turn, influence pain perception.[182,248]

It is important to assume that all reports of pain by the patient are serious in nature until proven otherwise with a thorough examination.[249]

Cl In ICAl PEARl

In general, the greater the degree of pain radiation, the greater the chance that the problem is acute or that it is occurring from a proximal structure or both.

Although the pain intensity and the functional response to symptoms are subjective, patterns of pain response to stimulation of the pain generator are quite objective (e.g., antalgic gait).[250]

Referred pain can be generated by[251]

- the convergence of sensory input from separate parts of the body to the same posterior (dorsal) horn neuron via primary sensory fibers (convergence-projection theory);[230,252–254]
- secondary pain resulting from a myofascial trigger point(MTrP);[255]
- sympathetic activity elicited by a spinal reflex;[256] and
- pain-generating substances.[230]

MacNab[257] recommends the following classification for referred pain/symptoms:

- Viscerogenic
- Vasculogenic
- Neurogenic
- Psychogenic
- Spondylogenic

Viscerogenic Symptoms

T e pain/symptoms in this category can be referred from any viscera in the trunk or abdomen. Visceral pain can be produced by chemical damage, ischemia, or spasm of the smooth muscles.

Viscerogenic pain may be produced when the nociceptive fibers from the viscera synapse in the spinal cord with some of the same neurons that receive pain from the skin. When the visceral nociceptors are stimulated, some are transmitted by the same neurons that conduct skin nociception and take on the same characteristics. Visceral pain has five important clinical characteristics:

- It is not evoked from all viscera.
- It is not always linked to visceral injury.
- It is diffuse and poorly localized.
- It is referred to other locations.
- It is often accompanied by autonomic reflexes, such as nausea and vomiting.

Viscerogenic pain tends to be diffuse because of the organization of visceral nociceptive pathways in the CNS. T is organization demonstrates an absence of a separate pathway for visceral sensory information and a low proportion of visceral afferent nerve fibers compared with those of somatic origin.

Pain arising from problems in the peritoneum, pleura, or pericardium differs from that of other visceral impairments because of the innervation of these structures. T e parietal walls of these structures are supplied extensively with both fast and slow pain fibers and, thus, can produce the sharp pain of superficial impairments.

Cl In ICAl PEARl

A visceral source of the symptoms should always be suspected if the symptoms are not altered with movement or position changes.

In general, symptoms from a musculoskeletal condition are provoked by certain postures, movements, or activities and relieved by others. However, this generalization must be viewed as such. It is also important to remember that musculoskeletal structures can refer symptoms (Table 3-5). Determining the mechanism often will clarify the cause of the

TABLE 3-5	Muscles Most Likely to Refer Pain to a Given Area
Location	**Potential Muscles Involved**
Chest pain	Pectoralis major Pectoralis minor Scaleni Sternocleidomastoid (sternal) Sternalis Iliocostalis cervicis Subclavius External abdominal oblique
Side of chest pain	Serratus anterior Latissimus dorsi
Abdominal pain	Rectus abdominis External abdominal oblique Transversus abdominis Iliocostalis thoracis Multifidi Quadratus lumborum Pyramidalis
Low thoracic back pain	Iliocostalis thoracis Multifidi Serratus posterior inferior Rectus abdominis Latissimus dorsi
Lumbar pain	Gluteus medius Multifidi Iliopsoas Longissimus thoracis Iliocostalis lumborum Iliocostalis thoracis Rectus abdominis
Pelvic pain	Coccygeus Levator ani Obturator internus Adductor magnus Piriformis Obliquus internus abdominis
Buttock pain	Gluteus medius Quadratus lumborum Gluteus maximus Iliocostalis lumborum Longissimus thoracis Semitendinosus Semimembranosus Piriformis Gluteus minimus Rectus abdominis

Data from Travell JG, Simons DG. Myofascial Pain and Dysfunction—The Trigger Point Manual. Baltimore, MD: Williams & Wilkins; 1983.

symptoms. In addition, what appears to be a musculoskeletal injury can actually be a systemic problem (see Chapter 5). For example, acute low back pain (LBP) can result in symptoms of varying intensity and distribution that can be caused by neuromuscular structures as well as underlying or coexisting systemic pathology (Table 3-6), such as a gastrointestinal pathology (Table 3-7).

Signs and symptoms that could increase suspicion for a gastrointestinal pathology include a report of pain that has no specific mechanism of injury, is unrelated to activity, and that occurs following eating. In addition, reports of night pain unrelated to movement, fever, unexpected weight loss, nausea/vomiting, bowel dysfunction, and food intolerance should also highlight the possibility of a gastrointestinal source. An abdominal palpation examination can be used to identify gross masses, pulsating masses, and/or pain.[258] Palpatory findings of tenderness, gross abnormal masses, or abnormal pulsations are indicative of a broad range of abdominal pathologies, including tumor, aneurysm, obstruction, and infection.

TABLE 3-6	Signs/Symptoms Suggestive of Back Pain due to Systemic Pathology
History	Insidious onset and progressive pattern of pain Sacral pain of nontraumatic origin Malignant disease Excessive fatigue Chronic immunosuppressive medication use Chronic corticosteroid or intravenous drug use Trauma related to physiological changes associated with aging (i.e., osteoporosis)
Age	Younger than 20 years and older than 45 years
Pain description	Nocturnal back pain that disrupts sleep Pain that causes constant movement or makes the patient curl up Pain that is unrelieved with rest or recumbency Pain that is unaffected by exertion or activity Severe, persistent back pain with full and painless movement of the spine Back pain accompanied by multiple joint pain or sustained morning stiffness Pain described as throbbing or pulsating sensation
Constitutional	Fever, sweats, nausea, or vomiting symptoms
Other	Palpable pulsating mass in the abdomen Severe/progressive bilateral weakness of lower extremities Neurological findings persisting longer than 1 mo Bowel or bladder incontinence Urinary retention Urinary tract infection Constipation

Data from Stowell T, Cioffredi W, Greiner A, et al. Abdominal differential diagnosis in a patient referred to a physical therapy clinic for low back pain. J Orthop Sports Phys Ther. 2005;35:755–764.

TABLE 3-7	Potential Areas of Cutaneous Referral from Various Viscera
Visceral Organ	**Pain Referral**
Heart (T1–5), bronchi, and lung (T2–4)	Under sternum, base of neck, over shoulders, over pectorals, and down one or both arms (L> R)
Esophagus (T5–6)	Pharynx, lower neck, arms, midline chest from upper to lower sternum
Gastric (T6–10)	Lower thoracic to upper abdomen
Gallbladder (T7–9)	Upper abdomen, lower scapular, and thoracolumbar
Pancreas	Upper lumbar or upper abdomen
Kidneys (T10–L1)	Upper lumbar, occasionally anterior abdomen approximately 4–5 cm lateral to umbilicus
Urinary bladder (T11–12)	Lower abdomen or low lumbar
Uterus	Lower abdomen or low lumbar

Data from Head H. Studies in Neurology. London: Oxford Medical Publications; 1920.

Vasculogenic Symptoms

Vasculogenic symptoms tend to result from venous congestion or arterial deprivation to the musculoskeletal areas. Vasculogenic pain may mimic a wide variety of musculoskeletal, neurologic, and arthritic disorders, because this type of pain is often worsened by activity. An example of a vasculogenic cause of symptoms occurs with an abdominal aortic aneurysm (Table 3-8).[258,259]

To help exclude a vasculogenic cause, it is important to review the cardiopulmonary, hematologic, and neurologic systems during the examination. Clinical evidence of arterial insufficiency includes lower extremity asymmetry, skin condition changes, skin temperature and color changes, and diminishing pulses.

Doppler examination, which is not within the scope of physical therapy practice, is the cornerstone of the vascular examination. This test examines blood flow in the major arteries and veins in the arms and the legs with the use of ultrasound. The ultrasound transducer produces high-frequency sound waves that echo off the blood vessels, resulting in a "swishing" noise during blood flow. A faster flow produces a higher pitch and a steeper waveform. In the lower extremity, segmental pressures are usually taken from six sites:

- High thigh
- Above the knee
- Below the knee
- Ankle
- Forefoot
- Digit

A pressure gradient of less than 20 mm Hg is normal, 20–30 mm Hg is borderline, and greater than 30 mm Hg is considered abnormal. Pressure differences of less than 20 mm Hg between limbs are considered normal.

After the segmental pressures of the lower extremity are measured, brachial pressure on both sides is measured. Comparisons are made between ankle–arm, forefoot–arm, and digit–arm ratios. Normal values are >1 for the ankle–arm index, >0.75 for the forefoot–arm, and >0.65 for each digit–arm index.

Neurogenic Symptoms

The neurologic tissues comprise those tissues that are involved in nerve conduction. Neurogenic causes of symptoms may include:

- tumor compressing and irritating a neural structure of the spinal cord or the meninges;
- spinal nerve root irritation;
- peripheral nerve entrapment; and
- neuritis.

Psychogenic Symptoms

It is common to find emotional overtones in the presence of pain, particularly with low back and neck pain. These overtones are thought to result from an inhibition of the pain-control mechanisms of the CNS from such causes as grief, the side effects of medications, or fear of reinjury. Somatosensory amplification refers to the tendency to experience somatic sensation as intense, noxious, and disturbing. Barsky et al.[260] introduced the concept of somatosensory amplification as an important feature of hypochondriasis. Somatosensory amplification is observed in patients whose extreme anxiety leads to an increase in their perception of pain.

The term nonorganic was proposed by Waddell et al.[261] to define the abnormal illness behaviors exhibited by patients who have depression, emotional disturbance, or anxiety states. The presence of three of the following five Waddell signs has been correlated significantly with disability:[262]

- Superficial or nonanatomic tenderness to light touch that is widespread and refers pain to other areas.
- Simulation tests. These are a series of tests that should be comfortable to perform. Examples include axial loading of the spine through the patient's head with light pressure to the skull and passive hip and shoulder rotation with the patient positioned standing. Neither of these tests should produce LBP. If pain is reported with these tests, a nonorganic origin should be suspected.
- Distraction test.[263] This test involves checking a positive finding elicited during the examination on the distracted patient. For example, if a patient is unable to perform a seated trunk flexion maneuver, the same patient can be observed when asked to remove his or her shoes. A difference of 40–45 degrees is significant for inconsistency.
- Regional disturbances. These signs include sensory or motor disturbances that have no neurologic basis.
- Overreaction. This includes disproportionate verbalization, muscle tension, tremors, and grimacing during the examination.

TABLE 3-8 Common Signs and Symptoms of Pathologies Associated with Abdominal and Back Pain

Pathology/Condition	Signs/Symptoms
Abdominal aortic aneurysm (AAA)	Pain located in central lumbar region Palpable pulsating abdominal mass Pain described as pulsating or throbbing Patient unable to find comfortable position History of AAA or vascular claudication
Cancer (i.e., pancreatic, ovarian, and prostate metastasis to spine)	Night pain that disrupts sleep Pain that is unrelieved by rest Unexplained weight loss Fever and sweats Extreme fatigue Altered gastrointestinal or genitourinary function
Intestinal obstruction (i.e., volvulus, adhesions, tumor, and functional)	Colicky abdominal pain Abdominal distention Nausea/vomiting/sweating Constipation
Gastrointestinal infection/inflammation (i.e., peritonitis, appendicitis, and pancreatitis)	Abdominal pain and muscle guarding Rebound tenderness Any movement aggravates pain Fever, chills, sweating, and vomiting Pain relieved by sitting and leaning forward (pancreatitis)
Renal disorders (i.e., nephrolithiasis, urinary tract infection, and pyelonephritis)	Severe pain along upper urinary tract pain pattern Altered urinary tract function (frequency, urgency, and dysuria) Hematuria
Gynecological (i.e., endometriosis, pelvic inflammatory disease, and ovarian cysts)	Lumbopelvic and lower abdominal pain Cyclical pain, nausea, and vomiting Dysmenorrhea Abnormal uterine bleeding

Data from Stowell T, Cioffredi W, Greiner A, et al. Abdominal differential diagnosis in a patient referred to a physical therapy clinic for low back pain. J Orthop Sports Phys Ther. 2005;35:755–764.; Goodman CC, Boissonnault WG, Fuller KS. Pathology: Implications for the Physical Therapist, 2nd ed. Philadelphia, PA: WB Saunders; 2003.

The Somatosensory Amplification Rating Scale (SARS; Table 3-9) is a version of the Waddell's nonorganic physical signs, which has been modified to allow for a more accurate appraisal of the patient with exaggerated illness behavior.[260]

Clinical Pearl

It is important to remember that the Waddell and SARS assessment tools are not designed to detect whether patients are malingering, but only to indicate whether they have symptoms of a nonorganic origin.

Spondylogenic Symptoms

A number of conditions can affect the musculoskeletal system, frequently producing pain. These include infections (e.g., osteomyelitis), inflammatory disorders, neoplasms, and metabolic disorders. Several findings are helpful in diagnosing such pathologic processes. These findings may include:

- severe and unrelenting pain;
- the presence of a fever;
- bone tenderness; and
- unexplained weight loss.

Pain-Control Mechanisms

One of the earliest pain-control mechanisms was proposed by Melzack and Wall[264] who postulated that interneurons in the substantia gelatinosa functioned like a gate to modulate sensory input. They proposed that the substantia gelatinosa interneuron projected to the second-order neuron of the pain–temperature pathway located in lamina V, which they called the transmission cell. It was reasoned that if the substantia gelatinosa interneuron were depolarized, it would inhibit the transmission of cell firing and, thus, decrease further transmission of input ascending in the spinothalamic

TABLE 3-9 Somatosensory Amplification Rating Scale

Examination	Percent	Score[a]
Sensory examination		
1. No deficit or deficit well localized to dermatome		0
Deficit related to dermatome(s) but some inconsistency		1
Nondermatomal or very inconsistent deficit		2
Blatantly impossible (i.e., split down midline or entire body with positive tuning fork test)		3
2. Amount of body involved:		
Evaluate similar to burn (% of surface areas for an entire leg is 18%)	<15%	0
	15–35%	1
	36–60%	2
	>60%	3
Motor examination		
1. No deficit or deficit well localized to myotomes		0
Deficit related to myotome(s) but some inconsistency		1
Nonmyotomal or very inconsistent weakness, exhibits cogwheeling or giving way, weakness is coachable		2
Blatantly impossible, significant weakness that disappears when distracted		3
2. Amount of body involved	<15%	0
	15–35%	1
	36–60%	2
	>60%	3
Tenderness		
1. No tenderness or tenderness clearly localized to discrete, anatomically sensible structures		0
Tenderness not well localized, some inconsistency		1
Diffuse or very inconsistent tenderness, multiple anatomic structures involved (skin, muscle, bone, etc.)		2
Blatantly impossible, significant tenderness of multiple anatomic structures (skin, muscle, bone, etc.), which disappears when distracted		3
2. Amount of body involved	<15%	0
	15–35%	1
	36–60%	2
	>60%	3
Additional tests: distraction tests		
Distraction SLR rating determined by the difference in measurements between supine and seated	<20 degrees	0
	20–45 degrees	1
	>45 degrees	2
SLR supine at less than 45 degrees		3
Standing flexion versus long sit test		
Rating determined by two factors		1
Difference between hip ROM, standing versus supine	<20 degrees	0
	20–40 degrees	1
	41–50 degrees	2
	>50 degrees	3
Distance measurement from middle finger to toes, standing versus supine (long sit)	<5 cm	0
	6–10 cm	1
	11–18 cm	2
	>18 cm	3
Total score possible		27

SLR, straight-leg raise; ROM, range of motion.

[a]SARS scores of 5 or greater are indicative of inappropriate illness behavior. The higher the score, the greater the exaggerated behavior.

tract. The degree of modulation appeared to depend on the proportion of input from the large A fibers and the small C fibers, so that the gate could be closed by either decreasing C fiber input or increasing A fiber (mechanoreceptive) input. The gate theory was, and is, supported by practical evidence (e.g., rubbing a sore area appears to decrease the pain), although the experimental evidence for the theory is lacking. Researchers have identified many clinical pain states that cannot be fully explained by the gate control theory.[265] A problem with this theory is that there is evidence to suggest that the A-beta fibers from the mechanoreceptor do not synapse in the substantia gelatinosa. In this case, the modulation at the spinal cord level must occur in lamina V, where there is a simple summation of signals from the pain fibers and the mechanoreceptor fibers. However, severe or prolonged pain tends to have the segment identifying all input as painful, and summation modulation has little, if any, effect.

Melzack and Wall expanded upon the gate theory and argued that the gate could be modified by a descending inhibitory pathway from the brain, or brain stem,[266] suggesting that the CNS apparently plays a part in this modulation in a mechanism called central biasing.

Numerous investigations have since been made of what is known as the descending analgesia systems. The thalamus represents the final link in the transmission of impulses to the cerebral cortex, processing almost all sensory and motor information prior to its transfer to cortical areas. The key brain sites involved in pain perception include the anterior cingulate cortex, anterior insular cortex, primary somatosensory cortex, secondary somatosensory cortex, a number of regions in the thalamus and cerebellum, and, interestingly, areas such as the premotor cortex that are normally linked to motor function.[182,267] Indeed, it is clear that both the basal ganglia (associated with planned action), the PAG of the midbrain region, and the raphe nucleus in the pons and the medulla receive nociceptive input as well as coordinating important aspects of movement and motor control.[182,268,269]

The PAG area of the upper pons sends signals to the raphe magnus nucleus in the lower pons and the upper medulla. This nucleus relays the signal down the cord to a pain-inhibitory complex located in the posterior (dorsal) horn of the cord. The nerve fibers derived from the PAG area secrete enkephalin and serotonin, whereas the raphe magnus releases enkephalin only. The PAG is also believed to be involved in complex behavioral responses to stressful or life-threatening situations or to promote recuperative behavior after a defense reaction.

Enkephalin is believed to produce presynaptic inhibition of the incoming pain signals to laminae I to V, thereby blocking pain signals at their entry point into the cord.[270] It is further believed that the chemical releases in the upper end of the pathway can inhibit pain signal transmission in the reticular formation and the thalamus. The inhibition from this system is effective on both fast and slow pains.

In the cortex, a negative-feedback loop, called the corticofugal system, originates at the termination point of the various sensory pathways.[271] Excessive stimulation of this feedback loop results in a signal being transmitted down from the sensory cortex to the posterior horn of the level from which the input arose. This response produces lateral or recurrent inhibition of the cells adjacent to the stimulated cell, thereby preventing the spread of the signal. This is an automatic gain control system to prevent overloading of the sensory system.

Finally, two other neuroactive peptides, beta endorphin and dynorphin, have been discovered, both of which are theorized to be used as analgesics in the body to numb or dull pain in addition to promoting feelings of well-being and increasing relaxation.

Nonpharmacological Control of Pain

The pharmacological control of pain is discussed in Chapter 9. Clinicians can use several nonpharmacological therapeutic interventions to manage pain. These include:

- Transcutaneous electrical nerve stimulation (TENS). TENS is frequently used to treat a number of pain conditions including back pain, osteoarthritis, in fibromyalgia to name a few (see Chapter 8).
- Interferential current (see Chapter 8). Clinically, interferential current therapy is beneficial for treating painful conditions such as osteoarthritic pain. The potential mechanisms behind this pain control include an increase in blood flow, and the same mechanisms as TENS—segmental inhibition and activation of descending inhibitory pathways
- Thermal physical agents (see Chapter 8).
- Cryotherapy (see Chapter 8).
- Manual therapy (see Chapter 10).
- Exercise (see Chapters 12–15).
- Patient education. Patients can be educated on pain management techniques (relaxation, cognitive behavioral approaches, and biofeedback), positions and activities to avoid, and positions and activities to adopt.

Concussion

A concussion is classified as a form of mild traumatic brain injury (TBI) that results from trauma to the head.[272] The Centers for Disease Control and Prevention provide a more descriptive definition: "a complex pathophysiological process affecting the brain, induced by traumatic biomechanical forces secondary to direct or indirect forces to the head." A loss of consciousness is not necessary to diagnosis concussion. There are usually no findings on routine imaging such as CT with a concussion, which complicates the diagnosis.[273] While concussions can occur in nearly every walk of life, the greatest frequency occurs in collision and contact sports, including football, lacrosse, hockey, rugby, soccer, and basketball. It is estimated that 3.8 million concussions occur annually.[274] While the majority of patients with a sports-related concussion may recover within a 7- to 10-day period, children and adolescents require more time to recover than do collegiate or professional athletes.[275] Persistence of symptoms beyond the generally accepted timeframe for recovery may represent a prolonged concussion, or may herald the development of postconcussion syndrome (PCS).[276]

Cl In ICAl PEARl

Based on a fact sheet available from the Centers for Disease Control and Prevention (http://cdc.gov/concussion/HeadsUp/high_school.html), an individual who is suspected of suffering from a concussion should not be left alone and should be brought to the emergency department if any of the following is present:

- a headache that worsens,
- drowsiness or inability to be woken up,
- inability to recognize people or places,
- repeated vomiting,
- worsening confusion/irritability,
- seizures,
- hemiparesis/hemi sensory loss,
- unsteadiness, or
- slurred speech.

Sex differences among concussed athletes are well documented and demonstrate dissimilarities between male and female athletes that range from anthropometrics, neuromuscular, and strength differences, to postconcussion symptoms and cognitive dysfunctions that can influence an individual's recovery time.[277] T ere are number of potential explanations for this disparity:[277]

- Females have longer cervical spine segments and may not be as ef cient at transmitting impact forces from their head into their torso via their cervical musculature during a concussive event.
- Females may also be more likely to seek medical treatment for concussion symptoms and to honestly report symptoms when they suffer a concussion.

With increased awareness of the rate of concussion injury in sports and the potential detrimental long-term effects, a number of efforts have been made to identify the health consequences of repeated blows to the head while concurrently seeking to implement strategies to better protect the athlete from these injuries.[278] It is important to note that concussion may or may not involve a loss of consciousness, and can result in a constellation of physical, cognitive, emotional, and sleep-related symptoms.[279] Acute signs and symptoms of a concussion include confusion, loss of consciousness, posttraumatic amnesia, retrograde amnesia, balance deficits, dizziness, visual problems, personality changes, fatigue, sensitivity to light/noise, numbness, and vomiting.[280] Chronic signs and symptoms of a concussion have a degree of overlap and include cognitive deficits in attention or memory, and at least two or more of the following symptoms: fatigue, sleep disturbance, headache, dizziness, irritability, affective disturbance, apathy, or personality change.[281] Since most cognitive deficits resolve within 1–3 months after a mild TBI in the majority of patients, there is considerable controversy regarding PCS because of the nonspecificity of its symptoms.[282] T e following two findings can help determine whether the prolonged symptoms reflect a version of the concussion pathophysiology or a manifestation of a secondary process, such as premorbid clinical depression:[283]

1. If symptoms that were experienced early after the injury are exacerbated by exertion, but improved with rest, then the original concussion pathophysiology is likely persisting.
2. If ongoing symptoms are exacerbated with minimal activity and no longer respond to rest, this may represent psychological symptoms related to prolonged inactivity and frustration with inability to return to usual activities.

Concussions have traditionally been diagnosed through a clinical examination performed by a healthcare professional on the sideline at the time of injury. On those occasions when the assessment is not performed on the sidelines, it is critical that the clinician determines a clear description of the mechanism and force of the head trauma, the number and severity of symptoms, and a history of any prior concussions, including mechanism, symptom type, and duration.[272] T e nature, burden, and duration of symptoms appear to be the primary determinant of injury severity in concussion.[272,284] A history of multiple concussions appears to increase the risk for PCS.[276]

T e diagnosis and subsequent management of concussion continues to evolve and several tests now exist to identify the deficits found in this population. What is clear is that concussion symptoms may be immediate after injury, or appear in a delayed fashion several hours post injury, so it is important to stay vigilant.[273] T e sideline assessment of concussion is best accomplished with standardized instruments that are widely available, including the Sport Concussion Assessment Tool-2 (SCAT-2),[272] which has been adopted by nearly every professional sports team and many college teams. T e Modified Maddocks Score[285] can be used to assess orientation by asking the athlete about game events that day and the week before.[273] T e physical examination should include an assessment of concentration (e.g., drills such as stating the months of the year in reverse), memory (recall of three words at 5 minutes), the cervical spine, gait, balance, cerebellar testing (e.g., finger-to-nose test), and an examination of the CNs, particularly extraocular motion, since PCS patients can have persistent abnormalities of smooth pursuit saccadic eye movements.[272,276,286] Other tests include, the Immediate Postconcussion Assessment and Cognitive Testing (ImPact), the postconcussion symptom scale, and the Balance Error Scoring System (BESS) (see Neuromuscular Control and Balance Testing). T e cervical spine should also be carefully assessed. Current recommendations are that the athlete undergo baseline testing in these areas prior to the season and, if a concussion is suspected, undergo the same battery of tests so that scores may be compared.

A standardized process projecting the length of recovery time after concussion has remained an elusive piece of the puzzle. T e recovery time associated with such an injury once diagnosed can last anywhere from one week to several months. Parents are typically advised to keep the patient at rest and, for at least 24 hours, to have the patient avoid strenuous activity, recreational drugs, alcohol, sleeping medication, and aspirin or nonsteroidal anti-inflammatory drugs.

Obviously, moves toward prevention would seem prudent. T e most common attempted prevention strategy of concussion has occurred with American Football that has seen

modifications to helmets that include innovations in design, padding, mouth guards, and product materials. However, despite aggressive enforcement of helmet and protective padding use, epidemiological and laboratory studies have not shown significant reductions in concussion instances or the extent of concussive injury to the brain.[287] One hypothesis is that such devices and equipment do little to nothing to prevent or mitigate the rapid acceleration and deceleration of the brain and related fluids inside the rigid cranium.[278] Based on the science of fluid dynamics, slosh refers to the movement of liquid inside containers that are also typically undergoing motion. When the head is exposed to rapid acceleration/deceleration, the brain may be at risk for slosh-induced injury as tissues of differing density (i.e., blood, spine, brain, and skull) decelerate at different rates, thereby creating shear and cavitation (vapor bubble creation and implosion).[278]

Current management guidelines recommend a period of cognitive and physical rest in the early post injury. However, there is no scientific evidence that prolonged rest for more than several weeks in concussed patients is beneficial.[276] Neurocognitive rehabilitation, which uses cognitive tasks to improve cognitive processes and attention processes, can be used once the concussion symptoms have subsided.[276] Once the patient is asymptomatic at rest, a progression from light aerobic activity such as walking, to sport- or work-specific activities can be introduced.[272] The Cantu[288] grading scale has been helpful in assessing severity of concussion and for making return to play decisions (see Table 3-10).

Orthopaedic Neurologic Testing

An examination of the transmission capability of the nervous system can be performed as part of the orthopaedic examination to detect the presence of either an upper motor neuron (UMN/CNS) lesion, a lower motor neuron (LMN/PNS) lesion, or both. In essence, neurological tissue is tested during active, passive, and resisted isometric movement, as well as those tests specific to the nervous system (e.g., reflex testing, sensory testing). Neurodynamic mobility testing is covered in Chapter 11.

UMNs are located in the white columns of the spinal cord and the cerebral hemispheres. An UMN lesion, also known as a central palsy, is a lesion of the neural pathway above the anterior horn cell or motor nuclei of the CNS. Signs and symptoms associated with an UMN lesion follow.

TABLE 3-10 Cantu Grading Scale

Grade	Description
1	Includes posttraumatic amnesia less than 30 minutes and no loss of consciousness
2	Defined as loss of consciousness less than 5 minutes, or amnesia 30 minutes to 24 hours
3	Includes loss of consciousness greater than 5 minutes or amnesia greater than 24 hours

Data from Cantu RC. Posttraumatic retrograde and anterograde amnesia: pathophysiology and implications in grading and safe return to play. J Athl Train. 2001;36:244–248.

Clinical Pearl

An UMN lesion is characterized by spastic paralysis or paresis, little or no muscle atrophy, hyper-reflexive muscle stretch (deep tendon) reflexes in a nonsegmental distribution, and the presence of pathologic signs and reflexes.

- **Nystagmus.** Nystagmus is characterized by an involuntary loss of control of the conjugate movement of the eyes (around one or more axes) involved with smooth pursuit or saccadic movement. When the eyes oscillate like a sine wave, it is called pendular nystagmus. If the nystagmus consists of drifts in one direction with corrective fast phases, it is called jerk nystagmus. The more benign types of nystagmus include the proprioceptive causes of spontaneous nystagmus, postural nystagmus, and nystagmus that is elicited with head positioning or induced by movement (vestibular nystagmus). A unidirectional nystagmus is related to the geometric relationship of the SSC, with a change in head position often exacerbating the nystagmus. On the other hand, a central vestibular nystagmus, which is caused by disease of the brain stem or the cerebellum, exhibits bidirectionality to the nystagmus (i.e., left beating on left gaze and right beating on right gaze).[289] The more serious causes of nystagmus include, but are not limited to, vertebrobasilar ischemia, tumors of the posterior cranial fossa, intracranial bleeding, craniocervical malformations, and autonomic dysfunction. Differentiation between the benign and serious causes of nystagmus is obviously very important.
- Proprioceptive nystagmus occurs immediately upon turning the head (i.e., there is no latent period).
- The ischemic type of nystagmus has a latent period and is usually only evident when the patient's neck is turned to a position and maintained there for a period of a few seconds up to 3 minutes.[290,291]
- **Dysphasia.** Dysphasia is defined as a problem with vocabulary and results from a cerebral lesion in the speech areas of the frontal or temporal lobes. The temporal lobe receives most of its blood from the temporal branch of the cortical artery of the vertebrobasilar system and may become ischemic periodically, producing an inappropriate use of words.
- **Wallenberg syndrome.** This is the result of a lateral medullary infarction.[292] Classically, sensory dysfunction in lateral medullary infarction is characterized by selective involvement of the spinothalamic sensory modalities with dissociated distribution (ipsilateral trigeminal and contralateral hemibody/limbs).[293] However, various patterns of sensory disturbance have been observed in lateral medullary infarction that includes contralateral or bilateral trigeminal sensory impairment, restricted sensory involvement, and a concomitant deficit of lemniscal sensations.[294,295]
- **Ataxia.** Ataxia is often most marked in the extremities. In the lower extremities, it is characterized by the so-called

drunken-sailor gait pattern, with the patient veering from one side to the other and having a tendency to fall toward the side of the lesion. Ataxia of the upper extremities is characterized by a loss of accuracy in reaching for, or placing, objects. Although ataxia can have a number of causes, it generally suggests CNS disturbance, specifically a cerebellar disorder, or a lesion of the posterior columns.[296–298]

- **Spasticity.**[299–301] Spasticity is defined as a motor disorder characterized by a velocity-dependent increase (resistance increases with velocity) in tonic stretch reflexes with exaggerated tendon jerks, resulting from hyperexcitability of the stretch reflex. T e spinal cord experiences spinal shock immediately following any trauma causing tetraplegia or paraplegia, resulting in the loss of reflexes innervated by the portion of the cord below the site of the lesion. T e direct result of this spinal shock is that the muscles innervated by the traumatized portion of the cord, the portion below the lesion, as well as the bladder, become flaccid. Spinal shock, which wears off after 24 hours and 3 months after injury, can be replaced by spasticity in some, or all of these muscles.

  Spasticity occurs because the reflex arc to the muscle remains anatomically intact, despite the loss of cerebral innervation and control via the long tracts. During spinal shock, the arc does not function, but as the spine recovers from the shock, the reflex arc begins to function without the inhibitory or regulatory impulses from the brain, creating local spasticity and clonus.

Cl In ICAl PEARl

Medical etiologies for increased spasticity include a new or enlarged CNS lesion, genitourinary tract dysfunction (infection, obstruction, etc.), gastrointestinal disorders (bowel impaction, hemorrhoids, etc.), venous thrombosis, fracture, muscle strain, and pressure ulcers.

- **Drop attack.** A drop attack is described as a loss of balance resulting in a fall, but with no loss of consciousness. Because it is the consequence of a loss of lower extremity control, it is never a good or benign sign. T e patient, usually elderly, falls forward, with the precipitating factor being extension of the head. Recovery, providing nothing is injured in the fall, is usually immediate. Causes include:
  - a vestibular system impairment;[302]
  - neoplastic and other impairments of the cerebellum;[303]
  - vertebrobasilar compromise[304] (see Chapter 24);
  - sudden spinal cord compression;
  - third ventricle cysts;
  - epilepsy; and
  - type 1 Chiari malformation.[305]

- **Wernicke's encephalopathy.** T is is an impairment, typically localized to the posterior (dorsal) part of the midbrain,[306] that produces the classic triad of abnormal mental state, ophthalmoplegia, and gait ataxia.[307]

- **Vertical diplopia.** A history of "double vision" should alert the clinician to this condition. Patients with vertical diplopia complain of seeing two images, one atop or diagonally displaced from the other.[308]

- **Dysphonia.** Dysphonia presents as a hoarseness of the voice. Usually, no pain is reported. Painless dysphonia is a common symptom of Wallenberg syndrome.[294]

- **Hemianopia.** T is finding, defined as a loss in half of the visual field, is always bilateral. A visual field defect describes sensory loss restricted to the visual field and arises from damage to the primary visual pathways linking the optic tract and striate cortex (see section "Supraspinal Reflexes").

- **Ptosis.** Ptosis is defined as a pathologic depression of the superior eyelid such that it covers part of the pupil. It results from a palsy of the levator palpebrae and Müller's muscle.

- **Miosis.** Miosis is defined as the inability to dilate the pupil (damage to sympathetic ganglia). It is one of the symptoms of Horner syndrome.

- **Horner syndrome.** T is syndrome is caused by interference with the cervicothoracic sympathetic outflow resulting from a lesion of (1) the reticular formation, (2) the descending sympathetic system, and (3) the oculomotor nerve caused by a sympathetic paralysis.[309] T e other clinical signs of Horner syndrome are ptosis, enophthalmos, facial reddening, and anhydrosis. If Horner syndrome is suspected, the patient should immediately be returned or referred to a physician for further examination.

- **Dysarthria.** Dysarthria is defined as an undiagnosed change in articulation. Dominant or nondominant hemispheric ischemia, as well as brain stem and cerebellar impairments, may result in altered articulation.

T e LMN begins at the α motor neuron and includes the posterior (dorsal) and anterior (ventral) roots, spinal nerve, peripheral nerve, neuromuscular junction, and muscle–fiber complex.[310] T e LMN consists of a cell body located in the anterior gray column and its axon, which travels to a muscle by way of the cranial or peripheral nerve. Lesions to the LMN can occur in the cell body or anywhere along the axon. A LMN lesion is also known as a peripheral palsy. T ese lesions can be the result of direct trauma, toxins, infections, ischemia, or compression. T e characteristics of a LMN lesion include muscle atrophy and hypotonus, diminished or absent muscle stretch (deep tendon) reflex of the areas served by a spinal nerve root or a peripheral nerve, and absence of pathologic signs or reflexes.

Cl In ICAl PEARl

The differing symptoms between an UMN lesion and a LMN lesion are the result of injuries to different parts of the nervous system. LMN impairment involves damage to a neurologic structure distal to the anterior horn cell, whereas UMN impairment involves damage to a neurologic structure proximal to the anterior horn cell, namely, the spinal cord or CNS.

TABLE 3-11 Upper-Quarter Scanning Motor Examination

Muscle Action	Muscle Tested	Root Level	Peripheral Nerve
Shoulder abduction	Deltoid	Primarily C5	Axillary
Elbow flexion	Biceps brachii	Primarily C6	Musculocutaneous
Elbow extension	Triceps brachii	Primarily C7	Radial
Wrist extension	Extensor carpi radialis longus, brevis, and extensor carpi ulnaris	Primarily C6	Radial
Wrist flexion	Flexor carpi radialis and flexor carpi ulnaris	Primarily C7	Median nerve for radialis and ulnar nerve for ulnaris
Finger flexion	Flexor digitorum superficialis, flexor digitorum profundus, and lumbricales	Primarily C8	Median nerve for superficialis and both median and ulnar nerves for profundus and lumbricales
Finger abduction	Posterior (dorsal) interossei	Primarily T1	Ulnar

The Scanning Examination

Designed by Cyriax,[311] the upper (Table 3-11) and lower (Table 3-12) quarter scanning examinations are based on sound anatomic and pathologic principles. The clinician must choose which scanning examination to use, based on the presenting signs and symptoms.

The purpose of the scanning examinations is to help rule out the possibility of symptom referral from other areas, to ensure that all possible causes of the symptoms are examined, and to ensure a correct diagnosis.

The scanning examination is typically applied to patients presenting with neuromusculoskeletal complaints and differs from the five elements of patient/client management from The Guide in that the latter can be used as a system to approach virtually any type of patient, ranging from a pediatric patient with a permanent neurological condition to a patient with a serious injury to the integument, such as a burn patient.[312] The other major difference between the two approaches is that the scanning examination is designed to identify a specific pathoanatomical dysfunction, while The Guide works within movement-based diagnostic categories known as practice patterns.[312] Thus, the tests used in the scanning examinations (Table 3-13) may produce a medical diagnosis (e.g., intervertebral disk protrusion, prolapse, or extrusion; acute arthritis; specific tendinopathy; muscle belly tear; spondylolisthesis; or lateral recess stenosis) rather than a physical therapy one.[313]

Often, the scanning examination does not generate enough signs and symptoms to formulate a working hypothesis or a diagnosis. A negative scanning examination does not imply that there were no findings; rather, the results of examination were insufficient to generate a diagnosis upon which an intervention could be based. In this case, further testing with the tests and measures outlined in The Guide are required in order to proceed.

The thoroughness of the scanning examination is influenced by both patient tolerance and professional judgment. A general guideline is that the examination must continue until the clinician is confident that the patient's symptoms are not the result of a serious condition that demands medical attention.

The tests included in the scanning examination are strength testing, sensation testing (light touch and pinprick), muscle stretch reflexes, and the pathological reflexes (Table 3-13). The various tests of the scanning examinations specific to the cervical, thoracic, and lumbar spine are described in the relevant chapters.

Although two studies[314,315] questioned the validity of some aspects of the selective tissue tension examination, no

TABLE 3-12 Lower-Quarter Scanning Motor Examination

Muscle Action	Muscle Tested	Root Level	Peripheral Nerve
Hip flexion	Iliopsoas	L1–2	Femoral to iliacus and lumbar plexus to psoas
Knee extension	Quadriceps	L2–4	Femoral
Hamstrings	Biceps femoris, semimembranosus, and semitendinosus	L4–S3	Sciatic
Dorsiflexion with inversion	Tibialis anterior	Primarily L4	Deep fibular (peroneal)
Great toe extension	Extensor hallucis longus	Primarily L5	Deep fibular (peroneal)
Ankle eversion	Fibularis (peroneus) longus and brevis	Primarily S1	Superficial fibular (peroneal) nerve
Ankle plantarflexion	Gastrocnemius and soleus	Primarily S1	Tibial
Hip extension	Gluteus maximus	L5–S2	Inferior gluteal nerve

TABLE 3-13	Components of the Scanning Examination and the Structures Tested
Component	**Description**
Active ROM	Willingness to move, ROM, integrity of contractile and inert tissues, pattern of restriction (capsular or noncapsular), quality of motion, and symptom reproduction
Passive ROM	Integrity of inert and contractile tissues, ROM, end-feel, and sensitivity
Resisted	Integrity of contractile tissues (strength and sensitivity)
Stress	Integrity of inert tissues (ligamentous-disk stability)
Dural	Dural mobility
Neurologic	Nerve conduction
Dermatome	Afferent (sensation)
Myotome	Efferent (strength and fatigability)
Reflexes	Afferent–efferent and CNS

ROM, range of motion.

definitive conclusions were drawn from these studies. The scarcity of research to refute the work of Cyriax would suggest that its principles are sound and that its use should be continued.

Complaints of Dizziness

Although most causes of dizziness can be relatively benign, dizziness may signal a more serious problem, especially if it is associated with trauma to the neck or the head or with motions of cervical rotation and extension (e.g., vertebral artery compromise). The clinician must ascertain whether the symptoms result from vertigo, nausea, giddiness, unsteadiness, or fainting, among others. Nausea is an uneasiness of the stomach that often accompanies the urge to vomit but does not always lead to the forcible voluntary or involuntary emptying of stomach contents into the mouth (vomiting). If vertigo is suspected, the patient's physician should be informed, for further investigation. However, in and of itself, vertigo is not usually a contraindication to the continuation of the examination. Differential diagnosis includes primary CNS diseases, vestibular and ocular involvement, and, more rarely, metabolic disorders.[316] A patient complaining of dizziness can be classified into four subtypes (Table 3-14). Careful questioning can help in the differentiation of the cause. This differentiation is important, as certain types of dizziness are amenable to physical therapy interventions (Table 3-15); others produce contraindications to certain interventions, while still other causes of dizziness require medical referral.[317] The presence of presyncope would suggest compromise of the function of the cerebral hemispheres or the brainstem.[317] Different conditions can cause either a pancerebral hypoperfusion (Table 3-16) or a selective hypoperfusion of the brainstem, the latter of which includes vertebrobasilar insufficiency, vertebrobasilar infarction, and subclavian steal syndrome.[317] The presence of vertigo, nystagmus, hearing loss

TABLE 3-14	The Four Subtypes of Dizziness
Subtype	**Description**
Vertigo	A false sensation of movement of either the body or the environment, usually described as spinning, which suggests vestibular system dysfunction
	Usually episodic with an abrupt onset and often associated with nausea or vomiting
	The dysfunction can be located in the peripheral or central vestibular system
	Often accompanied by other signs and symptoms including impulsion (the sensation that the body is being hurled or pulled in space), oscillopsia (the visual illusion of moving back and forth or up and down), nystagmus, gait ataxia, nausea, and vomiting
Presyncope	Described as a sensation of an impending faint or loss of consciousness, which is not associated with an illusion of movement
	May begin with diminished vision or a roaring sensation in the ears
	May be accompanied by a transient neurological signs, e.g., dysarthria, visual disturbances, and extremity weakness
	Results from conditions that compromise the brain's supply of blood, oxygen, or glucose
Disequilibrium	A sense of imbalance without vertigo, or a sense that a fall is imminent, which is generally attributed to neuromuscular problems
	The unsteadiness or imbalance occurs only when erect and disappears when lying or sitting
	May result from visual impairment, peripheral neuropathy, musculoskeletal disturbances and may include ataxia
Other dizziness	Described as a vague or floating sensation with the patient having difficulty relating to specific feeling to the clinician
	Includes descriptions of a lightheadedness, heavy headedness, or wooziness that cannot be classified as any of the three previous subtypes
	The main causes of this subtype are psychiatric disorders including anxiety, depression, and hyperventilation

TABLE 3-15	Signs and Symptoms Indicative of Pathologies Amenable to Sole Physical Therapy Management
BPPV	Precipitated by positioning, movement, or other stimuli (see below) Short latency: 1–5 seconds Brief duration: <30 seconds Fatigable with repeated motion Associated signs and symptoms: nystagmus, nausea, and at times vomiting Occurs in people older than 40 years with peak incidence of onset in the sixth decade Rare in people under 20 years Medical history of head trauma, labyrinthine infection, surgical stapedectomy, chronic suppurative otitis media, and degenerative changes to the inner ear may indicate nonidiopathic BPPV
Posterior SCC BPPV	Patients complain of dizziness when they quickly transfer to a supine position, especially when the head is turned to the affected side Positive response of vertigo and apogeotropic torsional nystagmus on ipsilateral Hallpike–Dix maneuver
Anterior SCC BPPV	Patients also complain of dizziness when they quickly transfer to a supine position, especially when the head is turned to the affected side, but there is less specificity as to the direction of head rotation Bilateral positive response on Hallpike–Dix maneuver with vertigo and geotropic torsional nystagmus on ipsilateral test Hallpike–Dix maneuver may also cause downbeating vertical nystagmus Positive response on straight head-hanging test
Horizontal SCC BPPV	Dizziness is brought on when rolling over in supine but can also occur with flexion and extension of the head or when transferring from supine to upright A bilaterally positive test with a purely horizontal nystagmus on Hallpike–Dix maneuver. The nystagmus will be geotropic beating in the direction of the face turn or downside ear. Nystagmus will occur in both directions but is generally stronger when the head is turned toward the affected side Positive roll test Positive walk–rotate–walk test to affected side
Cervicogenic dizziness	Intermittent positioning-type dizziness Precipitated by head-and-neck movement No latency period: onset of symptoms is immediate upon assuming the provoking position Brief duration but may last minutes to hours Fatigable with repeated motion Associated signs and symptoms: nystagmus, neck pain, suboccipital headaches, sometimes paresthesie in the trigeminal nerve distribution Possible lateral head tilt due to tightness of the sternocleidomastoid or upper trapezius Possible forward head posture Medical history of cervical spine trauma and degeneration Motion dysfunction in the upper cervical segments on AROM and PIVM testing Positive neck torsion test: nystagmus with reproduction of dizziness
Musculoskeletal impairments	Subjective complaints of weakness and unsteadiness Insidious onset Postural deviations negatively affecting the location of the COG in relation to the BOS: trunk flexion, hip flexion, knee flexion, and ankle plantar flexion contractures Decreased trunk extension, hip extension, knee extension, and ankle dorsiflexion on ROM testing Loss of strength and endurance in antigravity muscles Impaired joint position sense lower extremity

BPPV, benign paroxysmal positional vertigo; SCC, semicircular canal; PIVM, passive intervertebral motion.
Data from Huijbregts P, Vidal P. Dizziness in orthopaedic physical therapy practice: history and physical examination. J Man Manip Ther. 2005;13:221–250.

or tinnitus, and brainstem signs can help the clinician differentiate between a central or a peripheral vestibular lesion (Table 3-17).[317] Peripheral vertigo is manifested with general complaints such as unsteadiness and lightheadedness. Central vertigo is usually caused by a cerebellar disorder, an ischemic process, or a disturbance of the vestibular system (Table 3-18). Cervical vertigo, on the other hand, may be produced by localized muscle changes and receptor irritation.[291]

- Dizziness provoked by head movements or head positions could indicate an inner ear dysfunction. Dizziness

TABLE 3-16 Characteristics of Pancerebral Hypoperfusion

Pancerebral Hypoperfusion	Description
Vasovagal presyncope	Parasympathetic hyperactivity causes a decrease in cardiac output with a subsequent decrease in cerebral blood flow Rarely occurs in the recumbent position
Cardiovascular presyncope	Should be suspected when syncope occurs with the patient in a recumbent position, during or after physical activity, or any patient with a known medical history of heart disease
Migraine	Characterized by a headache that is usually unilateral and of a pulsatile quality Nausea, photophobia, vomiting, and lassitude are frequently associated with migraine
Takayasu's disease	Most common in Asian-descent women. Can occur after exercise, standing, or head movement and is associated with impaired vision and confusion.
Carotid sinus syndrome	Pressure on the carotid sinus due to a tight collar or local neck tumor will cause vagal stimulation, leading to bradycardia and subsequent syncope.
Orthostatic hypotension	Syncope and presyncope happen when rapidly rising to a standing position, standing motionless for prolonged periods, and standing after prolonged recumbency.
Hyperventilation	Hyperventilation causes hypocapnia, which in turn results in cerebral vasoconstriction and CNS hypoperfusion.
Cough-related syncope	Syncope (and presyncope) may be caused by an increase in intracranial pressure due to coughing with resultant cerebral hypoperfusion.
Micturition syncope	Episodes occur mainly in men at night before, during, or after micturition. Peripheral blood pooling, vagus-induced bradycardia, and prolonged recumbency are likely responsible.
Glossopharyngeal neuralgia	The result of a glossopharyngeal–vagal reflex circuit causing transient brady-arrhythmia that results in cerebral hypoperfusion.
Hypoglycemia	Asking the patient whether the dizziness occurs mainly when he or she has not eaten may clue in the clinician to hypoglycemia as the cause for the dizziness.

Data from Huijbregts P, Vidal P. Dizziness in orthopaedic physical therapy practice: Classification and pathophysiology. J Man Manip Ther. 2004;12:199–214.

provoked by certain cervical motions, particularly extension or rotation, also may indicate vertebral artery compromise. Dizziness resulting from vertebral artery compromise should be associated with other signs and symptoms, which could include neck pain and nausea. The pain associated with vertebral artery compromise develops on one side of the neck in one-fourth of patients and usually is confined to the upper anterolateral cervical region.[75] Persistent, isolated neck pain may mimic idiopathic carotidynia, especially if it is associated with local tenderness. Pain is also usually the initial manifestation of a carotid artery dissection, and the median time to the appearance of other symptoms is 4 days.[75]

TABLE 3-17 Differential Diagnostic Characteristics of Central Versus Peripheral Vertigo

	Central Lesions	Peripheral Lesions
Vertigo	Often constant Less severe	Often intermittent Severe
Nystagmus	Sometimes absent Uni- or multidirectional May be vertical	Always present Unidirectional Never vertical
Hearing loss or tinnitus	Rarely present	Often present
Brainstem signs	Typically present	Never present

Data from Simon RP, Aminoff MJ, Greenberg DA. Clinical Neurology. 4th ed. Stanford, CT: Appleton and Lange; 1999; Huijbregts P, Vidal P. Dizziness in orthopaedic physical therapy practice: Classification and pathophysiology. J Man Manip Ther. 2004;12:199–214.

- Dizziness associated with tinnitus or a hearing loss could indicate a tumor of CN VIII.
- Dizziness can occur if the calcareous deposits that lie on the vestibular receptors are displaced to new and sensitive regions of the ampulla of the posterior canal, evoking a hypersensitive response to stimulation with certain head positions or movements.[318,319] The Dix–Hallpike test can be used to help determine if the cause of the patient's dizziness is a vestibular impairment (benign paroxysmal positional vertigo, or BPPV—see Chapter 23), resulting from an accumulation of utricle debris (otoconia), which can move within the posterior SCC and stimulate the vestibular sense organ (cupula). This test usually is performed only if the vertebral artery test and cervical instability tests do not provoke

TABLE 3-18 Central Vestibular Disorders

Disorder	Description
Drug intoxication	Many drug intoxication syndromes produce global cerebellar dysfunction including alcohol, sedative hypnotics, anticonvulsants, hallucinogens, and street drugs
Wernicke's encephalopathy	Comprises the diagnostic triad of ataxia, ophthalmoplegia (lateral rectus palsy), and confusion
Inflammatory disorders	Viral cerebellar infections can occur in patients with St. Louis encephalitis, AIDS dementia complex, and meningeal encephalitis
Multiple sclerosis	Rarely the first symptom of multiple sclerosis but is common during the course of the disease
Alcoholic cerebellar degeneration	Usually occurs in patients with a history of 10 or more years of binge drinking
Phenytoin-induced cerebellar degeneration	Long-term treatment with phenytoin (antiepileptic medication) may produce a global cerebellar degeneration
Hypothyroidism	Most common in middle-aged or elderly women Gait ataxia is the prominent finding
Paraneoplastic cerebellar degeneration	Appears to involve antibodies to tumor cell antigens cross-reacting with cerebellar Purkinje cells
Hereditary spinocerebellar degenerations	Autosomal-dominant spinocerebellar ataxias characterized by adult onset, slowly progressive cerebellar ataxia, e.g., Friedrich's ataxia
Ataxia telangiectasia	Autosomal-recessive disorder with an onset before age of 4 yr and global cerebellar involvement
Wilson's disease	A disorder of the copper metabolism with copper deposition in multiple body tissues
Creutzfeldt–Jakob disease	Characterized by dementia, cerebellar signs, and gait ataxia
Posterior fossa tumors	Present with headache, ataxia, nausea, vomiting, vertigo, and CN palsies
Posterior fossa malformations	Type 1 Arnold–Chiari malformation may have cerebellar involvement
Familial paroxysmal ataxia	A hereditary recurrent ataxia associated with nystagmus and dysarthria

Data from Huijbregts P, Vidal P. Dizziness in orthopaedic physical therapy practice: Classification and pathophysiology. J Man Manip Ther. 2004;12:199–214.

symptoms. The test involves having the clinician move the patient rapidly from a sitting to a supine position with the head turned so that the affected ear (provocative position) is 30–45 degrees below the horizontal to stimulate the posterior SCC.[8] The endpoint of the test is when the patient's head overhangs the end of the table, so that the cervical spine is extended (Fig. 3-26). A positive test reproduces the patient's symptoms of vertigo and/or nystagmus.

- Dizziness associated with a recent change in medication is suggestive of an adverse drug reaction.[320]

Strength Testing

A myotome is defined as a muscle or group of muscles served by a single nerve root. Key muscle is perhaps a more accurate term. Manual muscle testing is traditionally used by the clinician to assess the strength of a muscle or muscle group that is representative of the supply from a particular nerve root. Valuable information can be gleaned from these tests, including:

- The amount of force the muscle is capable of producing and whether the amount of force produced varies with the joint angle.
- Whether any pain or weakness is produced with the contraction.
- The endurance of the muscle and how much substitution occurs during the test.

From the neurologic perspective, strength testing assesses the nerve supplying the muscle (Tables 3-19 and 3-20). Muscle weakness, if elicited, may be caused by an UMN lesion (along with spasticity, hyperactive reflexes, etc.), injury to a peripheral nerve, pathology at the neuromuscular junction, a nerve root lesion, or a lesion or disease (myopathy) of the muscle, its tendons, or the bony insertions themselves.[321] Pain, fatigue, and disuse atrophy can also cause weakness. For suspected nerve root lesions, key muscle testing is the method of choice, and the clinician attempts to determine if there are any specific patterns of muscle weakness (weakness in other muscles served by the same nerve root). However, as manual muscle testing was originally developed to examine motor function in patients with polio, a LMN syndrome, its use may be inappropriate for patients with an UMN syndrome. More information about strength testing is provided in Chapter 4.

Reflex Testing

As previously discussed, a reflex is a subconscious, programmed unit of behavior in which a certain type of stimulus from a receptor automatically leads to the response of an

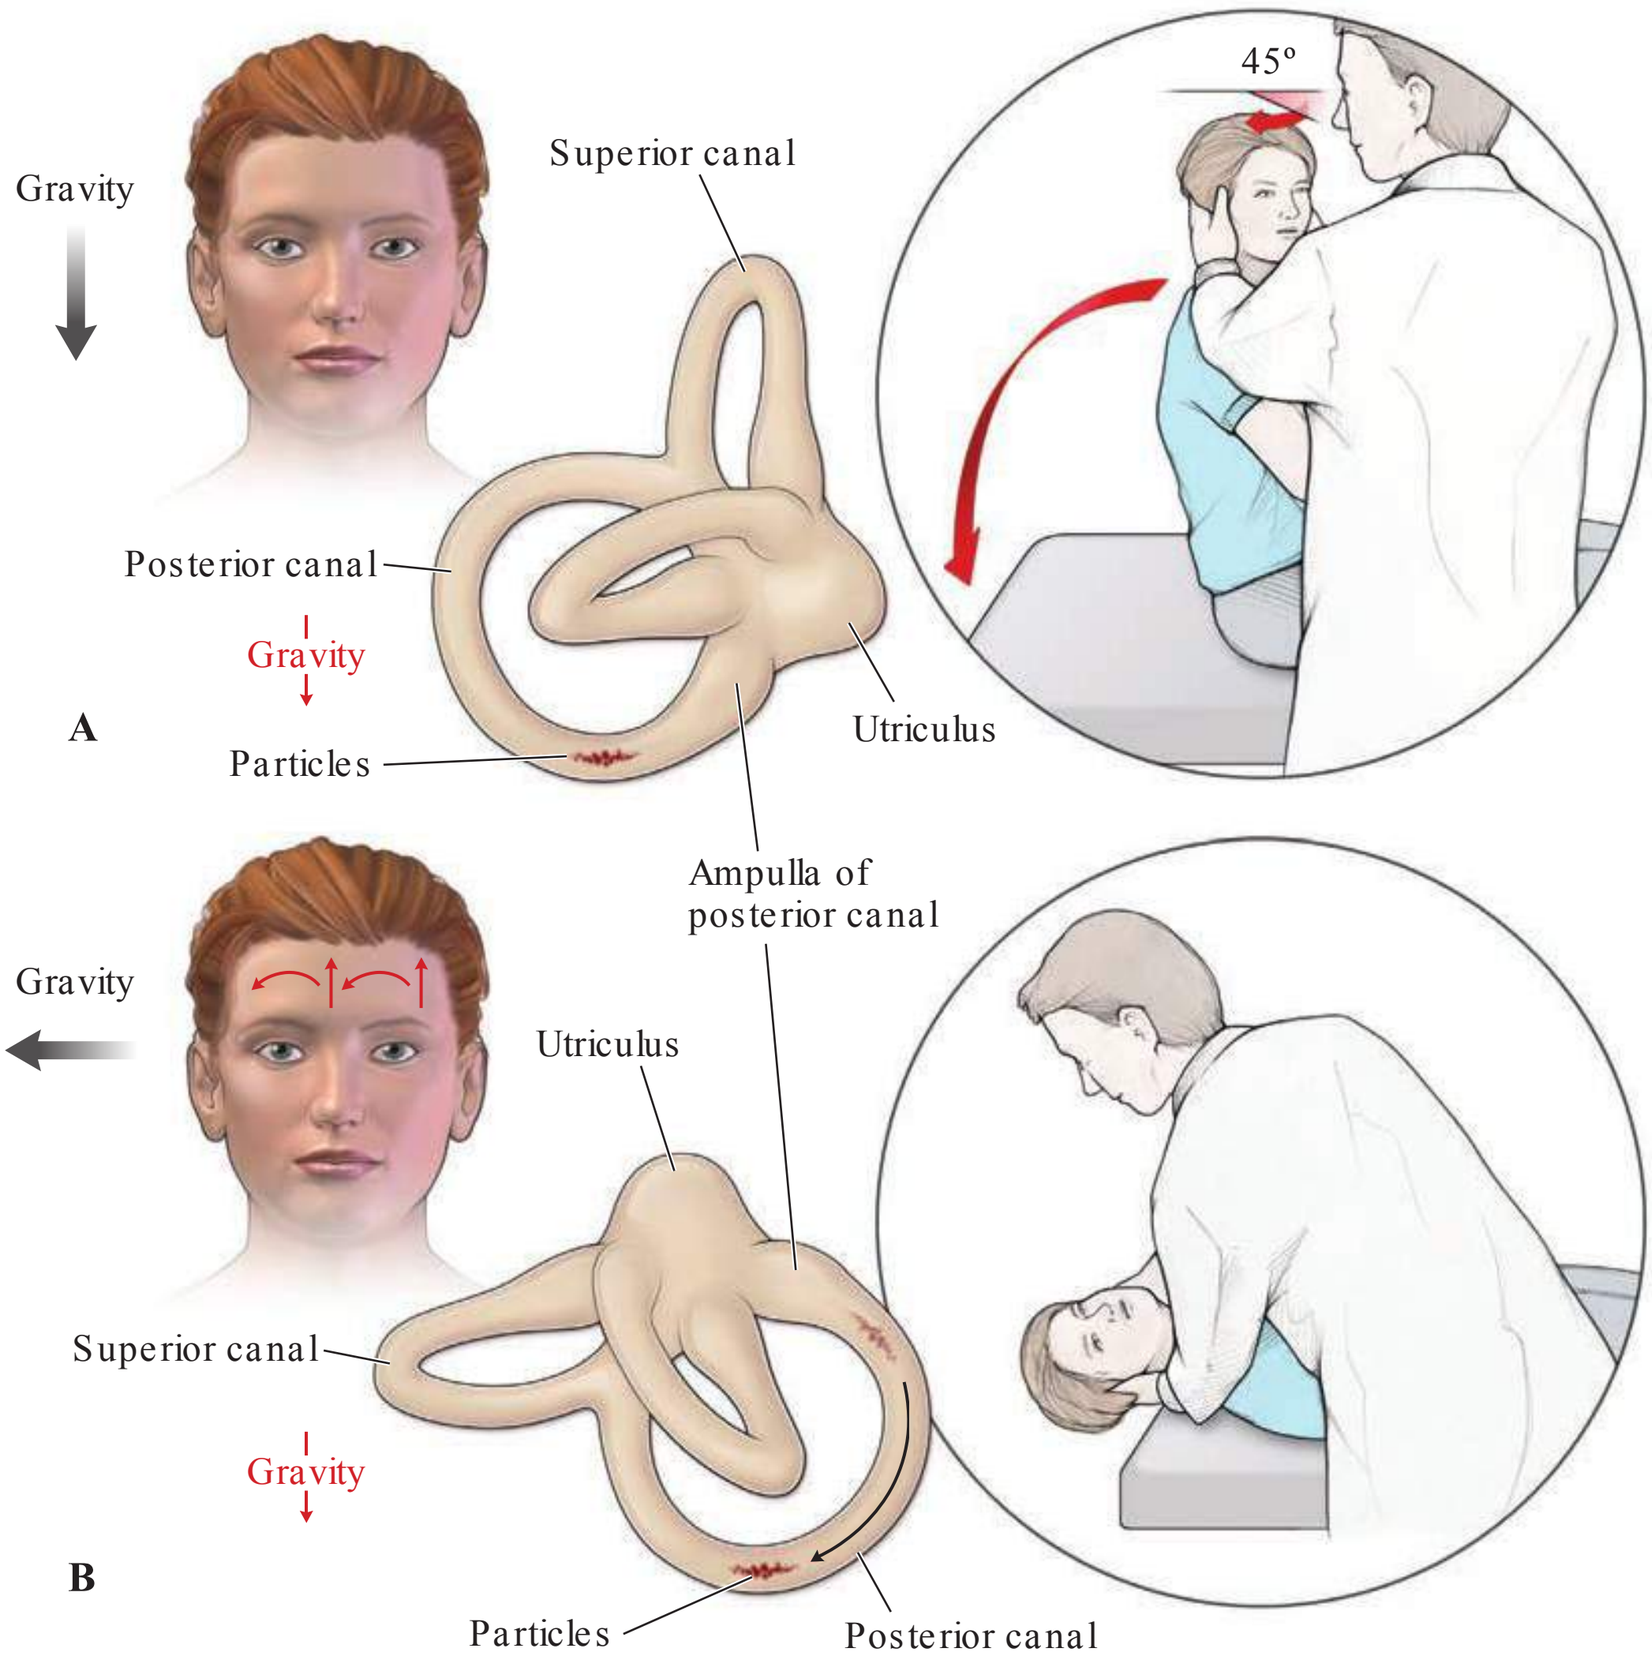

FIGURE 3-26 The Dix-Hallpike maneuver.

effector. The response can be a simple behavior, movement, or activity. Indeed, many somatic and visceral activities are essentially reflexive. The circuitry that generates these patterns varies greatly in complexity, depending on the nature of the reflex, with each influenced by a hierarchy of control mechanisms. The muscle stretch reflex (myotatic or deep tendon) is one of the simplest known reflexes, depending on just two neurons and one synapse,[322] which is influenced by cortical and subcortical input, and from the stimulation of two types of receptors: the GTO and the muscle spindle. Thus, tendon reflex activity depends on the status of the large motor neurons of the anterior horn (alpha motor neurons), the muscle spindles with the afferents fibers, and the small anterior horn cells (gamma neurons) whose axons terminate on the small intrafusal muscle fibers within the spindles.[323]

TABLE 3-19 Evidence-Based Tests Using Manual Muscle Testing to Detect Cervical Radiculopathy

Manual Muscle Test	Reliability (kappa)	Sensitivity	Specificity	LR+	LR−	DOR	QUADAS Score

Cl In ICAl PEARl

Although used extensively, the term deep tendon ref ex is a misnomer because tendons have little to do with the response other than being responsible for mechanically transmitting the sudden stretch from the reflex hammer to the muscle spindle. In addition, in some muscles the stretch reflexes have no tendons.[323]

Muscle stretch reflexes are elicited by a short, sharp tap with the reflex hammer delivered to the tendon of a gently extended muscle. T e physiology of a muscle stretch reflex is described using the quadriceps reflex as an example. T e tap of a reflex hammer on the tendon of the quadriceps femoris muscle, as it crosses the knee joint (Fig. 3-27), causes a brief stretch of the tendon and the muscle belly where the GTO and the muscle spindle are stimulated. Impulses are conducted along the axons of these motor neurons to the neuromuscular junctions, exciting the effectors (quadriceps femoris muscle), and producing a brief, weak contraction, which results in a momentary straightening of the leg (knee jerk).[322] T e stretch reflex can be divided into the following two:

- Dynamic stretch reflex, in which the primary endings and type Ia fibers are excited by a rapid change in length. T e speed of conduction along the type Ia fibers and the monosynaptic connection in the spinal cord ensure that a very rapid contraction of the muscle occurs to control the sudden and potentially dangerous stretch of the muscle. T e dynamic stretch reflex is over within a fraction of a second, but a secondary static reflex continues from the secondary afferent nerve fibers.
- Static stretch reflex. As long as a stretch is applied to the muscle, both the primary and the secondary endings in the nuclear chain continue to be stimulated, causing prolonged muscle contraction for as long as the excessive length of the muscle is maintained, thereby affording a mechanism for prolonged opposition to prolonged stretch.

T e most important observation during reflex examination is the reflex's amplitude.[323] When a load is suddenly removed from a contracting muscle, shortening of the intrafusal fibers reverses both the dynamic and the static stretch reflexes, causing both sudden and prolonged inhibition of the muscle such that rebound does not occur.

Cl In ICAl PEARl

Although several types of reflex hammers are popular today, no study has demonstrated any hammer to be superior to another.

Reflex integrity is defined as the intactness of the neural path involved in a reflex and the assessment of reflexes is extremely important in the diagnosis and localization of neurologic lesions.[1,324] T e testing of the muscle stretch reflex provides the clinician with a direct way of assessing the PNS and an indirect way of examining the CNS. Six of these are regularly tested (Tables 3-21 and 3-22): the biceps (C5), brachioradialis (C6), and triceps (C7) in the upper extremity, and the quadriceps (L4), extensor digitorum brevis (L5–S1), and Achilles (S1) in the lower extremities. It is worth noting that it is dif cult to elicit a reflex response with the extensor digitorum brevis test, which is why it is not often performed.

Cl In ICAl PEARl

The abdominal and cremaster reflexes (superficial skin reflexes) are decreased or absent on the side affected by a corticospinal tract lesion and, thus, serve as adjuncts to the muscle stretch and plantar reflexes.[325]

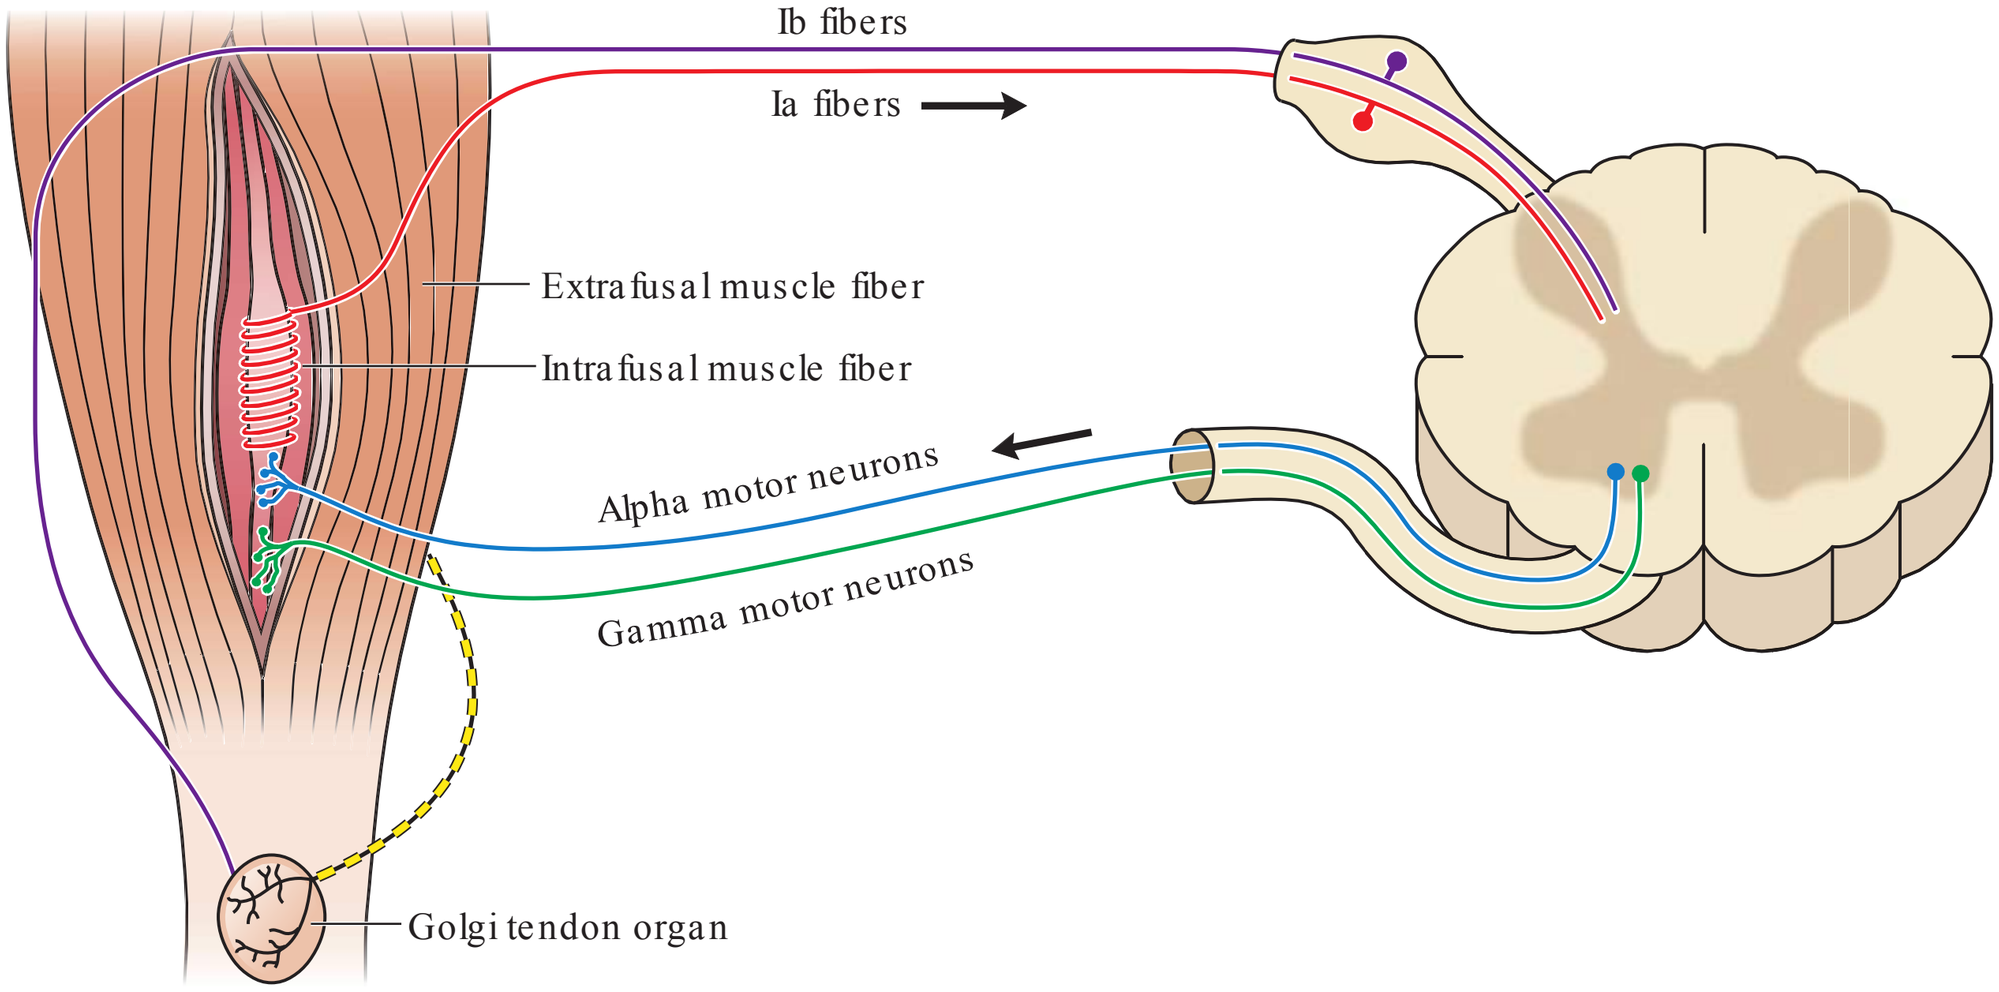

FIGURE 3-27 The physiology of a myotatic reflex.

MUSCl E STRETCH REFl Ex ES

To perform a muscle stretch reflex, the chosen tendon is normally struck directly and smartly with the reflex hammer. An exception is the biceps reflex, which is best tested by tapping the thumb, which has been placed over the tendon. T e limb to be tested should be relaxed and in a flexed or semiflexed position. T e Jendrassik maneuver can be used during testing to enhance a muscle reflex that is dif cult to elicit.[326]

- For the upper extremity reflexes, the patient is asked to cross the ankles and then to isometrically attempt to abduct the legs.
- For the lower extremity reflexes, the patient is asked to interlock the fingers and then to isometrically attempt to pull the elbows apart (Fig. 3-28).

FIGURE 3-28 Jendrassik maneuver used during testing to enhance a muscle reflex.

TABLE 3-21 Common Deep Tendon Reflexes

Ref ex	Site of Stimulus	Normal Response	Pertinent CNS Segment
Jaw	Mandible	Mouth closes	CNV
Biceps	Biceps tendon	Biceps contraction	C5–6
Brachioradialis	Brachioradialis tendon or just distal to musculotendinous junction	Flexion of elbow and/or pronation of forearm	C5–6
Triceps	Distal triceps tendon above olecranon process	Elbow extension	C7–8
Patella	Patellar tendon	Leg extension	L3–4
Medial hamstrings	Semimembranosus tendon	Knee flexion	L5, S1
Lateral hamstrings	Biceps femoris tendon	Knee flexion	S1–2
Tibialis posterior	Tibialis posterior tendon behind medial malleolus	Plantar flexion of foot with inversion	L4–5
Achilles	Achilles tendon	Plantar flexion of foot	S1–2

CN, cranial nerve.

TABLE 3-22 Evidence-Based Neurologic Reflex Tests

Test	Study Description	Reliability	Sensitivity	Specificity	LR+	LR−	DOR	QUADAS Score
Hoffmann's	Retrospective study of 67 patients, seen during a 4-year period, with cervical pathology requiring surgical correction[a]	NT	0	0	0	0	0	6

Clinical Pearl

In the elderly, up to 50% without neurologic disease lack an Achilles reflex bilaterally,[327] and small percentages (3–5%) of normal individuals have generalized hyperreflexia.[328]

Two muscle stretch reflex scales can be used to grade a reflex: National Institute of Neurological Disorders and Stroke (NINDS) scale and the Mayo Clinic scale. The NINDS scale uses the following five-point grading system:

- 0, absent (areflexia). The absence of a reflex signifies an interruption of the reflex arc.
- 1, slight and less than normal (hyporeflexia).
- 2, in the lower half of normal range.
- 3, in the upper half of normal range (brisk).
- 4, enhanced and more than normal (hyperreflexive). Includes clonus if present. A hyperreflexive reflex denotes a release from cortical inhibitory influences.

One of the problems with the NINDS scale is that it does not have a separate category for normal, making it necessary to choose between a low normal and a high normal.

The Mayo Clinic uses the following nine point scale:[329]

- Absent: − 4
- Just elicitable: − 3
- Low: − 2
- Moderately low: − 1
- Normal: 0
- Brisk: + 1
- Very brisk: + 2
- Exhaustible clonus: + 3
- Continuous clonus: + 4

An absent or exaggerated reflex is significant only when it is associated with one of the following:[330]

- The reflex is unusually brisk compared with reflexes from a higher spinal level.
- The exaggerated reflexes are associated with other findings of the UMN disease.
- The absent reflexes are associated with other findings of LMN disease.
- The reflex amplitude is asymmetric. Reflex asymmetry has more pathologic significance than the absolute activity of the reflex—a bilateral patella reflex of 3 is less significant than a 3 on the left and a 2 on the right. Additionally, in cases where the reflex findings are symmetrical, but either elevated or depressed, further investigation is required. For example, a patient presenting with symmetrically brisk patella tendon and Achilles stretch reflexes, while simultaneously having absent stretch reflexes in the upper extremity, requires further investigation (this is a typical finding with amyotrophic lateral sclerosis or Lou Gehrig disease, a mixed UMN and LMN pathology).[312]

The findings from the muscle reflex testing can occur as a generalized, or local, phenomenon:

- Generalized hypore*fl*exia. The causes of generalized hyporeflexia run the gamut from neurologic disease, chromosomal metabolic conditions, and hypothyroidism to schizophrenia and anxiety.[228]
- Nongeneralized hypore*fl*exia. Generally, an asymmetrically depressed or absent reflex is suggestive of pathology that is impacting the reflex arc directly, such as a LMN lesion or sensory paresis, which may be segmental (root), multisegmental (cauda equina), or nonsegmental (peripheral nerve). Nongeneralized hyporeflexia can result from peripheral neuropathy, spinal nerve root compression, and cauda equina syndrome. It is thus important to test more than one reflex and to evaluate the information gleaned from the examination, before reaching a conclusion as to the relevance of the findings.

In those situations demonstrating an elevated or brisk reflex, the CNS's normal role of integrating reflexes may have been disrupted, indicating an UMN lesion, such as a brain stem or cerebral impairment, spinal cord compression, or a neurologic disease. However, the distinction has to be made between a brisk reflex and the one that is hyperreflexive. True neurological hyperreflexia contains a clonic component and is suggestive of CNS (UMN) impairment. The clinician also should note any additional recruitment that occurs during the reflex contraction of the target. A brisk reflex is a normal finding, provided that it is not masking a hyperreflexia caused by an incorrect testing technique. Unlike hyperreflexia, a brisk reflex does not have a clonic component. As with hyporeflexia, the clinician should assess more than one reflex before coming to a conclusion about a hyperreflexia. The presence of an UMN impairment can be confirmed by the presence of the pathologic reflexes (see next section).

Cl In ICAl PEARl

Even though muscle stretch reflexes have long been assumed to be good objective signs, the interrater reliability of muscle stretch reflex grading for the same subject is quite variable and subjective due to both patient and physician factors.[329,331]

Pathologic Reflexes

There are two basic pathologic reflexes: the Babinski and its variants (Chaddock, Oppenheim, Gordon, etc.) and the Hoffman and its variants (ankle and wrist clonus) (Table 3-23). A number of primitive reflexes are normally integrated by individuals as they develop. Pathologic reflexes occur when an injury or a disease process results in a loss of this normal suppression by the cerebrum on the segmental level of the brain stem or the spinal cord, resulting in a release of the primitive reflex.[332] Thus, the presence of pathologic reflexes is suggestive of CNS (UMN) impairment and requires an appropriate referral.

- **Babinski.** In this test, the clinician applies noxious stimuli to sole of the patient's foot by running a pointed object along the plantar aspect (Fig. 3-29).[333] A positive test, demonstrated by extension of the great toe (extensor toe sign) and a splaying (abduction) of the other toes, is indicative of an injury to the corticospinal tract.[334–336] A negative finding is slight toe flexion, smaller digits greater than the great toe. As Babinski observed,[334] the pyramidal tracts are not well developed in infants, and these signs, which are abnormal past the age of 3 years, are usually present.
- **Gonda–Allen.** The Gonda–Allen sign is a variant of the Babinski. The patient is positioned in supine. Grasping the patient's foot, the clinician provides a forceful downward stretch or snaps the distal phalanx of the second or fourth toe (Fig. 3-30). A positive response is the extensor toe sign.[337] The Gonda–Allen method is considered more sensitive than the classic Babinski method.[338]
- **Allen–Cleckley.** The Allen–Cleckley sign is another variant of the Babinski. The set up is exactly the same as for the Gonda-Allen test. The clinician provides either a sharp upward flick of the second toe or pressure over the distal aspect or ball of the toe (Fig. 3-31). A positive response is the extensor toe sign.[338]

TABLE 3-23 Pathologic Reflexes

Reflex	Eliciting Stimulus	Positive Response	Pathology
Babinski	Stroking of lateral aspect of side of foot	Extension of big toe and fanning of four small toes; normal reaction in newborns	Pyramidal tract lesion; organic hemiplegia
Chaddock	Stroking of lateral side of foot beneath lateral malleolus	Same response as above	Pyramidal tract lesion
Oppenheim	Stroking of anteromedial tibial surface	Same response as above	Pyramidal tract lesion
Gordon	Squeezing of calf muscles firmly	Same response as above	Pyramidal tract lesion
Brudzinski	Passive flexion of one lower limb	Similar movement occurs in opposite limb	Meningitis
Hoffmann	"Flicking" of terminal phalanx of the index, middle, or ring finger	Reflex flexion of distal phalanx of the thumb and of distal phalanx of the index or middle finger (whichever one was not "flicked")	Increased irritability of sensory nerves in tetany; pyramidal tract lesion
Lhermitte	Neck flexion	Electric shock-like sensation that radiates down spinal column into upper or lower limbs	Abnormalities (demyelination) in posterior part of cervical spinal cord

- **Oppenheim sign.** The patient is positioned in supine. The clinician applies noxious stimuli along the shin of the patient's tibia by running a fingernail downward toward the foot (Fig. 3-32). A positive test, demonstrated by the extensor toe sign, is theoretically indicative of UMN impairment. However, the diagnostic value of this test is as yet unknown.[339]
- **Chaddock sign.** The patient is positioned in supine or sitting. The clinician strokes the lateral malleolus from proximal to distal with a solid, relatively sharp object (Fig. 3-33). A positive response is the extensor toe sign. The diagnostic value of this test is as yet unknown.[339]
- **Schaefer sign.** The patient is positioned in supine or sitting. The clinician provides a sharp, quick squeeze of the Achilles tendon (Fig. 3-34). A positive response is the extensor toe sign. This test remains unstudied for diagnostic value.
- **Hoffmann.** The Hoffmann sign, also referred to as the digital reflex, the snapping reflex, Tromner sign and Jakobson sign, is the upper limb equivalent of the Babinski. However, unlike the Babinski, some normal individuals can exhibit a Hoffmann sign.[325] The clinician holds the patient's middle finger and briskly pinches the distal phalanx, thereby applying a noxious stimulus to the nail bed of the middle finger (Fig. 3-35).[325] A positive test is adduction and opposition of the thumb and slight flexion of the fingers. There are no known studies assessing the interexaminer reliability of this test (Table 3-18), and its significance remains disputed in the literature. Denno and Meadows[340] devised a dynamic version of this test to assist in the diagnosis of early spondylotic cervical myelopathy, which involved the patient performing repeated flexion and extension of the head before being tested for the Hoffmann sign.
- **Cross up going toe sign.** This is another variation of the Babinski. The patient is positioned in supine. The clinician passively raises the opposite limb into hip flexion

FIGURE 3-29 Babinski.

FIGURE 3-30 Gonda–Allen sign.

FIGURE 3-31 Allen–Cleckley sign.

FIGURE 3-33 Chaddock sign.

(Fig. 3-36) and then instructs the patient to hold the leg in flexion while the clinician applies a downward force on the leg. A positive test is associated with great toe extension of the opposite leg during resistance the hip flexion. Of the few studies of this test, Willoughby and Eason[341] found the test to have little value as a sensitive indicator of a pyramidal tract lesion in 125 normal subjects and 192 patients with neurological disorders due to the high frequency of false positive signs in normal subjects and patients with other neurological disorders.

- **Clonus.** The patient is positioned in supine or sitting. The technique can be applied to the wrist (sudden wrist extension) or to the ankle (sudden dorsiflexion) (Fig. 3-37). The stretch is then maintained. A positive response is more than three involuntary beats of the ankle or wrist (two to three twitches are considered normal). In some patients, there is a more sustained clonus; in others, there is only a very short-lived finding. During the testing, the patient should not flex the neck, as this can often increase the number of beats. A positive test is theoretically indicative of UMN impairment, but the diagnostic value of this test is as yet unknown.

Other pathological reflexes include:

- **Inverted radial (supinator) reflex.** The inverted radial reflex sign, introduced by Babinski, is commonly used in clinical practice to assess cervical myelopathy. There are

FIGURE 3-34 Schaefer sign.

FIGURE 3-32 Oppenheim sign.

FIGURE 3-35 Hoffman reflex.

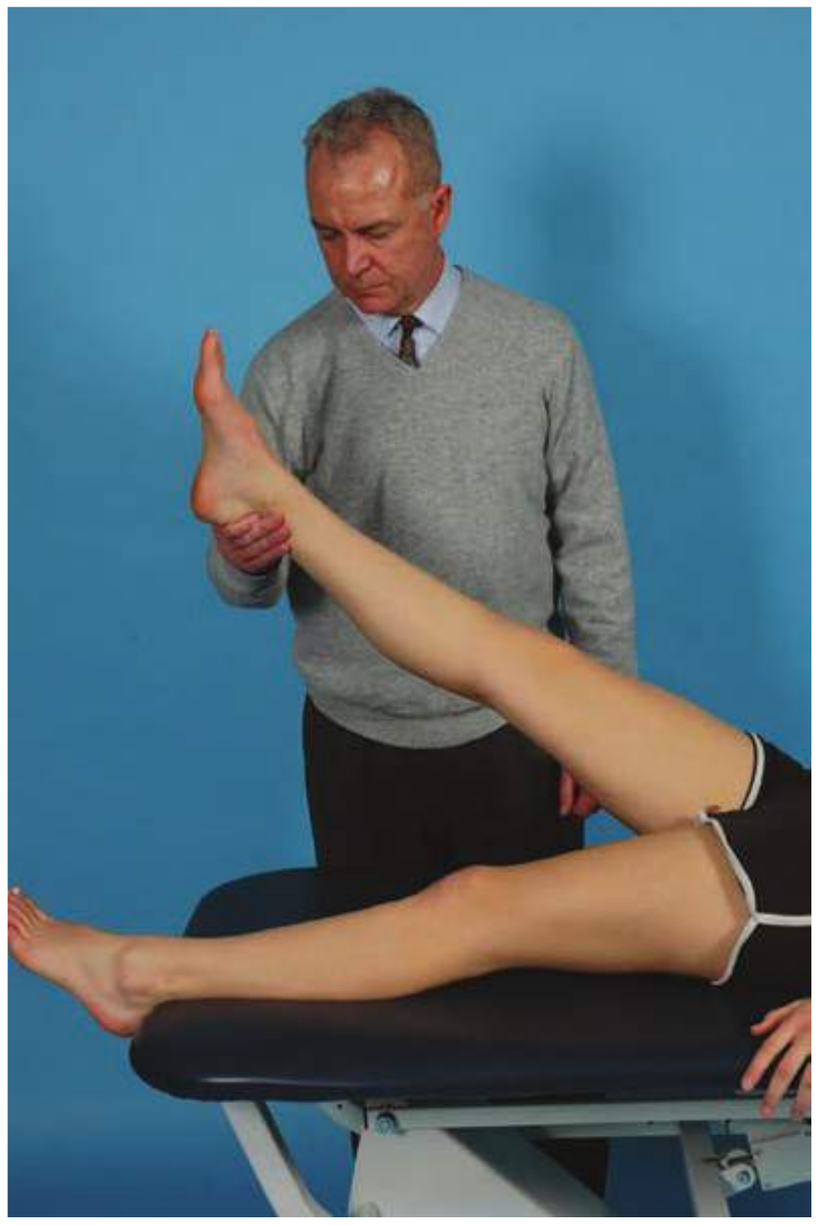

FIGURE 3-36 Cross up going toe sign.

two components of this abnormal reflex: (1) an absence of contraction of the brachioradialis muscle when the styloid process of the radius is tapped (Fig. 3-38), and (2) a hyperactive response of the finger flexor muscles (Fig. 3-38); a response that is subserved by a lower spinal

FIGURE 3-37 Clonus.

FIGURE 3-38 Inverted radial (supinator) reflex.

cord segment (C8).[342] To date, it is unknown whether the sign correlates with the presence or severity of myelopathy. Indeed, an isolated, inverted supinator reflex may be a variation of a normal clinical examination.[343] Theoretically, a true response is likely related to increased alpha motor neuron excitability below the level of the lesion; however, a possible contribution of the dynamic muscle spindles cannot be excluded.

- **Finger escape sign.** The patient is positioned in sitting. The clinician asks the patient to hold all of his/her fingers in extension and adduction. A positive sign involves the involuntary flexion and abduction within 1 minute of the extended and adducted fingers when held statically. To date there has only been one study[344] that examined the sensitivity of the finger escape sign, which identified a sensitivity of 55% in a sample of 36 subjects with myelopathy.
- **Palmomental reflex.** The patient is positioned in supine or sitting. A number of methods to elicit this reflex have been advocated. The clinician may stroke the thenar eminence of the hand in a proximal to distal direction with a reflex hammer (Fig. 3-39) or may stroke the hypothenar eminence in a similar fashion. The procedure can be repeated up to five times to detect a continuous response. If the response diminishes, the test is considered

FIGURE 3-39 Palmomental reflex.

negative. A positive test is contraction of the mentalis and orbicular oris muscles causing wrinkling of the skin of the chin and slight retraction (and occasionally elevation of the mouth). A study by Owen and Mulley[345] found that the reflex is often present in normal people and may be absent in disease states. T e study concluded that testing merely for the presence or absence of the reflex lacks both specificity and sensitivity, but that a strong, sustained, and easily repeatable contraction of the mentalis muscle, which can be elicited by stimulation of areas other than the palm, is more likely to indicate cerebral damage. Another study[346] found diagnostic value in using combinations of two or three pathologic reflexes to distinguish between neurologically damaged patients and normal age-matched controls.

- **Beevor sign.** T e patient is positioned in supine, with the knees flexed and both feet flat on the bed. T e patient is asked to raise the head against resistance, cough, or attempt to sit up with the hands resting behind the head.[347] T e clinician observes for motion at the umbilicus, which should remain in a straight line. Beevor sign, an upward deflection of the umbilicus on flexion of the neck, is the result of paralysis of the inferior portion of the rectus abdominis muscle, so that the upper fibers predominate, pulling the umbilicus upward. T e condition may be caused by spinal cord injury at or below the level of T10.[300]

Cl In ICAl PEARl

Beevor sign is a common finding in patients with facioscapulohumeral dystrophy, even before functional weakness of abdominal wall muscles is apparent, but is absent in patients with other facioscapulohumeral disorders.[348]

- **Lhermitte symptom or "phenomenon."** T is is not so much a pathologic reflex as it is a symptom, described as an electric shock-like sensation that radiates down the spinal column into the upper or the lower limbs with flexion of the neck with the patient in the long sit position (Fig. 3-40). It may also be precipitated by extending the head, coughing, sneezing, bending forward, or moving the limbs.[349] Lhermitte's sign is most prevalent in patients with multiple sclerosis,[350] cervical spondylotic myelopathy, cervical radiation injury, and neck trauma.[351] Smith and McDonald[352] postulated that there is an increased mechanosensitivity to traction on the cervical cord of injured axons located within the posterior (dorsal) columns. Although a herniated disk is an anteriorly placed lesion and the spinothalamic tract is usually more affected than the posterior columns, flexion of the neck will produce stretching of the posterior aspects of the cord, but not the anterior part at the site of the impairment, and this may explain this particular symptom. To date, there are no reports investigating the interexaminer reliability of this test. One study[353] reported a sensitivity of 27%, specificity of 90%, positive predictive value of 55%, and negative predictive value of 75% for the active flexion and extension test, which partly resembles this test.
- **Mendel Bechtrew sign.** T e patient is positioned in supine or sitting. T e clinician taps on the dorsal aspect of the cuboid bone using the sharp end of a reflex hammer (Fig. 3-41). A positive response is flexion of the four lateral toes. T is test remains unstudied for diagnostic value.

Supraspinal Reflexes

T e supraspinal reflexes produce movement patterns that can be modulated by descending pathways and the cortex. A number of processes, which are involved in locomotor function, are oriented around these reflexes and are referred to as righting reflexes. Righting reflexes can be subcategorized as the following: visual righting reflexes, labyrinthine righting reflexes, neck righting reflexes, body on head righting reflexes, and body on body righting reflexes. T e primary purpose of the righting reflexes is to maintain a constant position of the head in relation to a dynamic external environment.

T e head and the neck are areas of intense reflex activity. Head movements, which occur almost constantly, must be regulated to maintain normal eye–head–neck–trunk relationships and to allow for visual fixation during head movements (Table 3-24). T e visual field and pathway are important regulators of postural control. Visual input for postural control helps fixate the position of the head and the upper trunk in

FIGURE 3-40 Lhermitte symptom.

FIGURE 3-41 Mendel Bechtrew sign.

TABLE 3-24 Reflex Activities Involving the Cervical Spine

Reflex	Eliciting Stimulus	Motor Response	Purpose
Tonic neck reflex	Neck movement that produces stretch to muscle spindles	Alteration of muscle tone in trunk and extremities	Assists with postural stability and enhances coordination
Cervicocollic reflex	Neck movement that produces stretch to muscle spindles	Eccentric contraction of the cervical muscles that oppose the initiating movement	Maintains smooth and controlled cervical movement
Cervicorespiratory reflex	Neck movement that produces stretch to muscle spindles	Alteration in respiratory rate	Assists in adjustments of respiration with changes in posture
Cervicosympathetic reflex	Neck movement that produces stretch to muscle spindles	Alteration in blood pressure	Assists in prevention of orthostatic hypotension with changes in posture
Trigeminocervical reflex	Touch stimulus to face	Head retraction	Protects against blows to face
Cervico-ocular reflex	Neck movement that produces stretch to muscle spindles	Movement of eyes in opposite direction of neck movement	Maintains gaze fixation during movements of head
Vestibulo-ocular reflex	Head movement stimulating semicircular canals	Movement of eyes in opposite direction of head movement	Maintains gaze fixation during movements of head
Smooth pursuit	Visual target moving across retinal field	Movement of eyes in the direction in which target is moving	Maintains gaze fixation on moving target
Saccades	New visual target in retinal field	Movement of eyes in the direction of new target	Fixates eyes on new target
Optokinetic reflex	Visual target moving across retinal field, causing perceived movement of head	Movement of eyes in opposite direction of perceived head movement	Maintains gaze fixation on moving target

space, primarily so that the COG of the trunk maintains its position over the well-defined limits of foot support. Aside from the visual field itself providing an important source of postural control, the extraocular muscles may also provide proprioceptive information through two distinct pathways into the oculomotor nuclei, one serving to generate eye rotations, while the other providing sensory information regarding eye alignment and stabilization.[354,355]

While the visual and vestibular systems are individually two of the most important providers of information, it is their constant interaction with each other and with cervical mechanoreceptors (particularly the short-range rotators, i.e., the obliquus capitis posterior inferior, rectus capitis posterior major, splenius capitis, and SCM) that makes the control of upright posture possible, especially when considering their combined role in the reflex modulation of muscular tone through various groups of postural muscles:[356]

- **Vestibulo-ocular reflex (VOR).** The VOR is stimulated by movement of the head in space and creates certain eye movements that compensate for head rotations or accelerations. The VOR may be subdivided into three major components:
  - The rotational VOR, which detects head rotation through the SCC.
  - The translational VOR, which detects linear acceleration of the head via the utricle and saccule.
  - The ocular counter-rolling response, or optokinetic reflex, which adapts eye position during head tilting and rotation.

The VOR can be tested in a number of ways:

- **Dynamic visual acuity.**[320] After establishing baseline visual acuity with a Snellen chart, this test measures visual acuity with concurrent head movement. The patient's head is moved from side to side at a frequency of 1 Hz while the patient reads the Snellen chart. A decrease by two lines is suspicious and, by three or more, is indicative of an abnormal VOR.
- **Doll's head test.**[320] The clinician faces the patient, who fixes gaze on the clinician's nose. The clinician then oscillates the patient's head 30 degrees side to side at 0.5–1 Hz. Eye movements that are not smooth but interrupted by saccades toward the fixation target indicate bilateral vestibular lesions.
- **Head-shaking nystagmus test.**[320] The clinician holds the patient's head firmly, with the palms of the hands against the patient's cheeks, and produces a series of rapid but small horizontal head turns for approximately 30 seconds, with the patient's eyes closed. Upon opening the eyes, the nystagmus will beat away from the side of a unilateral peripheral vestibular lesion, or toward the lesioned side in patients with Ménière disease.

- **Head-thrust test.**[320] The patient fixates gaze on the clinician's nose. The clinician then moves the patient's head in a horizontal plane in a rapid, passive manner with unpredictable timing and direction. If the reflexive movement of the eyes is inappropriate (too big or too small), a corrective (saccadic) movement will occur. A patient with vestibular loss will have difficulty in maintaining gaze fixation, requiring a corrective saccade (fast eye movement) to maintain gaze fixation on the nose. Presence of this corrective action may indicate a lesion of the vestibular nerve.[357]
- **The cervico-ocular reflex.** The cervico-ocular reflex serves to orient eye movement to changes in neck and trunk position. Visual fixation at high speeds requires the contraction of the extraocular muscles to allow eye movements to counteract the effect of the head movements, even if the head is turning in the opposite direction. The ability to track and focus on a moving target that is moving across a visual field is termed smooth pursuit and requires a greater degree of voluntary control than the cervico-ocular and VORs can provide. The area in the brain stem where this integration of horizontal eye movements takes place is the paramedian pontine reticular formation. The ability to read a book or to scan a page requires saccadic eye movements. Unlike smooth pursuit, saccades can occur with a visual stimulus, by sound, verbal command, or tactile stimuli. However, like smooth pursuit, saccades are generated in the paramedian pontine reticular formation. The cervico-ocular reflex can be tested using three methods:
  - Visual *fix*ation. The patient is seated and is asked to look straight ahead and focus on the tip of a pencil, which is held by the clinician at an arm's length from the patient. The test is repeated, with the patient's eyes turned to the extremes of horizontal and vertical gaze and the pencil tip positioned accordingly.
  - Smooth pursuit can be tested by having the patient fix his or her gaze on an object placed directly in front. The object is then moved to the right, while the patient follows it with the eyes. The clinician looks to see if the patient has any difficulty tracking the object. An abnormal response is observed if the patient's fixation on the target moving synchronously with the head is interrupted by rapid eye movements or saccades, which indicates that the pursuit is not holding the eye on the moving target. The object is moved back to the start position before being moved to the left, while the patient again follows it with the eyes. The object can then be moved in various directions, combining horizontal, vertical, and diagonal movements, to test if the patient can follow the object with the eyes without saccadic movements.
  - Saccade test. The patient is asked to rapidly move the eyes back and forth between two widely spaced targets while keeping the head still. An abnormal finding is if the patient takes multiple eye movements, rather than a single jump, to exactly fix on a target.

Difficulty with these tests may indicate a lesion of the cerebellum, reticular formation, cerebral cortex, or a CN lesion (oculomotor, trochlear, or abducens).[357]

- **The cervicocollic reflex (CCR).** The CCR serves to orient the position of the head and the neck in relation to disturbed trunk posture. Acting similarly to a stretch reflex, this reflex involves reflexive correction of cervical spine position through cocontraction of specific cervical muscles.
- **The vestibulocollic reflex (VCR).** The VCR maintains postural stability by actively stabilizing the head relative to space, through reflexive contraction of those cervical muscles opposite to the direction of cervical spine perturbation. It should be noted that this reflex is distinct and largely dissociated from the vestibulospinal reflex, which orients the extremities to the position of the head and the neck.[356]

The CCR and VCR reflexes appear perfectly suited through their dynamic and somatotopic characteristics to compensate for positional disturbances of the head and the neck with respect to the trunk.[358–360]

Sensation and Sensibility Testing

Sensation is the conscious perception of basic sensory input. Sensibility describes the neural events occurring at the periphery, nerve fibers, and nerve receptors. Sensation is what a clinician re-educates, whereas sensibility is what a clinicians assesses.[361] The assessment of sensibility involves an understanding of the entire peripheral and central sensory pathways from the skin to the thalamus.

Altered sensory perceptions can result from injuries to peripheral nerves or from spinal nerve root compression. The posterior (dorsal) roots of the spinal nerves are represented by restricted peripheral sensory regions called dermatomes (Fig. 3-42). The peripheral sensory nerves are represented by more distinct and circumscribed areas (see Fig. 3-42). Paresthesia is a symptom of direct involvement of the nerve root. Paresthesia can be defined as an abnormal sensation of pins and needles, numbness, or prickling. Further irritation and destruction of the neural fibers interfere with conduction, resulting in a motor or sensory deficit, or a combination of both. It is, therefore, possible for a nerve root compression to cause pure motor paresis, a pure sensory deficit, or both, depending on which aspect of the nerve root is compressed. If pressure is exerted from above the nerve root, sensory impairment may result, whereas compression from below can induce motor paresis. Pain results if there is irritation of the neural fibers. In general, if a patient has a sensory deficit involving a peripheral nerve, he or she is able to accurately localize the area of anesthesia.[362] Sensory or sensibility testing examines the integrity and the intactness of cortical sensory processing, including proprioception, pallesthesia (the ability to sense mechanical vibration), stereognosis (the ability to perceive, recognize, and name familiar objects), and topognosis (the ability to localize exactly a cutaneous sensation).[324]

Two types of sensibility can be assessed:[363]

- Protective. This is evidenced by the ability to perceive pinprick, touch, and temperature.
- Functional. This is evidenced by a return of sensibility to a level that enables the hand to engage in full ADLs.

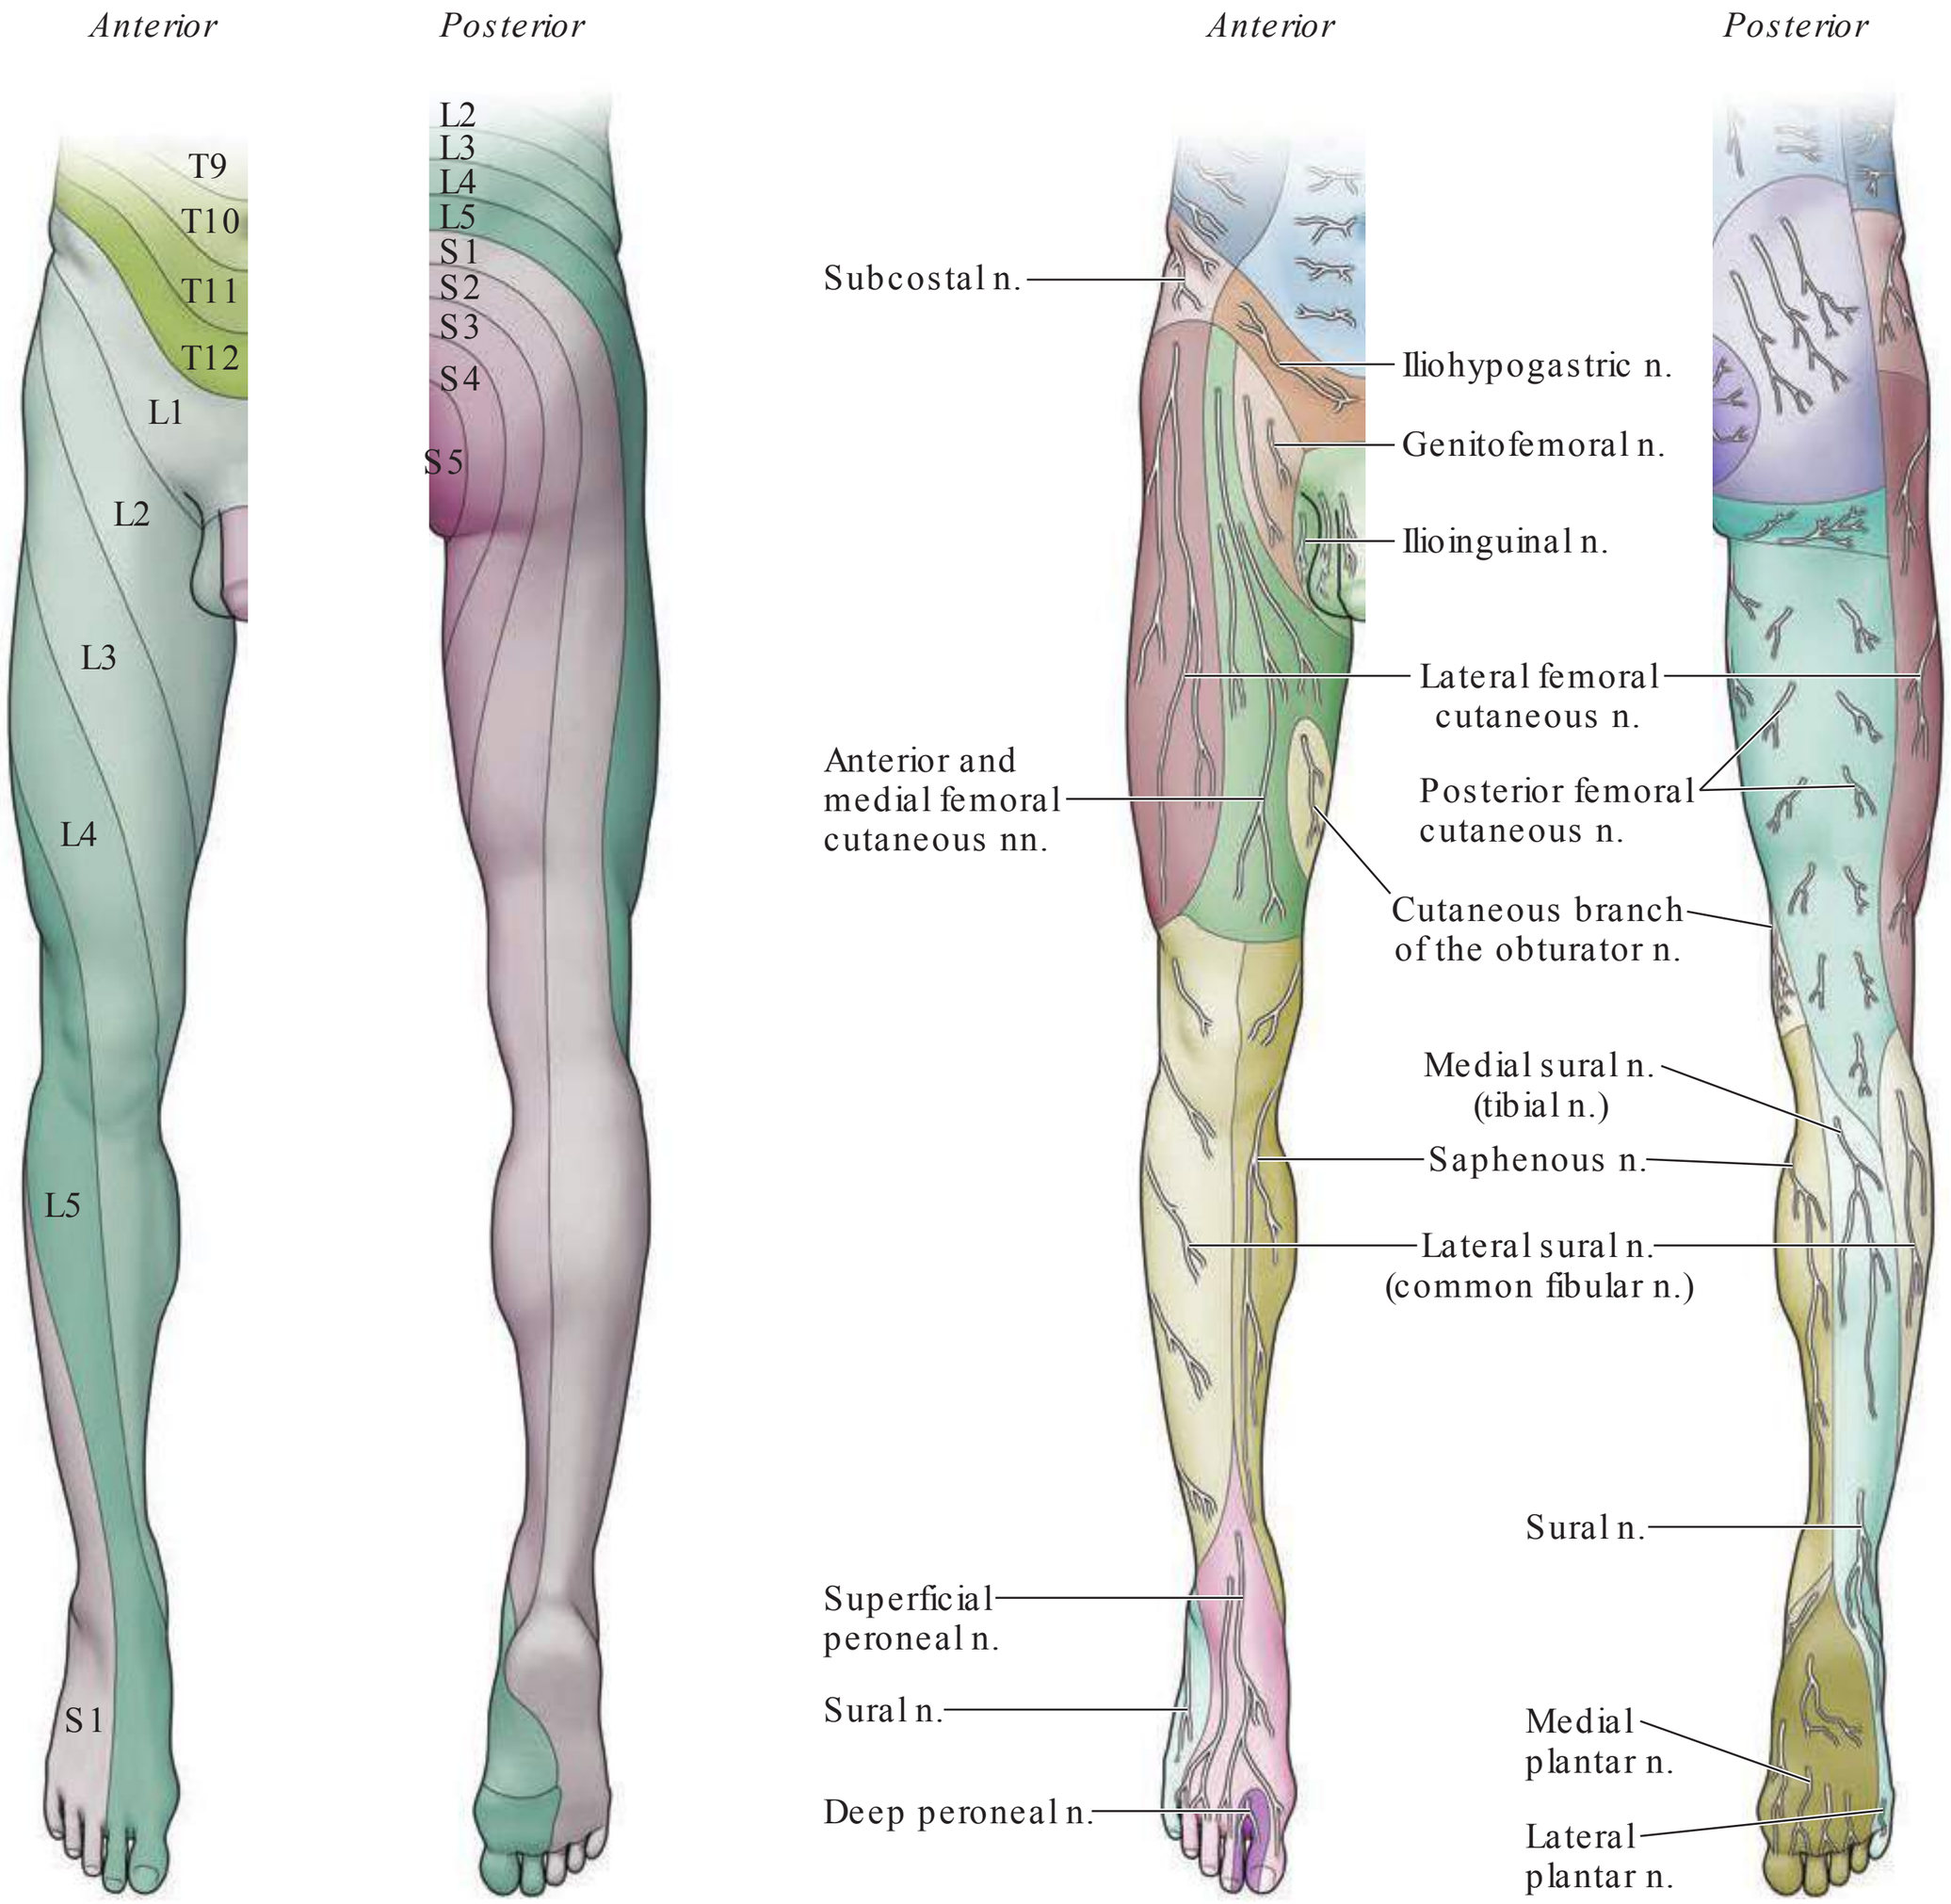

FIGURE 3-42 Approximate lower extremity dermatomes. (Reproduced, with permission, from Chapter 34. Overview of the Lower Limb. In: Morton DA, Foreman K, Albertine KH. eds. The Big Picture: Gross Anatomy. New York, NY: McGraw-Hill; 2011.)

Clinical Pearl

There exists a hierarchy of sensibility capacity[363,364]:

- Detection. This is the simplest level of function and requires that the patient be able to distinguish a single-point stimulus from normally occurring atmospheric background stimulation.
- Innervation density or discrimination. This represents the ability to perceive that stimulus A differs from stimulus B.
- Quantification. This involves organizing tactile stimuli according to degree, texture, etc.
- Recognition. This is the most complicated level of function, and involves the identification of objects with the vision occluded.

Based on the hierarchy of sensibility capacity, testing is classified neurophysiologically into four types: threshold tests, stress tests, innervation density tests, and sensory nerve conduction studies.[365]

- Threshold tests. Examples of threshold tests include vibratory testing and Semmes–Weinstein monofilament testing (see Specific Sensory Tests).
- Stress tests. Stress tests are those that combine the use of sensory tests with the activities that provoke the symptoms of nerve compression. These tests are helpful in cases of patient reports of mild nerve compression when no abnormalities are detected by baseline sensory testing. Examples of stress tests include the Phalen's test at the wrist (see Chapter 18).

- Innervation density tests. T ese are a class of sensory tests that test the ability to discriminate between two identical stimuli placed close together on the skin. T ese tests are helpful in assessing sensibility after nerve repair and during nerve regeneration (see Specific Sensory Tests).[366]
- Sensory nerve conduction studies. Sensory nerve conduction studies are electrophysiologic tests that assess the conduction of sensory action potentials along a nerve trunk.[365] T ese tests require only passive cooperation of the patient, not subjective interpretation of a stimulus. A slowing of nerve conduction velocity or an alteration in potential amplitudes indicates a compression or partial laceration of the nerve.[10]

A full examination of the sensory system involves specific testing of pain, temperature, pressure, vibration, position, and discriminative sensations. For patients with no apparent neurologic symptoms or signs, an abbreviated examination may be substituted.

Specif c Sensory Tests

Sensation

- **Origin.** Lateral spinothalamic tract (see Box 3-2).

  T e segmental innervation of the skin has a high degree of overlap, especially in the thoracic spine, requiring that the clinician tests the full area of the dermatome. T is is done to seek out the area of sensitivity, or autogenous area, which is a small region of the dermatome with no overlap, and the only area of a dermatome that is supplied exclusively by a single segmental level.[367] T ere are two components to the dermatome tests:

- Light touch. Information about light touch, two-point discrimination, vibration, and proprioception are carried by the posterior (dorsal) column–medial lemniscal tract. Light touch tests for hypoesthesia throughout the dermatome. In terms of sensation loss, light touch is the most sensitive and the first to be affected with palsy. If the light touch test is positive, the areas of reduced sensation are mapped out for the autogenous area, and then the pinprick test is performed to map out the whole of the autogenous area.[8] T e use of a vibrating tuning fork has been found to be a valid and reliable test of the functional integrity of the large myelinated nerve fibers.[368]
- Pinprick. Information about pain is carried by the lateral spinothalamic tract (see Box 3-2). T e pinprick test examines for near anesthesia in the autonomous, no overlap area. T is test is performed using a sharp safety pin, occasionally substituting the blunt end for the point as a stimulus. Pinprick testing is the most common way of determining the sensory "level" caused by a spinal cord lesion, because information about pain, temperature, and crude touch is carried by the spinothalamic tract.[326] When investigating an area of cutaneous sensory loss, it is recommended that the clinician begins the pinprick test in the area of anesthesia and works outward until the border of normal sensation is located.[313] T e clinician stimulates in the aforementioned patterns and asks the patient "Is this sharp or dull?" or, when making comparisons using the sharp stimulus, "Does this feel the same as this?"(Note: It is important that the clinician uses as light a touch as the patient can perceive and not, under any circumstances, presses hard enough to draw blood). Pinprick sensation is dif cult to test because of the natural variations in the pressure put on the pin and the sensitivity of different parts of the skin.

Table 3-25 outlines some of the studies that have been performed to assess the reliability, sensitivity, and specificity of various sensibility tests in detecting radiculopathy.

TABLE 3-25 Sensibility Testing for Radiculopathy

Nerve or Dermatome Tested	Method	Reliability (kappa)	Sensitivity	Specificity	LR+	LR–	DOR	QUADAS Score
Axillary	Light touch[a]	0.69	NT	NT	NA	NA	NA	NA
Musculocutaneous	Light touch[a]	0.67	NT	NT	NA	NA	NA	NA
Radial	Light touch[a]	0.31	NT	NT	NA	NA	NA	NA
Median	Light touch[a]	0.73	NT	NT	NA	NA	NA	NA
Ulnar	Light touch[a]	0.59	NT	NT	NA	NA	NA	NA
C5	Pinprick[b]	0.67	29	86	2.07	0.82	2.51	10
C6	Pinprick[b]	0.28	24	66	0.70	1.15	0.61	10

[b]Wainner RS, Fritz JM, Irrgang JJ, et al. Reliability and diagnostic accuracy of the clinical examination and patient self-report measures for cervical radiculopathy. Spine. 2003;28:52–62.

Temperature

- Origin. Lateral spinothalamic tract.
- *T*est. Using two test tubes, filled with hot and cold water, the clinician touches the skin and asks the patient to identify "hot" or "cold." T e impulses for temperature sensation travel together with pain sensation in the lateral spinothalamic tract. T e testing of skin temperature can also help the clinician to differentiate between a venous and an arterial insuf ciency.[313] With venous insuf ciency, an increase in skin temperature is usually noted in the area of occlusion, and the area also appears bluish in color. Pitting edema, especially around the ankles, sacrum, and hands, also may be present. However, if pitting edema is present and the skin temperature is normal, the lymphatic system may be at fault. With arterial insuf ciency, a decrease in skin temperature is usually noted in the area of occlusion, and the area appears whiter. It is also extremely painful.

Pressure

- Origin. Spinothalamic tract.
- *T*est. Firm pressure is applied to the patient's muscle belly.

Sensory Threshold

- Origin. Posterior (dorsal) column/medial lemniscal tract (Box 3-4).
- T reshold tests measure the intensity of the stimulus necessary to depolarize the cell membrane and produce an action potential—the ability to detect. T reshold tests are helpful in assessing diminished sensibility in nerve compressions and in monitoring nerve recovery after surgical decompression.[365,369] Examples of threshold tests include vibratory testing and Semmes–Weinstein monofilament testing.
- *T*est. Vibration testing is performed using a 128-Hz tuning fork applied to a bony prominence such as the ulna or radius in the upper extremity, and the patella or tibia in the lower extremity. T e patient is asked to report the perception of both the start of the vibration sensation and the cessation of vibration on dampening. T e time difference (in seconds) is recorded and compared with the uninvolved side. Alternatively, a vibrometer, such as the Bio-T esiometer can be used.[365] T e Bio-T esiometer is an electrically controlled testing instrument that produces vibration at a fixed frequency (120 Hz) with variable amplitude. T e vibrating head is applied to the patient's fingertip, and the amplitude is slowly and gradually increased. T e threshold is recorded as the voltage required to perceive the vibratory stimulus.[365] T e clinician applies a series of five trials to determine the cumulative ability of correct responses. A positive test is decreased ability to report when the vibration is applied and reports of vibration dampening while still being applied. If vibration sense is absent, the clinician should retest, moving proximally along the extremity.
- *T*est. T e assessment of cutaneous sensibility was first described in 1899, using horse hairs of varying thickness.[370] In 1960, Semmes et al.[371] made the testing procedure more exacting when they introduced the use of pressure-sensitive nylon monofilaments mounted onto Lucite rods (Fig. 3-43). T ese monofilaments, which are graded according to thickness, are calibrated to exert specific pressures. Each kit consists of 20 probes, each numbered from 1.65 to 6.65, a number that represents the logarithm of 10 multiplied by the force in milligrams required to bow the filaments.[372] T e patient is blindfolded, or turns away, during the examination and the clinician applies each filament perpendicular to the skin until the filament bends, starting with the filament with the lowest number and gradually moving up the scale until the patient feels one before or just as it bends.[373,374] T e test is repeated three times for confirmation.[375]

Box 3-4 Posterior (Dorsal) Medial lemniscus Tract

The posterior (dorsal) medial lemniscus tract conveys impulses concerned with well-localized touch and with the sense of movement and position (kinesthesia). It is important in moment-to-moment (temporal) and point-to-point (spatial) discrimination and makes it possible for a person to perform a task such as putting a key in a door lock without light or to visualize the position of any part of his or her body without looking. Lesions to the tract from destructive tumors, hemorrhage, scar tissue, swelling, infections, and direct trauma, among others, abolish or diminish tactile sensations and movement or position sense. The cell bodies of the primary neurons in the posterior (dorsal) column pathway are located in the spinal ganglion. The peripheral processes of these neurons begin at receptors in the joint capsule, muscles, and skin (tactile and pressure receptors).

Cl In ICAl PEARl

A cross-sectional multi-group comparison study[376] that examined three screening sensory tests (the Semmes–Weinstein 10-g monofilament examination, superficial pain sensation, and vibration by the on–off method) found all three screening tests to be significantly and positively correlated with nerve conduction studies.

FIGURE 3-43 Semmes and Weinstein filament testing.

Position Sense (Proprioception)

- Origin. Posterior (dorsal) column/medial lemniscal tract (see Box 3-4).
- *Test.* Proprioception here refers to an awareness of the position of joints at rest. The patient is tested for his/her ability to perceive passive movements of the extremities, especially the distal portions. The clinician grasps the patient's big toe, holding it by its sides between the thumb and the index finger, and then pulls it away from the other toes to avoid friction and to prevent extraneous tactile stimulation from indicating a change of position.[313] "Down" and "up" are demonstrated to the patient as the clinician moves the patient's toe clearly downward and upward, respectively. Then, with his or her eyes closed, the patient is asked for an "up" or "down" response as the clinician moves the toe in a small arc. This movement is repeated several times on each side, avoiding simple alternation of the stimuli. If position sense is impaired, then the clinician should retest, moving proximally along the extremity. Alternatively, the patient is asked to duplicate the position with the opposite extremity. The joint position sense component of proprioception can also be assessed through the reproduction of both active and passive joint repositioning with the patient blindfolded. The clinician positions the limb to be tested at a preset target angle and holds it there for a minimum of 10 seconds to allow the patient to process mentally the target angle.[313] Following this, the limb is returned to the starting position. The patient is then asked to move the limb to the preset the target angle. The angular displacement is recorded as the error in degrees from the preset target angle.

Movement Sense (Kinesthesia)

- Origin. Posterior (dorsal) column/medial lemniscal tract (see Box 3-4).
- *Test.* The patient is asked to indicate verbally the direction of movement while the extremity is in motion. The clinician must grip the patient's extremity over neutral borders.

Stereognosis

- Origin. Posterior (dorsal) column/medial lemniscal tract (see Box 3-4).
- *Test.* The patient is asked to recognize, through touch alone, various small objects such as comb, coins, pencils, and safety pins that are placed in his or her hand.

Graphesthesia

- Origin. Posterior (dorsal) column/medial lemniscal tract (see Box 3-4).
- *Test.* The patient is asked to recognize letters, numbers, or designs traced on the skin. Using a blunt object, the clinician draws an image on the patient's palm, asking the patient to identify the number, the letter, or the design.

Neuromuscular Control and Balance Testing

Assessment of neuromuscular control can be examined clinically by assessing the ability of the subject to maintain postural control within a given BOS. A number of balance test types are recognized:[199]

- Static balance tests. Static balance tests require the patient to maintain the BOS while minimizing movement of body segments and the COM.[377] This includes observation of the patient maintaining different postures. Standardized tests include the single-leg balance stance test, Romberg test; sharpened (tandem) Romberg, stork stand test, timed stance battery, and the Balance Error Scoring System (BESS) (Table 3-26). The BESS consists of three stances performed on a firm surface: double-leg stance (hands on the hips and feet together) (Fig. 3-44), single-leg stance (SLS) (standing on the nondominant leg with hands on hips) (Fig. 3-45), and a tandem stance (standing with the nondominant foot behind the dominant foot in a heel-to-toe fashion) (Fig. 3-46), followed by the same tests on a foam surface (Figs. 3-47 to 3-49) with the eyes closed. Any errors (opening the eyes, stumbling or falling out of the position, lifting the hands of the hips, lifting the forefoot or heel, stepping, abducting the hip by more than 30 degrees, or failing to return to the test position for more than 5 seconds) counted during each 20-second trial. The reliability of the BESS ranges from moderate (< 0.75) to good (> 0.75) when assessing static balance while some studies report reliability coefficients below clinically acceptable levels.[378] The BESS can detect balance deficits in participants with concussion and fatigue.[378]
- Dynamic balance tests. Dynamic balance tests are used to assess the ability to maintain body control within a BOS during a functional task that requires movement of the COM.[379,380] This is includes observation of the patient standing or sitting on an unstable surface or performing

FIGURE 3-44 Double-leg stance on firm surface.

TABLE 3-26 Balance and Functional Assessment Tests

Test	Description
Romberg[a]	Assesses the patient's ability to stand with the feet parallel and together with the eyes open and then closed for 30 seconds. With the eyes open, the vision, proprioception, and vestibular systems provide input to the cerebellum to maintain truncal stability. If there is a mild lesion in the vestibular or proprioception systems, the patient is usually able to compensate with the eyes open. When the patient closes their eyes, however, visual input is removed and instability can be provoked (a positive Romberg sign). Patients with a vestibular lesion tend to fall in the direction of the lesion.[b] If there is a more severe proprioceptive or vestibular lesion, or if there is a midline cerebellar lesion causing truncal instability, the patient will be unable to maintain this position even with their eyes open.[b] Note that instability can also be seen with lesions in other parts of the nervous system such as the UMNs or LMNs or the basal ganglia, so these should be tested for separately in other parts of the exam. The Romberg test has predictive validity with regard to recurrent falls over a 6-month period in patients with Parkinson's disease: sensitivity was 65% and specificity greater than 90%.[c]
Sharpened (tandem) Romberg[a]	Assesses the patient's ability to stand with the feet in the heel-to-toe position with the arms folded across the chest and eyes closed for 1 min. The rationale for this test is the same as for the Romberg. The ataxic patient will prefer to stand with a wider BOS and will show reluctance when asked to stand with the feet close together.
Single-leg balance stance[d]	Assesses the patient's ability to stand on one leg without shoes and with the arms placed across the chest without letting the legs touch each other. Modifications include the test being performed on firm and compliant surfaces and with eyes open and closed. Five 30-second trials are performed for each leg, with the maximum possible score of 150 seconds per leg. Scoring can be the total number of losses of balance in a given time period or as the amount of time before a loss of balance occurs. EMG evidence demonstrates significant muscle activation of the gluteus medius during single-leg stance in order to keep the pelvis level to the ground. [5] Therefore, a single-leg stance position may reveal dysfunction of the hip abductors on the ipsilateral side. Provocation of pain during 30 seconds of single-leg stance has shown excellent sensitivity (100%) and specificity (97.3%) in detecting tendinopathy of the gluteus medius and minimus. [7] In the acute stage of vestibular loss, a patient will be unable to perform this test[e]; however, patients who have a compensated vestibular loss may test normal.[e] This screening test is not specific to vestibular loss, as patients with other balance disorders may have dif culty performing single-leg stance[e]
Stork stand[f]	Assesses the patient's ability to stand on both feet with the hands on the hips, then lift one leg and place the toes of that foot against the knee of the other leg. On command from the tester, the patient then raises the heel to stand on the toes and try to balance as long as possible without letting either the heel touch the ground or the other foot move away from the knee. Normal adults should be able to balance for 20–30 seconds on each leg
Functional reach[g] and the Multidirectional reach[h]	Both of these tests require the patient to reach in different directions as far as possible without changing the BOS
Star excursion balance (SEBT)[8]	A test of lower extremity reach that challenges an individual's balance and postural stability. The patient balances on the involved leg at the center of a circle placed on the floor, with eight lines extending from the center at 45-degree increments. While maintaining the single-leg stance in the center of the circle, the individual is asked to maximally reach in the 8 designated vectors or directions with the opposite lower extremity. The vectors are named in reference to the stance leg. The individual is asked to touch the furthest point on each line with the reach foot and return to the start position while maintaining balance. The test intends to demonstrate dynamic balance deficits by comparing the performance of the involved limb to the uninvolved limb as the ability to reach a distant point along a given vector requires a combination of postural stability, strength, and controlled motion on the stance leg. It is worth noting that a strengthening program targeting the gluteus medius can improve SEBT performance.[6]
Y-balance test[9]	The Y-balance test, a modification of the SEBT, incorporates reachability in only the anterior, posterior–medial, and posterior–lateral directions. Hip abduction strength and hip extension strength have shown significant correlation to posterior–medial and posterior–lateral reach distances, respectively.[2]

(Continued)

TABLE 3-26 Balance and Functional Assessment Tests (Continued)

Test	Description
Cross-over reach test[4]	This test is designed to assess balance while moving into a position that commonly provokes pain in patients with intra-articular hip pathology. The individual is positioned in the single-leg stance position and, with the contralateral hand, is asked to reach as far as possible across the body to touch the floor and return to an erect posture while the stance foot remains in full contact with the floor. The distance the individual reaches is then recorded. Reach distance is thought to be less on the involved side of patients with intra-articular hip pathology due to the fact that patients with intra-articular sources of regional hip pain have a reduction of internal rotation and flexion at the hip joint.
Pull test[k]	The clinician stands behind the patient and asks the patient to maintain their balance when pulled backward. The clinician pulls back briskly to assess the patient's ability to recover, being careful to prevent the patient from falling
Backward release[l]	The patient is asked to stand with feet shoulder width apart. The clinician places their hand between the patient's scapulae and the patient is asked to lean back against the clinician's hand. Once the patient is leaning backward into the clinician's hand, the clinician unexpectedly removes the support. The amount of force created by the patient's lean should be suf cient to invoke a loss of balance that requires a change in the BOS (i.e., at least one backward step).
Postural stress test (PST)[m]	The PST measures an individual's ability to withstand a series of destabilizing forces applied at the level of the subject's waist. Scoring of the postural responses is based on a nine-point ordinal scale, where a score of 9 represents the most ef cient postural response and a score of 0 represents a complete failure to remain upright.
Balance error scoring system (BESS) [1]	This test assesses the ability of an individual to maintain balance in six different conditions including double-leg stance, single-leg stance, and tandem stance on firm and foam surfaces with the eyes closed and the hands placed on the hips. Each condition is attempted for 20 seconds while the clinician notes the number of errors, or deviations, from the specific stance position. An error is recorded if the individual opens the eyes, steps, stumbles and falls out of position, removes hands from the hips, flexes or abducts the hip beyond 30 degrees, or lifts the toes or heels off the ground. For a population aged between 20 and 54 years, the average number of errors was found to be between 11 and 13.[3]
Clinical test of sensory Integration on balance (foam and dome test)[n]	This test measures an individual's ability to balance under six different sensory conditions: 1. Standing on a firm surface with the eyes open 2. Standing on a firm surface with the eyes closed 3. Standing on a firm surface wearing a dome made from a modified Japanese lantern 4. Standing on a foam cushion with the eyes open 5. Standing on foam with the eyes closed 6. Standing on foam wearing the dome For each of these conditions the patient stands with the feet parallel and the arms at the sides or the hands on the hips a minimum of three 30-second trials of each condition are performed. Patients with vestibulopathy will have dif culty maintaining an upright posture.[e] Individuals who rely heavily on visual input for balance will become unstable or fall in conditions 2, 3, 5, and 6, whereas those who rely heavily on somatosensory inputs show deficits with conditions 4, 5, and 6.
Fukuda stepping test[o]	The test is performed by having the patient stand with the eyes closed and the arms extended forward to shoulder height. The patient is asked to march in place for 50 steps at the pace of a brisk walk. Progressive turning toward one side of 30 degrees or more is considered a positive test and indicates a unilateral peripheral vestibular deficit.
Dizziness handicap inventory[p]	This test assesses a person's perception of the effects of a balance problem and the emotional, physical, or functional adjustments that the person makes. Questionnaire consists of 25 items that are divided into functional (nine items), emotional (nine items), and physical (seven items) subscales. Each item is assigned a value of 4 for a yes, 2 points for a sometimes, and 0 points for a no.
The Berg balance scale (BBS)[q]	This 14-item scale was developed to measure balance among older people with impairment in balance function by assessing the performance of functional tasks.

TABLE 3-26 Balance and Functional Assessment Tests (Continued)

Test	Description
Timed up and go (TUG) test[r]	Patients are timed (in seconds) when performing the TUG under three conditions: 1. TUG alone—from sitting in a chair, stand up, walk 3 m, turn around, walk back, and sit down 2. TUG Cognitive—complete the task while counting backward from a randomly selected number between 20 and 100 3. TUG manual—complete the task while carrying a full cup of water The time taken to complete the task is strongly correlated to level of functional mobility (i.e. the more time taken, the more dependent in activities of daily living)
Tinetti performance-oriented mobility assessment (POMA)[s]	Easily administered task-oriented test that measures an adult's gait and balance abilities. Rates the ability of an individual to maintain balance while performing activities of daily living-related tasks. Components include balance, lower and upper extremity strength.

postural transitions and functional activities. Standardized tests include the functional reach test, multidirectional reach test, cross-over reach test, and the star excursion balance test (Table 3-26).

- Anticipatory postural control tests. T is includes observation of the patient catching a ball, opening doors, lifting objects of different weights.
- Reactive postural control tests. T is includes observation of the patient's responses to pushes (small or large, slow or rapid, anticipated and unanticipated). Standardized tests include the pull test, backward release, and postural stress test (Table 3-26).
- Sensory organization tests. T is can be tested using the clinical test of sensory integration on balance, also called the Foam and Dome test (Table 3-26).
- Vestibular tests. T is includes observation for nystagmus and vertiginous positions. Standardized tests include the Dix–Hallpike maneuver (see Dizziness section), VOR testing (see Reflex Testing section), oculomotor tests (see CN Examination section), Fukuda stepping test (Table 3-26), and the dizziness handicap inventory (Table 3-26).
- Balance during *f*unctional activities. Functional tasks are observed to test the patient's ability to demonstrate mobility (the ability to move from one position to another independently and safely), static postural control (the ability to maintain postural stability and orientation with the COM over the base support and the body at rest), dynamic postural control (the ability to maintain stability and orientation with the COM over the BOS while parts of the body are in motion), and skill (the ability to

FIGURE 3-45 Single-leg stance on firm surface.

FIGURE 3-47 Double-leg stance on foam surface.

consistently perform coordinated movement sequences for the purposes of investigation and interaction with the physical and social environment) during functional tasks.[381] Individuals over 65 tend to walk with a slower self-selected gait speed, a shorter stride width, and an increase in double support time (see Chapter 6). Some of these changes are the inevitable effects of aging (see Chapter 30) while others are due to pathology or disuse. In addition, elderly patients tend to demonstrate increased gait variability. For example, elderly individuals tend

FIGURE 3-46 Tandem stance on firm surface.

FIGURE 3-48 Single-leg stance on foam surface.

FIGURE 3-49 Tandem stance on foam surface.

to go through a decreased range of dorsiflexion during midstance.[382,383] However, significant changes in gait are not noted unless multiple joints are involved, or there are impairments in other systems such as loss of strength or motor control. Bloem et al.[384] in a study of individuals aged over 88 noted that 20% of the subjects exhibited unimpaired gait. Another study has demonstrated that those who exhibit senile gait disorders are more likely to go on to develop dementia and die earlier than age-matched individuals who walk normally.[385] T is raises the enticing possibility that gait changes associated with aging may actually be an early manifestation of pathologies such as subtle white matter changes, vestibular dysfunction, musculoskeletal disorders, or visual changes.[385] What is known is that sensory system impairments have a tremendous impact on gait and that training to improve proprioception can improve gait parameters and safety.[386] Standardized tests for this include the Tinetti performance-oriented mobility assessment (Table 3-26), timed up and go test (Table 3-26), Berg balance scale (Table 3-26), gait abnormality rating scale (see Chapter 6), and the Functional Gait Assessment (see Chapter 6). Returning to demanding physical activity requires more advanced functional testing, such as hop tests (see Chapter 4).

- Safety during gait, locomotion, or balance. T is includes documentation of the patient's fall history and a home assessment. Age-related balance dysfunctions can occur through a number of mechanisms including gradual degenerative changes in the vestibular apparatus of the inner ear, an inability to integrate sensory information, and muscle weakness. In addition, some diseases (benign paroxysmal positional vertigo—see Chapter 23), cerebrovascular disease, Ménière's disease, cerebellar dysfunction, vertebrobasilar artery insuf ciency, and cardiac disease common in aging populations can lead to further deterioration in balance function. Balance disorders can also be associated with a number of other causes including:
  - medications,
  - postural hypotension, and
  - visual/auditory deficits.

Falls in the elderly are often associated with significant morbidity and can be markers of poor health and declining function.[387] Elderly patients with known risk factors for falling should be questioned about falls on a periodic basis. Recurrent falls, defined as more than two falls in a 6-month period, should be assessed for treatable causes. It is particularly important to assess housing arrangements, environmental hazards, alcohol use, and compliance with medications.

Several functional balance measures have exhibited a strong correlation with a history of falling. T ese simple tests, which can also be used to measure changes in mobility after interventions have been applied, are quantifiable and correlate well with the ability of older adults to ambulate safely in their environment.

- *T*imed SLS. T e patient stands unassisted on one leg (by flexing the opposite knee to allow the foot to clear the floor) for 30 seconds. T e choice of which leg to stand on can be determined by the patient based on personal comfort. T e clinician times the patient's one-leg balance using a watch. T e ability to maintain SLS generally decreases with increasing age. One study[135] found that older adults in the community could maintain the SLS for 10 seconds about 89% of the time and nursing home residents for 45% of the time.
- T e timed "Up & Go" test. T e timed "Up & Go" test measures, in seconds, the time taken by an individual to stand up from a standard arm chair (seat height of approximately 46 cm/18.4 in, arm height 65 cm/25.6 in), walk a distance of 3 m (10 ft), turn, walk back to the chair, and sit down again. T e patient wears his/her regular footwear and uses his/her customary walking aid (none, cane, or a walker). T e subject walks through the test once before being timed in order to become familiar with the test. Either a wrist-watch with a second hand or a stop-watch can be used to time the performance.

The overall physical function should also be assessed. This is accomplished by evaluating the patient's ADLs and instrumental ADLs. The intervention is directed at determining the underlying cause of the fall, the identification of risks, and in preventing recurrence through patient and family/caregiver education on safety issues (adequate lighting, contrasting colors, and reduction of clutter). Functional training should include sitting to stand transfers, walking and turning, and stair negotiation. Therapeutic exercises should be designed to address any strength and flexibility deficits, and balance and/or gait deficits.

It is important to remember that frailty is not a natural consequence of aging (see Chapter 30). Physical activity throughout the aging years can produce a number of physiologic benefits:

- Substantial improvements in cardiovascular functioning.
- A significant impact on the maintenance of independence in old age.
- T e prevention and/or postponement of age-associated declines in flexibility, balance, and coordination.
- In contrast, disuse exacerbates the aging process. Intervention strategies to prevent disability from immobility should include the following while monitoring vital signs:
  - Minimize duration of bed rest. Avoid strict bed rest unless absolutely necessary. T e patient should be allowed to stand 30–60 seconds during transfers (bed to chair).
  - Encourage sitting up at a table for meals, and getting dressed in street clothes each day.
  - Encourage daily exercise as a basis of good care. Exercises should emphasize balance and proprioception, strength and endurance, coordination and equilibrium, aerobic capacity, and posture.
  - Design possible ways to enhance mobility through the use of assistive devices (e.g., walking aids, wheelchairs) and making the home accessible. If the patient is bed-bound, proper body alignment should be maintained, and the patient should change positions every few hours. Pressure padding and heel protectors may be used to provide comfort and prevent pressure sores.
  - Encourage socialization with family, friends, or caregivers.
  - Regular checks of skin integrity, protective and discriminatory sensations

Coordination

Voluntary movement patterns involve functionally linked muscles or synergies that act cooperatively to produce an action and are defined by precise spatial and temporal organization. T e movement patterns can be assessed using various simple coordination tasks.

FIGURE 3-50 Finger-to-nose test.

FIGURE 3-51 Finger-to-finger test.

- Finger-to-nose test.[320] In the finger-to-nose test, the patient is asked to move the index finger to the tip of the nose or the chin with the eyes open, while the clinician observes the quality of arm motion (Fig. 3-50). Closing the eyes eliminates visual substitution. Mild cerebellar ataxia results in an intention tremor near the beginning and the end of the movement with possible overshooting of the target.[388]
- Finger-to-*finger* test.[320] With the finger-to-finger test, the patient attempts to touch his or her finger to the clinician's finger (Fig. 3-51). Horizontal overshooting implicates a unilateral labyrinthine lesion; vertical overshooting occurs in patients with midline lesions to the medulla oblongata or the bilateral cerebellar flocculus.
- Heel-to-shin test.[320] T e heel-to-shin test, which tests for leg ataxia, involves having the supine patient track the heel of the foot smoothly up and down the contralateral shin (Fig. 3-52). Alternatively, the patient can be positioned in sitting and can be asked to touch the great toe to the clinician's finger.

Tonal Abnormality

An examination of tone consists of initial observation of resting posture and palpation, and passive motion testing, and active motion testing while observing for any abnormalities.[313]

FIGURE 3-52 Heel-to-shin test.

Spasticity

Spasticity is defined as a velocity-dependent resistance to passive stretch. Larger and quicker stretches produce a stronger resistance of the spastic muscle.

- Clasped-knife phenomenon. During rapid movement, initial high resistance (spastic catch) may be followed by a sudden inhibition or letting go of the limb (relaxation) in response to a stretch stimulus.
- Clonus. This is an exaggeration of the stretch reflex and is characterized by cyclical, spasmodic alternation of muscular contraction and relaxation in response to sustained stretch of the spastic muscle.

Rigidity

Rigidity is defined as an increased resistance to all motions, rendering body parts stiff and immovable.

- Cogwheel phenomenon. This is a ratchet-like response to passive movement, characterized by an alternate giving and increased resistance to movement.
- Lead pipe rigidity. Characterized by constant rigidity throughout the range of motion, this finding is common in patients with Parkinson disease.

Hypotonia

Hypotonia and flaccidity are the terms used to define decreased or absent muscular tone. This state is manifested by a diminished resistance to passive movement, dampened or absent stretch reflexes, and limbs that are easily moved.

Dystonia

Dystonia is a hyperkinetic movement disorder characterized by a disordered tone and involuntary movements involving large portions of the body. Dystonia typically results from a CNS lesion but can be inherited.

Posturing

In cases of significant brain lesions, the body can adopt two characteristic positions:

- Decorticate positioning. Upper extremities are held in flexion and the lower extremities, in extension.
- Decerebrate positioning. Upper and lower extremities are held in extension.

CN Examination

With practice, the entire CN examination can be performed in approximately 5 minutes (Table 3-27).[362] The following rhyme may be used to help remember the order and tests for the CN examination:[389]

Smell and see

And look around,

Pupils large and smaller.

Smile, hear!

Then say ah . . .

And see *if* you can swallow.

If you're le*ft* in any doubt,

Shrug and stick your tongue right out.

CN I (Olfactory)

The sense of smell is tested by having the patient identify familiar odors (e.g., coffee, lavender, and vanilla) with each nostril. The clinician should avoid irritant odors that can stimulate the trigeminal nerve.

CN II (Optic)

The optic nerve is tested by examining visual acuity and confrontation. Although the formal testing of visual acuity is presented here, in reality, it is sufficient to test this aspect of CN II at the same time that CN III, IV, and VI are being tested.

Visual Acuity

This is a test of central vision. If possible, the clinician should use a well-lit Snellen eye chart. The patient is positioned 20 ft from the chart. Patients who use corrective lenses other than reading glasses should be instructed to use them. The patient is asked to cover one eye and to read the smallest line possible. A patient who cannot read the largest letter should be positioned closer to the chart, and the new distance noted. The clinician determines the smallest line of print from which the patient can identify more than half the letters. The visual acuity designated at the side of this line, together with the use of glasses, if any, is recorded.

Visual acuity is expressed as a fraction (e.g., 20/20), in which the numerator indicates the distance of the patient from the chart and the denominator the distance at which a normal eye can read the letters.

Confrontation Test

This is a rough clinical test of peripheral vision that also highlights a loss of vision in one of the visual fields. The patient and the clinician sit facing each other, with their eyes level. Both the lateral and medial fields of vision are tested. The entire lateral field is tested with both eyes open, and the medial field is tested by covering one eye. When testing the medial field of vision, the patient covers the eye that is directly opposite to the clinician's own (not diagonally opposite).

With arms outstretched and hands holding a small object such as a pencil, the clinician slowly brings the object into the peripheral field of vision of the patient. This is performed from eight separate directions. Each time the patient is asked to say "now" as soon as he or she sees the object. During the examination, the clinician should keep the object equidistant between his or her own eye and the patient's so that the patient's visual field can be compared to the clinician's own.

CN III (Oculomotor), CN IV (Trochlear), and CN VI (Abducens)

These three CNs are tested together. The clinician:

- Inspects the size and the shape of each pupil for symmetry.

TABLE 3-27 CNs and Methods of Testing

Nerves	Function		Tests
	Afferent (Sensory)	Efferent (Motor)	
I—Olfactory	Smell	—	Unilateral identification of familiar odors (e.g., chocolate and coffee)
II—Optic	Sight	—	Visual acuity, peripheral vision, and pupillary light reflex
III—Oculomotor	—	Voluntary motor: levator of eyelid; superior, medial, and inferior recti; and inferior oblique muscle of eyeball Autonomic: smooth muscle of eyeball	Upward, downward, and medial gaze; reaction to light
IV—Trochlear	—	Voluntary motor: superior oblique muscle of eyeball	Extraocular eye movements: downward and lateral gaze
V—Trigeminal	Touch, pain: skin of face, mucous membranes of nose, sinuses, mouth, and anterior tongue	Voluntary motor: muscles of mastication	Corneal reflex; sensation above eye, between eye and mouth, below mouth to angle of jaw; clench teeth, push down on chin to separate jaws
VI—Abducens	—	Voluntary motor: lateral rectus muscle of eyeball	Lateral gaze (eye abduction)
VII—Facial	Taste: anterior two-thirds of tongue	Voluntary motor: facial muscles Autonomic: lacrimal, submandibular, and sublingual glands	Facial expressions (close eyes tight, smile and show teeth, and whistle and puff cheeks) and identify familiar tastes (e.g., sweet and sour)
VIII—Vestibulocochlear (acoustic nerve)	Hearing/equilibrium	—	Hearing tests and balance and coordination tests
IX—Glossopharyngeal	Visceral sensibility (pharynx, tongue, and tonsils); taste	Voluntary motor: unimportant muscle of pharynx Autonomic: parotid gland	Gag reflex, ability to swallow, and phonation
X—Vagus	Touch, pain; pharynx, larynx, trachea, bronchi, and lungs Taste: tongue and epiglottis	Voluntary motor: muscles of palate, pharynx, and larynx Autonomic: involuntary muscle and gland control	Gag reflex, ability to swallow, and speech (phonation)
XI—Accessory	—	Voluntary motor: movement of head and shoulders—sternocleidomastoid and trapezius muscles	Resisted head and shoulder shrug
XII—Hypoglossal	—	Voluntary motor: movement of tongue	Tongue protrusion (if injured, tongue deviates toward injured side) and inspection of tongue for atrophy

- Tests the consensual pupillary response to light. This is tested by having the patient cover one eye while the clinician observes the uncovered eye. The uncovered eye should undergo the same changes as the covered by first dilating, and then constricting when the covered eye is uncovered.
- Looks for the ability of the eyes to track movement in the six fields of gaze. The standard test is to smoothly move a target in an "H" configuration and then in the midline just above eye level toward the base of the nose (convergence).[8] The patient should be able to smoothly track a target at moderate speed, without evidence of nystagmus.
- Looks for ptosis of the upper eyelids.

Cn V (Trigeminal)

The patient is asked to clench the teeth, and the clinician palpates the temporal and masseter muscles. The three sensory branches of the trigeminal nerve are tested with pinprick

FIGURE 3-53 Jaw tendon reflex assessment.

close to the midline of the face because the skin that is more lateral is overlapped by the nerves of the face.[8] The jaw muscle stretch reflex is assessed for the presence of hyperreflexia (Fig. 3-53).

Cn VII (Facial)

The clinician inspects the face at rest and in conversation with the patient and notes any asymmetry. The patient is asked to smile. If there is any asymmetry, the patient is asked to frown or wrinkle the forehead. Loss or reduced ability to smile and frown is caused by a peripheral palsy, whereas the loss of the smile, only, is caused by a supranuclear lesion.[8]

Cn VIII (Vestibulocochlear)

The vestibular nerve can be tested in a number of ways, depending on the objective. Balance testing assesses the vestibulospinal reflex. Caloric stimulation can be used to assess the VOR. The VOR can also be assessed by testing the ability of the eyes to follow a moving object.

The clinician assesses the function of the cochlear component of the nerve—hearing—by gently rubbing two fingers equidistant from each of the patient's ears simultaneously or by using a 256-Hz tuning fork and asking the patient to identify in which ear the noise appears to be the loudest.

There are three basic types of hearing loss[389]

- Conductive. This type of hearing loss applies to any disturbance in the conduction of the sound impulse as it passes through the ear canal, the tympanic membrane, the middle ear, and the ossicular chain to the footplate of the stapes, which is situated in the oval window. As a general rule, an individual with conductive hearing loss speaks softly, hears well on the telephone, and hears best in a noisy environment.
- Sensorineural. This type of hearing loss applies to a disturbance anywhere from the cochlea through the auditory nerve and on to the hearing center in the cerebral cortex. As a general rule, an individual with a perceptive hearing loss usually speaks loudly, hears better in a quiet environment, and hears poorly in a crowd and on the telephone.
- Mixed. This type of hearing loss is a combination of conductive and sensorineural.

If hearing loss is present, then the clinician should test for lateralization and compare air and bone conduction.

Lateralization

The clinician places a tuning fork over the vertex, middle of the forehead, or front teeth. The patient is asked whether the vibration is heard more in one ear (Weber test). Normal individuals cannot lateralize the vibration to either ear. In conduction deafness (e.g., that caused by middle ear disease), the vibration is heard more in the affected ear. In sensorineural deafness, the vibration is heard more in the normal ear.

Air and Bone Conduction

Air conduction is assessed by placing the tuning fork in front of the external auditory meatus, whereas bone conduction is assessed by placing the tuning fork on the mastoid process (Rinne test). In a normal individual, the tuning fork is heard louder and longer by air than by bone conduction. In conduction deafness, bone conduction hearing is better. In sensorineural deafness, both air and bone conduction are reduced, although air conduction is the better of the two.

Cn IX (Glossopharyngeal)

The gag reflex is used to test this nerve, but this test is reserved for severely affected patients only.

Cn X (Vagus)

The clinician listens to the patient's voice and notes any hoarseness or nasal quality. The patient is asked to open the mouth and say "Aah," while the clinician watches the movements of the soft palate and pharynx. The soft palate should rise symmetrically, the uvula should remain in the midline, and each side of the posterior pharynx should move medially.

Cn XI (Spinal Accessory)

From behind the patient, the clinician notes any atrophy or fasciculation in the trapezius muscles and compares each side. The patient is asked to shrug both shoulders upward against the clinician's hand. The strength of contraction should be noted.

The patient is asked to attempt to turn his or her head to each side against the clinician's hand. The contraction of the SCM and the force of contraction should be noted.

Cn XII (Hypoglossal)

The clinician inspects the tongue, as it lies on the floor of the mouth, looking for fasciculation. The patient is then asked to stick out the tongue. The clinician looks for asymmetry, atrophy, or deviation from the midline. The patient is asked to move the tongue from side to side, as the clinician notes symmetry of movement.

SECTION II

EXAMINATION AND EVALUATION

CHAPTER 4

Patient/Client Management

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Understand the principles and considerations of a comprehensive examination.
2. Outline the various disablement models and the strengths and weaknesses of each.
3. Explain the difference between impairment and functional limitation.
4. List the components involved in the continuum of care.
5. Take a complete history.
6. Explain the importance of the systems review.
7. List the components of the tests and measures portion of the examination.
8. Understand the value of a complete observation of the patient and the information that can be gleaned from such an assessment.
9. Describe the differences between a traditional examination and a postsurgical examination.
10. Explain the differences between the examination and the evaluation.
11. Explain how to determine whether a technique is clinically useful.
12. Outline the components of clinical documentation.

OVERVIEW

Patient/client management comprises five elements[1]:

1. A comprehensive examination of the patient.
2. Evaluation of the data and the identification of problems.
3. Establishment of the diagnosis based on impairment of body structure and function, activity limitations (functional limitations), and participation restrictions (disability).
4. Determination of the prognosis and the plan *of* care (POC) based on patient-oriented goals.
5. Implementation of appropriate interventions as outlined in the POC.

T e examination process involves a complex relationship between the clinician and the patient. T e aims of the examination process are to provide an efficient and effective exchange and to develop a rapport between the clinician and the patient. T e success of this interaction involves a myriad of factors. Successful clinicians are those who demonstrate effective communication, sound clinical reasoning, critical judgment, creative decision making, and competence.

T e primary responsibility of a clinician is to make decisions in the best interest of the patient. Although the approach to the examination should vary with each patient, and from condition to condition, there are several fundamental components to the examination process. T e principles outlined in this chapter and integrated throughout this text, are based on the views of a number of experts,[2–12] as well as principles I have learned, and used, over the years.

All clinicians should commit to being lifelong students of their profession and should strive toward a process of continual self-education. Part of this process involves the utilization of the expertise of more experienced clinicians. T is necessitates that the early years of practice are spent in an environment in which the novice is surrounded by a staff of varying levels of clinical and life experiences, both of which can serve as valuable resources. T e clinician can also improve by investing time in reading relevant material, attending continuing education courses, completing home study courses, watching videos specializing in techniques, and observing exceptional clinicians. Exceptional clinicians are those who demonstrate excellent technical skills, combined with excellent people skills.

CLINICAL PEARL

From the patient's point of view, there is no substitute for interest, acceptance, and especially empathy on the part of the clinician.[13]

Finally, one must also never forget that the patient can serve as the most valuable resource. Each interaction with a patient is an opportunity to increase knowledge, skill, and

understanding. Integral to this relationship is patient confidentiality. Except when discussing the patient's condition with other clinicians with the object of teaching or learning, the clinician should not discuss the patient's condition with anyone without the patient's permission.

Much about becoming a clinician is being able to communicate with the patient, the patient's family, and the other members of the healthcare team. T e nonverbal cues are especially important because they often are performed subconsciously. Special attention needs to be paid to nonverbal communication such as voice volume, postures, gestures, and eye contact. T e appearance of the clinician is also important if a professional image is to be projected.

Communication between the clinician and the patient begins when the clinician first meets the patient and continues throughout any future sessions. Communication involves interacting with the patient using terms he or she can understand, and being sensitive to cultural diversity as appropriate. T e introduction to the patient should be handled in a professional yet empathetic tone. Listening with empathy involves understanding the ideas being communicated and the emotion behind the ideas. In essence, empathy is seeing another person's viewpoint, so that a deep and true understanding of what the person is experiencing can be obtained.

At the end of the first visit and at subsequent visits, the clinician should ask if there are any questions. Each session should have closure, which may include a handshake if appropriate.

Disablement Models

Perhaps one of the most important developments in health care in the past few decades has been the increased recognition of the importance of the patient's perception of health and functional outcomes.[14] T is increased recognition has shifted the focus of the physical therapy examination, evaluation, and subsequent diagnosis to the recognition of impairments and their relationship to any functional limitation or disability.

T e field of physical therapy has long recognized the traditional biomedical approaches to pain have been problematic in describing patient functioning.[15] T is is due mainly to the fact that there is an inconsistent relationship between pain and functioning, and the fact that pain may not be the patient's chief concern. Ideally, a disablement model is designed to detail the functional consequences and relationships of pain, disease, impairment, and functional limitations. Many disablement models have been proposed over the years, most of which are based on the Nagi original model which depicted the relationship between the following series of linked events:[16,17]

Pathology/Pathophysiology (the presence of disease), which may lead to impairments (anatomic and structural abnormalities), which may in turn lead to *f*unctional limitations (restrictions in basic physical and mental actions), which may then progress to disability (difficulty in doing activities of daily life). T e Guide of Physical T erapist Practice[18] employed terminology from the Nagi disablement model, but also described its framework as being consistent with other disablement models. Although a degree of inevitability is implied in many of the disablement models, many factors can have an impact on the pathology–disability pathway or disablement process.

In 2001 the Executive Board of the World Health Organization, in an attempt to provide a common language used by all health professions for documentation and communication, approved the International Classification of Functioning, Disability and Health (WHO-ICF). T e WHO-ICF framework includes all of the following elements: the health condition, body functions/structures, activity, participation, and contextual factors, all of which are interrelated and can potentially have an impact on each other. T e WHO-ICF places less emphasis on disease and greater emphasis on "components of health" rather than "consequences of disease" (i.e., participation rather than disability) and environmental and personal factors as important determinants of health. T e two main components of the WHO-ICF model, which provides a method that considers biological, individual, and social contributions, are functioning and disability, and contextual factors:[15,19]

1. Part 1: Functioning and disability. Functioning and disability consider the relationships among the physical phenomena and within the individual that are represented by the domains of body functions and structures, activities, and participation. Part 1 is further subdivided into two components:
   i. Body functions and structures. Body functions and structures are assessed in terms of change in a physiological function and anatomical structure such that a deficit in body structure is associated with a deficit in functional mobility.[15] For example, limited knee flexion range of motion may be associated with limitation in the ability to ascend stairs.
   ii. Activities and participation. An activity involves the execution of a task or action (e.g., moving from sitting to standing), while participation is defined as involvement in life affairs (e.g., the ability to drive a car).

T us, functioning is characterized by the integrity of body functions and structures, and the ability to participate in life activities.

2. Part 2: Contextual factors. Each component of functioning and disability can be broken down into standard categories referred to as contextual factors. Part 2 is also further subdivided into two components: environmental and personal contextual factors, both of which can influence functioning and disability:
   i. Environmental factors, including environmental barriers and facilitators to both the capacity and performance of actions and tasks in daily living. T ese include social attitudes, architectural characteristics, legal and social structures, as well as climate, and terrain.
   ii. Personal factors, including age, sex, ethnic background, depression or comorbidity (e.g., pressure sores, contractures, urinary tract infections), and socioeconomic status.

Characteristics of an illness that are not amenable to modification may be termed contextual variables. Contextual factors can be viewed as secondary conditions that may influence the level of disability but are not directly related to

the disease process itself.[20] Broader definitions for these conditions include self-concept, work, and social participation, health-related economic consequences for the individual or family, and other family members.[21,22]

In addition to these two basic components, the WHO-ICF has an extensive list of descriptions, classifications, and coding for all of the functions and structures of all body systems, personal activities and participation, and environmental factors. The WHO-ICF model has been advocated in the physical therapy literature as a potential successor to the Nagi model because it explicitly acknowledges bidirectional relationships among domains of function and contextual factors, while recognizing the impact of the patient's affective, social, and environmental factors that may be either barriers or facilitators to the physical therapy prognosis.[15]

The various disablement models introduced a number of terms throughout the years which are described in the following sections.

Health Condition

The original term that Nagi used, pathology, is perhaps self-explanatory. It refers to any diagnosed disease, injury, disorder, or abnormal condition that is (1) characterized by a particular cluster of signs and symptoms and (2) recognized by either the patient or clinician as abnormal.[18,23,24] Although knowledge of pathology and pathophysiology can help the clinician predict the range, severity, and prognosis of a particular condition, a medical diagnosis does not tell the clinician how to manage the patient. In contrast, the term health condition better identifies the impact of a condition on function. The WHO-ICF framework refers to acute or chronic diseases, disorders, or injuries that have an impact on a person's level of activity. While the presence of pathology may lead to distress or interference with functional status, different people with the same condition can be impacted differently. For example, consider the impact that hip osteoarthritis would have on someone who has a desk job, compared to that of a manual laborer. While pathology is primarily identified at the cellular level and is usually determined by the physician's medical diagnosis,[18,24] it does not necessarily tell the clinician the underlying etiology, or how the disease/dysfunction manifests itself as an alteration in, or attribute of, an individual's health status. Determining the underlying etiology is important in creating an optimal management plan. It is thus important to determine whether the abnormal movement resulted from the tissue pathology, or whether the abnormal movement caused the tissue pathology.[15] For example, if a patient presents with a chief concern of shoulder pain without a history of traumatic onset, the clinician must determine whether the shoulder pain was caused by an abnormal movement pattern, a muscle imbalance, a disease process, a postural dysfunction or whether the pain is being referred from elsewhere, to name but a few potential causes.

Impairment

The "Guide to Physical Therapist Practice" defines impairment as any loss or abnormality of anatomic, physiologic, mental, or psychological structure or function that both (1) results from underlying changes in the normal state, and (2) contributes to illness.[18] The ICF model subdivides impairments into impairments of body function and body structure where impairments can be viewed as abnormalities of structure or function as indicated by signs and symptoms. Physical therapists typically encounter patients with impairments of body function and/or body structure of the following systems: musculoskeletal, neuromuscular, integumentary, and cardiovascular/pulmonary.

Impairments of body function and body structure have the potential to create pain and subtle alterations in the normal functions of the involved joint and surrounding tissues. Such impairments can be manifested objectively, for example, by impaired balance or coordination, reduced range of motion, articular deformity, abnormal gait, and the loss of muscle performance (strength, power, endurance), or proprioception. Impairments can also be manifested subjectively, for example, through pain, tenderness, morning stiffness, or fatigue.

Thus, impairment refers to some form of loss. Loss or loss *of* use refers to a change from the normal or pre-existing state. The term normal refers to a range representing healthy functioning that can vary with age, gender, and other factors such as environmental conditions. For example, the normal range of motion for knee flexion is deemed to be 150 degrees.[24] Although a loss of more than 70 degrees of knee flexion may prevent a patient from performing such activities as getting in and out of a bathtub or walking up and down steps, the patient may still be able to ambulate around the house.

The ICF model describes primary, secondary, and composite impairments. Primary impairments arise directly from the health condition, whereas secondary impairments may be the result of a pre-existing impairment. A composite impairment is the result of multiple underlying causes that typically arises from a combination of primary or secondary impairments. As an example, consider a patient with low back pain. In this scenario, the patient may exhibit primary impairments of body function, such as limited range of motion of the trunk, pain, and muscle guarding during the examination. The secondary impairment may be osteoarthritis of the hip that produced a change in the patient's gait pattern, altering the biomechanics of the lower extremity, and resulting in low back pain. A composite impairment would be a loss of balance and coordination as a result of both the low back pain and the osteoarthritis of the hip.

One of the goals of the examination process is to determine which impairments are related to the patient's functional limitations while remembering that impairments affect people in different ways. For example, in two patients with a rotator cuff tendinitis, the impairment of one may be greater than the other due to pain. The perception of pain is highly individual, and different individuals may be impaired by pain to different degrees.

One of the goals of the examination process is to determine which impairments are related to the patient's functional limitations—the functionally relevant impairments—and to determine whether there are any underlying causes.

Functional Limitation

A functional limitation can be defined as a restriction of the ability to perform a fundamental physical action, task, or activity in an efficient, typically expected, or competent manner.[18] In other words, functional limitations are restrictions in performing expected basic physical and mental actions. Examples

of such functional limitations include difficulty with walking, and an inability to put on shoes. T e vast majority of the traditional tests used in physical therapy clinics, such as range of motion and strength, are measures of impairments and not function. Measurements of functional limitations include sensorimotor performance testing during such activities as walking, climbing, bending, transferring, lifting, and carrying.[18] It is important that these measurements assess the patient's ability to perform tasks that the patient feels are important. T e process of identifying meaningful, achievable functional goals should be a collaborative effort between the clinician and the patient, the patient's family, or the patient's significant other.[18] To identify functional goals, Randall and McEwen[25] recommend the following steps:

1. Determine the patient's desired outcome of the intervention.
2. Develop an understanding of the patient's self-care, work, and leisure activities and the environments in which these activities occur.
3. Establish goals with the patient that relate to the desired outcomes using the following questions[25,26]:
   i. If you were to concentrate your energies on one thing for yourself, what would it be?
   ii. What activities do you need help with that you would rather perform yourself?
   iii. What are your concerns about returning to work, home, school, or leisure activities?
   iv. What about your current situation would you like to be different in about 6 months? What would you like to be the same?

Once the goals have been agreed upon, the clinician must write the goals so that they contain the following elements:[25,27]

- Who (the patient)
- Will do what (activities)
- Under what conditions (the home or work environment)
- How well (the amount of assistance or number of attempts required for successful completion)
- By when (target date)

T us, the functional examination creates a functional diagnosis with functional goals. Once these functional goals are established, the clinician can grade them according to difficulty. Functional tasks can reproduce the whole task in its entirety or can break down the task into its required fundamental components and the physical demands necessary to perform each task. Regaining the smaller requirements may constitute the short-term goals whereas completion of the whole task may become the long-term goal. For example, exercises to improve sit-to-stand transfers could be initiated by having the patient perform triceps push-ups on the chair handle, perform bilateral mini-squats, or exercise on the leg press before progressing to the full functional activity.

Participation Restrictions and Disability

T e term Disability was used in the Nagi disablement model. T e ICF model uses the term Participation Restrictions. Both terms may be defined as having difficulty in the performance of social roles and tasks within a sociocultural and physical environment (from hygiene to hobbies, errands, to sleep), as a result of a health or physical problem.[21,28,29] Both disability, and participation restrictions, describe something that may be temporary or permanent, and is the gap between what a person can do and what the person needs or wants to do. T e ICF definition is not just related to any health impairment or medical condition, as it can encompass any activity limitation or participation restriction although a medical condition or impairment may cause or contribute to disability.

It is important that the clinician avoid viewing the disablement process as a unidirectional pathway with an inevitable progression to disability. Various factors, including the patient's level of interaction with the environment, the patient's coping skills, and the potential effects of rehabilitation, may cause a bidirectional interaction or reversal between the components of the disablement process.[18,30] T is bidirectional interaction may be referred to as the enabling process.[30] T e term health-related quality *of life* is often used interchangeably with the terms functional status, health status, and health outcomes. T e definitions of these terms, however, might range from negatively valued aspects of life, such as death, to more positively valued aspects, such as social functioning or happiness.[21,22,31–35]

Clearly, the role of a physical therapist is to either reduce the impact of disability or, better still, prevent the disability from occurring whenever possible. T e Guide outlines three prevention categories:[1]

- Primary. Prevention of disease in a susceptible or potentially susceptible population through specific measures such as general health promotion offers.
- Secondary. Efforts to decrease duration of illness, severity of the disease, and sequelae through early diagnosis and prompt intervention.
- Tertiary. Efforts to decrease the degree of disability and promote rehabilitation and restoration of function in patients with chronic and irreversible diseases.

Early preventative measures can involve addressing modifiable risk factors. Modifiable factors are characteristics that an individual can control or adjust. T e impact that the modifiable factors have on the pathology–disability pathway or disablement process can depend on both the capacities of the individual and the expectations that are imposed on the individual by those in the immediate social and occupational environment.[36] Specific examples of modifiable patient factors include the following:

- T e patient's activity level. A number of studies have made associations between low physical activity levels and the onset of disability.[37–48]
- T e patient's reaction to the illness. Different cultural backgrounds are associated with different beliefs about pain, coping strategies, expressions of pain, and response to health care.[49,50] T e term sick role has been used to define a status accorded to the individual by himself or herself and other members of society that may be variably associated with a medical condition.[36] An individual's sick role reflects not only his or her primary condition but also any additional or secondary conditions.[51,52]

- **The patient's educational background.** Patients with less formal education tend to have an increased frequency of disability.[53,54]
- **The patient's compensatory and coping strategies.** Some people simply do not have the emotional and social resources to deal with life, particularly in times of adversity.[55]
- **The patient's pain tolerance and motivation.** Various studies[50,56] have revealed both ethnic and gender differences in response to both clinical and experimental pain. Specifically, investigators have recently indicated that African Americans report greater levels of pain than whites for such conditions as glaucoma, acquired immunodeficiency syndrome, migraine, headache, jaw pain, postoperative pain, myofascial pain, angina pectoris, joint pain, nonspecific daily pain, and arthritis.[57] Interpretations of such findings remain difficult, however, because of potential group differences in disease severity and physician management.[57] There are also disparate reports about gender differences in sensitivity to pain in humans and in animals, indicating that women have a lower tolerance of pain than men.[58–60] Whether women are more willing to report pain than men are, or experience pain differently than men do, is unclear. Whatever be the reasons for the differences in pain tolerance and motivation, there is perhaps a reason to suppose that improved pain tolerance and motivation might be instrumental in reducing impairment and disability. The chronic pain-adaptation model of Lund et al.[61] describes a decreased activation of the muscles during movements in which they act as agonists and an increased activation during movements that require that they adopt the role of antagonists. These changes in muscle activation, characteristic of several types of chronic musculoskeletal pain, are described as a normal protective adaptation to avoid further pain and possible damage.[61]
- **The patient's personal and health habits.** The link between disability and health behavior, such as excessive alcohol use, is subtle because there are many potential pathways. The link between body weight and both morbidity and mortality has been examined extensively, but relatively little research has investigated the relation between body weight and disability. Among the studies that have investigated this relation, the findings are inconsistent.[62–65]
- **The patient's level of social support.** The *family* is the primary unit of society and the one in which the earliest and most powerful social learning occurs.[36] The literature on the role of the family in the development and maintenance of chronic pain and disability is extensive. Dysfunctional family systems may promote, permit, and maintain chronic pain and disability.[36]
- **The patient's marital status.** Considerable research shows that the spouse's reaction can modify the behavior of patients with chronic pain and disability.[36]
- **The extent to which the patient is involved in litigation and compensation.** Few issues around disability have given rise to more controversies than the question of litigation, compensation, and secondary gain. Anecdotal clinical and legal experience shows general agreement that some claimants magnify or exaggerate their symptoms and disability to varying degrees during the medical examination carried out specifically for legal proceedings.[36]

The Examination

An examination refers to the gathering of information from the chart, other caregivers, the patient, the patient's family, caretakers, and friends in order to identify and define the patient's problem(s), and to design an intervention plan.[18] In addition, the examination allows the clinician to confirm their pre-examination hypothesis regarding the pathology and movement dysfunction underlying the patient's symptoms and disablement.[15] In contrast, an evaluation is the level of judgment necessary to make sense of the findings in order to identify a relationship between the symptoms reported and the signs of disturbed function.[18]

Obtaining the necessary information to determine the clinical presentation of the patient's symptoms, is an important initial step in the diagnostic process. The information obtained will guide the physical examination for the purpose of identifying specific impairments and functional limitations that are associated with the injury. The examination is an ongoing process that begins with the patient referral, or initial entry into the health system and continues throughout the course of rehabilitation. During the examination phase, the clinician hypothesizes the clinical problem then chooses and implements measures to test the hypotheses. The examination must be performed in a systematic manner with scientific rigor that follows a predictable and strictly ordered thought process. The purpose of the examination is to obtain information that identifies and measures a change from normal. This is determined using information related by the patient, in conjunction with clinical signs and findings. The examination should not be viewed as an algorithm. Rather, it is a framework that has specific points that can be applied to various situations. The strength of an examination relies on the accuracy of the findings of the testing procedures. Diagnostic tests are divided into two main categories:[66]

1. Tests that result in a discrete outcome—they permit interpretations from the test as present/absent, disease/not disease, mild/moderate/severe.
2. Tests that result in a continuous outcome—they provide data on an interval, or a scale of measurement, such as degrees of range of motion.

For the clinician to formulate an appropriate interpretation and an accurate final diagnosis, the tests chosen must be useful. Reliability, validity, and significance are essential in determining the usefulness of a test (see Evaluation):

- Reliability. A test is considered reliable if it produces precise, accurate, and reproducible information.[67]
- Validity. Test validity is defined as the degree to which a test measures what it purports to be measuring, and how well it correctly classifies individuals with or without a particular disease condition.[68–70]

- Signi*fi*cance. T e term significance is used in statistics to describe the probability of something happening.

CLINICAL PEARL

The clinician must always remember that measurements may appear to be objective but that the interpretation of any measurement is always subjective.[71]

Patient discomfort should always be kept to a minimum. It is important that examination procedures only be performed to the point at which symptoms are provoked or begin to increase if they are not present at rest.

T e examination consists of three components of equal importance: (1) patient history, (2) systems review, and (3) tests and measures.[18] T ese three components are closely related, in that they often occur concurrently. One further element, observation, occurs throughout.

History

T e history taking, specific to each joint, is detailed in each of the chapters. T e history usually precedes the systems review and the tests and measures components of the examination. Whenever it occurs, it should always be used in conjunction with the findings from the system review and the tests and measures rather than performed in a vacuum. One of the purposes of the history (Table 4-1) is to collect enough clinical data to establish a diagnostic hypothesis that will focus the examination in terms of a complete differential diagnosis

TABLE 4-1 Data Generated from a Patient History

General demographics	Includes information about the patient's age, height, weight, and marital status and primary language spoken by the patient.[a]
Social history and social habits	Includes information about the patient's social history, including support systems, family and caregiver resources, and cultural beliefs and behaviors.[1] An individual's response to pain and dysfunction is, in large part, determined by his or her cultural background, social standing, educational and economical status, and anticipation of functional compromise.[b]
Occupation/ employment	Includes information about the patient's occupation, employment, and work environment, including current and previous community and work activities.[1] The clinician must determine the patient's work demands, the activities involved, and the activities or postures that appear to be aggravating the condition or determine the functional demands of a specific vocational or avocational activity to which the patient is planning to return. Work-related low back injuries and repetitive motion disorders of the upper extremities are common in patients whose workplaces involve physical labor. Habitual postures may be the source of the problem in those with sedentary occupations. Patients who have sedentary occupations may also be at increased risk of overuse injuries when they are not at work, as a result of recreational pursuits (the weekend warrior).
Growth and development	Includes information about the patient's developmental background and hand or foot dominance. Developmental or congenital disorders that the clinician should note include such conditions as Legg–Calvé–Perthes disease, cerebral palsy, Down syndrome, spina bifida, scoliosis, and congenital hip dysplasia.
Living environment	The clinician should be aware of the living situation of the patient, including entrances and exits to the house, the number of stairs, and the location of bathrooms within the house.
Functional status and activity level	Includes information about the patient's current and prior level of function, with particular reference to the type of activities performed and the percentage of time spent performing those activities.
Past history of current condition	It is important for the clinician to determine whether the patient has had successive onsets of similar symptoms in the past, because recurrent injury tends to have a detrimental effect on the potential for recovery. If the patient's history indicates a recurrent injury, the clinician should note how often, and how easily, the injury has recurred and the success or failure of previous interventions.
Past medical/surgical history	Includes information with regard to allergies, childhood illnesses, and previous trauma. In addition, information on any health conditions, such as cardiac problems, high blood pressure, or diabetes, should be elicited, as these may impact exercise tolerance (cardiac problems and high blood pressure) and speed of healing (diabetes). If the surgical history is related to the current problem, the clinician should obtain as much detail about the surgery as possible from the surgical report, including any complications, precautions, or postsurgical protocols. Although this information is not always related to the presenting condition, it does afford the clinician some insight as to the potential impact or response the planned intervention may have on the patient.
Family history and general health status	Certain diseases, such as rheumatoid arthritis, diabetes, cardiovascular disease, and cancer, have familial tendencies. The general health status refers to a review of the patient's health perception, physical and psychological function, as well as any specific questions related to a particular body region, or complaint.[1]

at the level of pathology, determining any potential underlying etiology, and prioritizing the tests and measures to be used, especially if the clinician has a good understanding of the underlying anatomy and biomechanics. T ere has been a recent trend to put less emphasis on the history and use the results from imaging studies to determine a clinical diagnosis, which is ironic given the fact that much of these diagnostic tests would be unnecessary if more attention was paid to the clinical examination.[72] Indeed, multiple studies have demonstrated the incidence of MRI abnormalities in the spine,[73] the shoulder,[74] the knee,[75] and other areas in normal subjects. Obviously, an improper diagnosis leads to inappropriate treatment.

CLINICAL PEARL

A study by O'Shea et al.[76] found that the correct diagnosis of knee injuries was made in 83% of patients utilizing the history and physical examination alone.

T e other purpose of the subjective examination is to develop a working relationship with the patient and to establish lines of communication with the patient. Ideally, the interview of a patient should be conducted in a quiet, well-lit room that offers a measure of privacy. To encourage good communication, the clinician and the patient should be at a similar eye level, facing each other, with a comfortable space between them (approximately 3 ft). T e clinician must record the history in a systematic fashion so that every question has a purpose, and no subject areas are neglected. Formal questioning using a questionnaire (Table 4-2) helps to ensure that all of the important questions are asked. A body chart (Fig. 4-1) can be used to ascertain the specific location and the nature of the symptoms. Discussing the information provided on the medical history form with the patient helps to establish a rapport with the patient. Knowing the importance of each question is based on the didactic background of the clinician, as is the ability to convert the patient's responses into a working hypothesis. For example, if the patient reports that lumbar flexion relieves their low back pain, but that lumbar extension aggravates it, the clinician needs to know which structures are stressed in lumbar extension, but unstressed in lumbar flexion.

A transfer of accurate information must occur between the patient and the clinician. T e method of questioning should be altered from patient to patient, as the level of understanding and answering abilities varies between each individual. In general, the interview should flow as an active conversation, not a question-and-answer session. A successful learning process requires the clinician to have patience, focus, and self-criticism.[6]

Open-ended questions or statements, such as "Tell me why you are here today," are used initially to encourage the patient to provide narrative information, help determine the patient's chief complaint, and to decrease the opportunity for bias on the part of the clinician.[77] More specific questions, such as "How did this pain begin?" are asked as the examination proceeds (Table 4-3). T e specific questions help to focus the examination and deter irrelevant information. T e clinician should provide the patient with encouraging responses, such as a nod of the head, when the information is relevant and when needed to steer the patient into supplying the necessary information. Neutral questions should be used whenever possible. T ese questions are structured in such a way so as to avoid leading the patient into giving a particular response. Leading questions, such as "Does it hurt more when you walk?" should be avoided. A more neutral question would be, "What activities make your symptoms worse"?

In addition to the details listed in Table 4-3, the history can help the clinician to:

- determine the chief complaint, its mechanism of injury, its severity, and its impact on the patient's function. It is worth remembering that a patient's chief complaint can sometimes differ from the chief concern, but both should be addressed.
- determine the irritability of the symptoms. Irritability is the amount of activity necessary to cause symptom worsening or improvement.[15]
- establish a baseline of measurements.
- ascertain which medications the patient is currently taking and whether they are prescribed or over the counter (see Chapter 9).
- elicit information about the past history of the current condition.
- determine the goals and the expectations of the patient from the physical therapy intervention. It is important that the clinician and the patient discuss and determine mutually agreed upon anticipated goals and expected outcomes. T e discussion can help the clinician determine whether the patient has realistic expectations or will need further patient education concerning his or her condition and typical recovery time frames.

CLINICAL PEARL

It is important to remember that symptoms can be experienced without the presence of recognized clinical signs and that signs can be present in the absence of symptoms. The former scenario is more common, but the latter can occur when a pathologic reflex or positive cranial nerve test (see Chapter 3) is detected in the absence of any subjective complaints. In such a scenario, a positive finding could be a false-positive result, or it could be prognostic.[4]

- elicit reports of potentially life-threatening symptoms, or red *fl*ags, that require an immediate medical referral (see Chapter 5). Examples include reports of pain made worse by rest but better with activity, fever or chills, and a sudden or insidious onset of symptoms.

T ere are key questions in every subjective examination of inquiries regarding:[78]

- the patient's age, general health, and medications;
- the mode of onset of symptoms;
- the location and behavior of symptoms, such as aggravating and relieving factors;
- the results of any imaging studies;

TABLE 4-2 Sample Medical History Questionnaire

GENERAL MEDICAL HISTORY GENERAL INFORMATION

Physician Diagnosis: _____ Date: _____

Last Name _____ First Name _____

The information requested may be needed if you have a medical emergency.

_____ _____ _____

Person to be notified in emergency _____ Phone _____ Relationship _____

Are you currently working? (Y) or (N) Type of work: If not, why?

GENERAL MEDICAL HISTORY

Please check (□) if you have been treated for:

( ) Heart problems
( ) Fainting or dizziness
( ) Shortness of breath
( ) Calf pain with exercise
( ) Severe headaches
( ) Recent accident
( ) Head trauma/concussion
( ) Muscular weakness
( ) Cancer
( ) Joint dislocation(s)
( ) Broken bone
( ) Difficulty sleeping
( ) Frequent falls
( ) Unexplained weight loss
( ) Tremors
( ) High blood pressure (hypertension)
( ) Kidney disease
( ) Liver disease
( ) Weakness or fatigue
( ) Hernias
( ) Blurred vision
( ) Bowel/bladder problems
( ) Difficulty swallowing
( ) A wound that does not heal
( ) Unusual skin coloration
( ) Lung disease/problems
( ) Arthritis
( ) Swollen and painful joints
( ) Irregular heart beat
( ) Stomach pains or ulcers
( ) Pain with cough or sneeze
( ) Back or neck injuries
( ) Diabetes
( ) Stroke(s)
( ) Balance problems
( ) Muscular pain with activity
( ) Swollen ankles or legs
( ) Jaw problems
( ) Circulatory problems
( ) Epilepsy/seizures/convulsions
( ) Chest pain or pressure at rest
( ) Allergies (latex, medication, food)
( ) Constant pain unrelieved by rest
( ) Pregnancy
( ) Night pain (while sleeping)
( ) Nervous or emotional problems
( ) Any infectious disease (TB, AIDS, hepatitis)
( ) Tingling, numbness, or loss of feeling? If yes, where?
( ) Constant pain or pressure during activity

Do you use tobacco? (Y) or (N) If yes, how much?

Are you presently taking any medications or drugs? (Y) or (N)

If yes, what are you taking them for?

1. Pain

On the line provided, mark where your "pain status" is today.

_____

No pain Most severe pain

2. Function. On a scale of 0–10 with 0 being able to perform all of your normal daily activities, and 10 being unable to perform any of your normal daily activities, give yourself a score for your current ability to perform your activities of daily living. _____

Please list any major surgery or hospitalization:

Hospital: _____ Approx. Date: _____

Reasons:

Hospital: _____ Approx. Date : _____

Reasons:

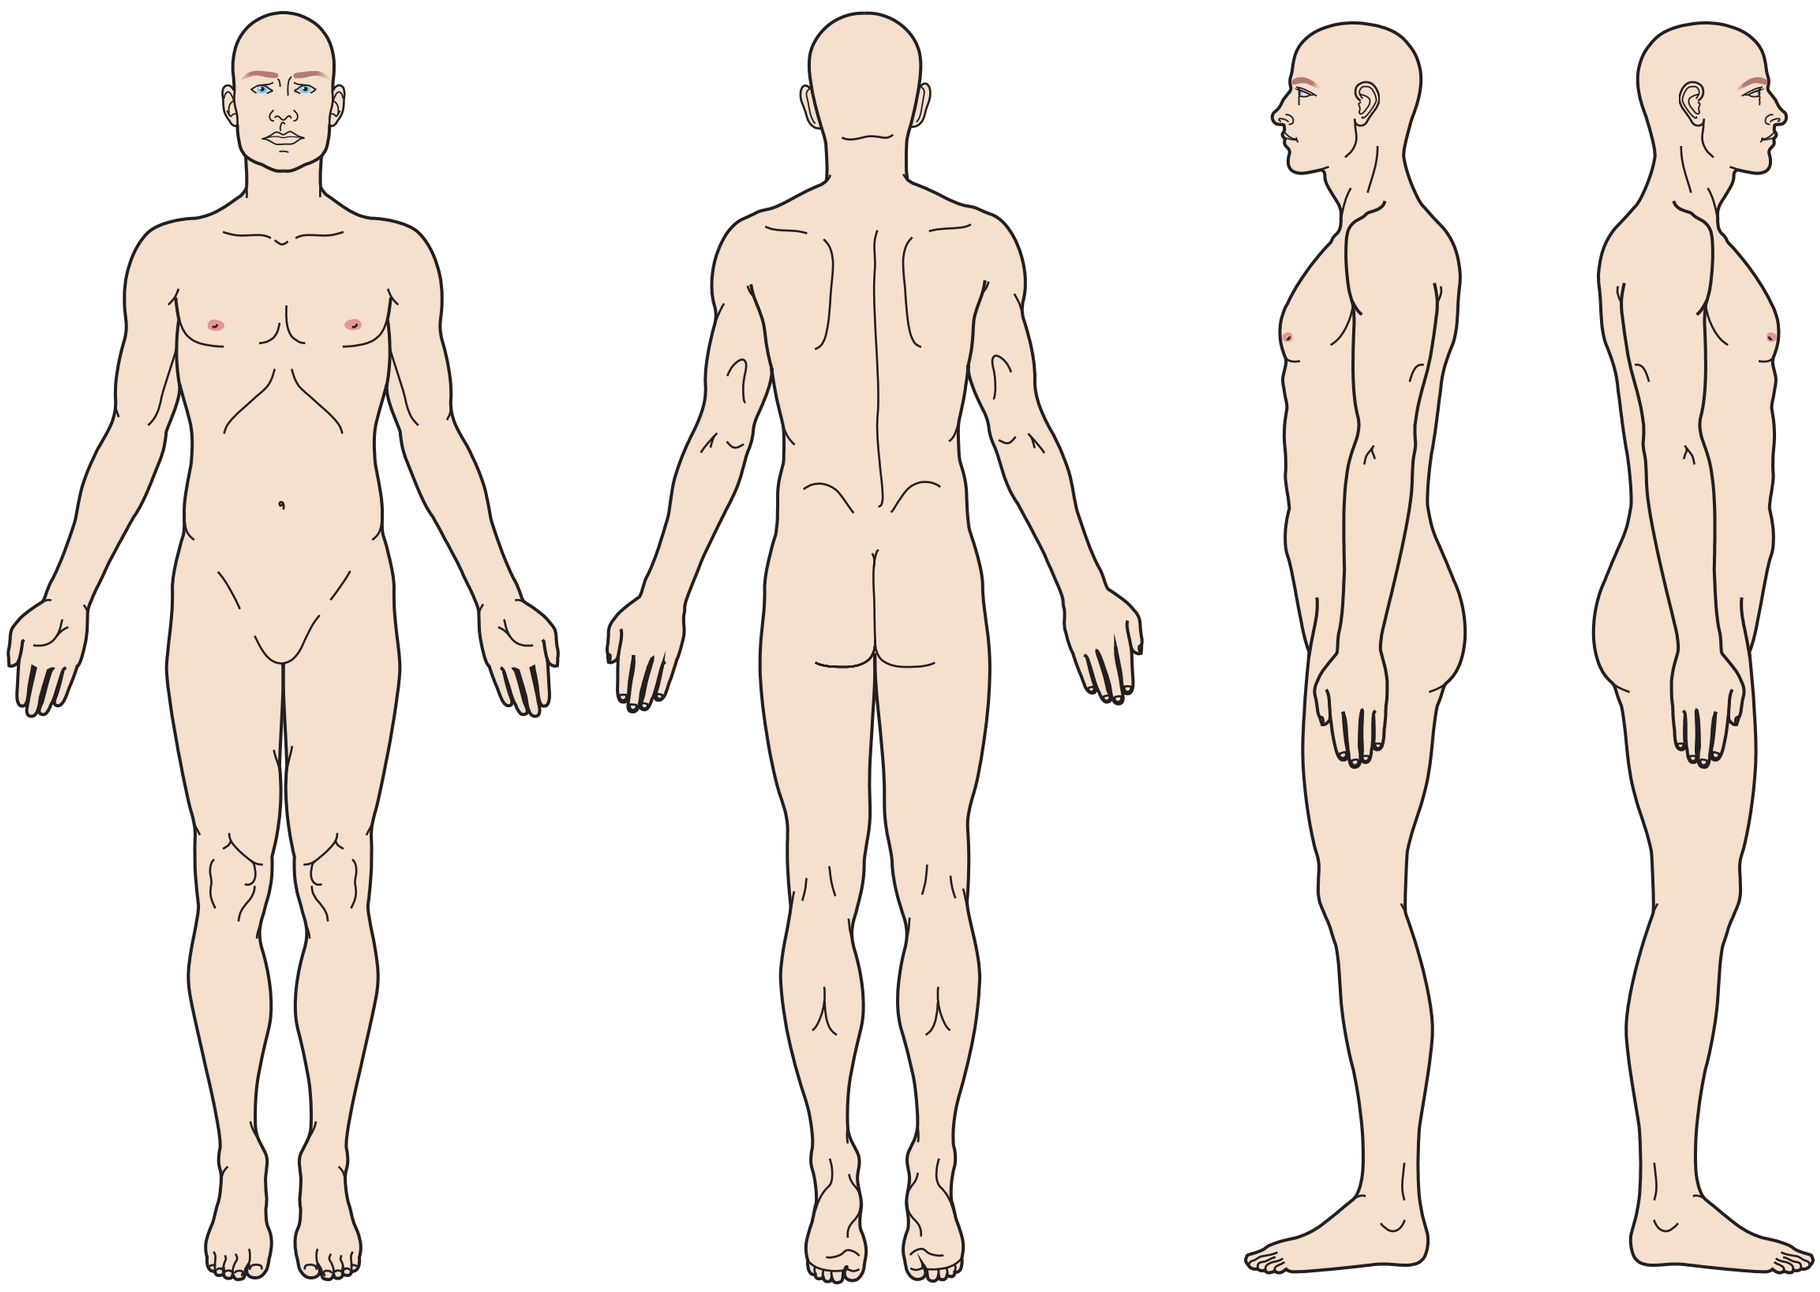
Have you recently had an x-ray, MRI, or CT scan for your condition? (Y) or (N)

Facility: _____ Approx. Date: _____

Findings: _____

Please mention any additional problems or symptoms you feel are important: _____

Have you been evaluated and/or treated by another physician, physical therapist, chiropractor, osteopath, or healthcare practitioner for this condition? (Y) or (N) If yes, please circle which one.



Name: _____

Date: _____ Signature: _____

Please use the diagram below to indicate where you feel symptoms right now.
Use the following key to indicate different types of symptoms.

KEY:

Pins and Needles= 000000 Stabbing= /////// Burning= XXXXX Deep Ache= ZZZZZZ

Please use the three scales below to rate your pain over the past 24 hours. Use the upper line to describe your pain level right now. Use the other scales to rate your pain at its worst and best over the past 24 hours.

RATE YOUR PAIN: 0= No Pain 10=Extremely Intense

1. Right now 0 1 2 3 4 5 6 7 8 9 10
2. At its worst 0 1 2 3 4 5 6 7 8 9 10
3. At its best 0 1 2 3 4 5 6 7 8 9 10

FIGURE 4-1 Body chart.

- the impact of the patient's pain/symptoms on sleeping;
- the patient's current occupation/leisure/sports activities and desired levels of activities and goals; and
- the patient's thoughts, beliefs, and feelings around their problem.

Age, Ethnicity, Gender, Morphology, and Family History

Certain conditions are related to age, ethnicity, gender, morphology, and family history. For example,

- Degenerative and overuse syndromes are more frequent in the over 40 age group.
- Cervical spondylosis is often seen in persons 25 years of age or older, and it is present in 60% of those older than 45 years and 85% of those older than 65 years of age.[79–81]
- The onset of ankylosing spondylitis often occurs between the ages of 15 and 35 years.[82]
- Both osteoporosis and osteoarthritis are more often associated with the older population.
- Diseases such as Legg–Perthes disease or Scheuermann's are seen in adolescents or teenagers.
- Prostate cancer has a higher incidence in men older than 50 years of age.[83]
- Among African Americans in the United States, 1 in 600 has sickle cell anemia.[84]
- Caucasians experience higher osteoporotic fracture rates than either Asians or African Americans.[85]
- Some diseases, such as hypertension and renal disease, are more prevalent in African-American populations than among Caucasians.[86,87]

TABLE 4-3 Contents of the History

History of Current Condition

Did the condition begin insidiously or was trauma involved?

How long has the patient had the symptoms?

Where are the symptoms?

How does the patient describe the symptoms?

Reports about numbness and tingling suggest neurologic compromise. Reports of pain suggest a chemical or mechanical irritant. Pain needs to be carefully evaluated in terms of its site, distribution, quality, onset, frequency, nocturnal occurrence, aggravating factors, and relieving factors.

Past History of Current Condition

Has the patient had a similar injury in the past?

Was it treated or did it resolve on its own? If it was treated, how was it treated and did intervention help?

How long did the most recent episode last?

Past Medical/Surgery History

How is the patient's general health?

Does the patient have any allergies?

Medications Patient is Presently Taking

Other Tests and Measures

Has the patient had any imaging tests such as x-ray, MRI, CT scan, bone scan?

Has the patient had an EMG test, or a nerve conduction velocity test, which would suggest compromise to muscle tissue and/or neurologic system?

Social Habits (Past and Present)

Does the patient smoke? If so, how many packs per day?

Does the patient drink alcohol? If so, how often and how much?

Is the patient active or sedentary?

Social History

Is the patient married, living with a partner, single, divorced, or widowed?

Is the patient a parent or single parent?

Family History

Is there a family history of the present condition?

Growth and Development

Is the patient right- or left-handed?

Were there any congenital problems?

Living Environment

What type of home does the patient live in with reference to accessibility?

Is there any support at home?

Does the patient use any extra pillows or special chairs to sleep?

Occupation/Employment/School

What does the patient do for work?

How long has he or she worked there?

What does the job entail in terms of physical requirements?

What level of education did the patient achieve?

Functional Status/Activity Level

How does the present condition affect the patient's ability to perform activities of daily living?

How does the present condition affect the patient at work?

How does the patient's condition affect sleep?

Is the patient able to drive? If so, for how long?

CT, computed tomography; EMG, electromyogram; MRI, magnetic resonance imaging.
Data from Clarnette RG, Miniaci A. Clinical exam of the shoulder. Med Sci Sports Exerc. 1998:30;1–6.

- Basal cell carcinoma and melanoma are more common among Caucasians.
- T e male-to-female ratio of bladder cancer is 2:1 to 4:1 and the disease is twice as common in male Caucasians as in African-American men in the United States.[88,89]
- Breast cancer is the most frequently diagnosed cancer and the second leading cause of cancer-related deaths among women in the United States.[90]
- Melanoma is the leading cause of cancer death in women aged 25–36 years.[91]

- Anterior knee pain caused by patellofemoral syndrome is most common in young teenage girls and young men in their 20s.[92]
- Obesity has been linked to many diseases such as diabetes, cardiovascular disease, and degenerative joint disease.
- Many diseases can be linked to family history, including diabetes, cardiovascular disease, and Charcot Marie Tooth disease.

Mode of Onset of Current Condition

T is portion of the history-taking can prove to be the most challenging as it involves the gathering of both positive and negative findings, followed by the dissemination of the information into a working hypothesis. An understanding of the patient's history of the current condition can often help determine the prognosis and guide the intervention.

T e clinician should determine the circumstances and manner in which the symptoms began and the progression of those symptoms.[6] T e onset and duration (stage) of symptoms provide clinicians with information as to whether the injury is acute or chronic. T is information is very important in that the mechanisms of a certain injury may be similar; however, the time associated with symptom presentation may differ significantly.[93] For example, an acute muscle strain injury that occurs during a sport will present with immediate pain and an easily identifiable mechanism. Conversely, a muscle strain injury that occurs through an overuse mechanism may present insidiously.[93] Establishing a symptom timeline can help the clinician collect information about the duration of symptoms.[94] T e symptom timeline is a brief description that lists any significant event during the course of the patient's symptoms such as the number of times that the symptoms improved, the number of times that the symptoms worsen, any interventions that were tried, and any visits to healthcare providers that occurred.[15]

T e mode of onset, or the mechanism of injury, is usually either a major traumatic event over a short period of time, such as a fall or motor vehicle accident (macrotraumatic), or a series of minor traumatic events over a prolonged period of time, such as the habitual use of a lifting/sitting/training technique (microtraumatic) either of which can give clues as to the extent and nature of the damage caused. However, it is important to remember that the patient's description of injury mechanism should be interpreted with caution because the mechanism ascribed to the onset of symptoms could be falsely assumed, causing the clinician to overlook the presence of an another pathology.[15]

If the injury is traumatic, the clinician should determine the time of onset, and the specific mechanism in terms of both the direction and the force, and relate the time and mechanism to the presenting symptoms. If the injury is recent, an inflammatory source of pain is likely. A sudden onset of pain, associated with trauma, could indicate the presence of an acute injury such as a soft tissue tear or even a fracture, whereas immediate pain and locking are most likely to result from an intraarticular block. Joint locking and twinges of pain may indicate a loose body is moving within the joint. Reports of a joint "giving way" usually indicate joint instability, or a reflex inhibition or weakness of muscles. An injury that is not recent but which the symptoms have persisted could indicate a biomechanical dysfunction. Often-times a particular motion or posture may continue to aggravate the condition.

If the onset is gradual or insidious, the clinician must determine if there are any predisposing factors, such as changes in the patient's daily routines or exercise programs. Symptoms of pain, or limitations of movement, with no apparent reason, are usually a result of inflammation, early degeneration, repetitive activity (microtrauma), or sustained positioning and postures.[95] However, such symptoms may also be associated with something more serious, such as a vascular insufficiency, a tumor, or an infection.

If pain is present, the clinician's major focus should be to seek the cause and methods to control it. Pain may be constant, variable, or intermittent.

- Variable pain is pain that is perpetual, but that varies in intensity. Variable pain usually indicates the involvement of both a chemical and a mechanical source. T e mechanical cause of constant pain is less understood but is thought to be the result of the deformation of collagen, which compresses or stretches the nociceptive-free nerve endings, with the excessive forces being perceived as pain.[96] T us, specific movements or positions should influence pain of a mechanical nature.
- Chemical, or inflammatory, pain is more constant and is less affected by movements or positions than mechanical pain.
- Intermittent pain is unlikely to be caused by a chemical irritant. Usually, this type of pain is caused by prolonged postures, a loose intraarticular body, or an impingement of a musculoskeletal structure.

CLINICAL PEARL

Constant pain following an injury continues until the healing process has suf ciently reduced the concentration of noxious irritants.

Unfortunately, the source of the pain is not always easy to identify, because most patients present with both mechanical and chemical pain.

Finally, the clinician should determine if this is the first episode requiring treatment, or if a specific intervention has been used in the past for the same condition and, if so, the clinician should ask about the effectiveness of that intervention. If it is a repeat episode, the clinician should ascertain how long it took to recover from the previous one, and what therapy was beneficial if any.

Location

T e clinician should determine the location of the symptoms because this can indicate which areas need to be included in the physical examination. However, it must be remembered that the location of symptoms for many musculoskeletal conditions is quite separate from the source, especially in those peripheral joints that are more proximal, such as the shoulder and the hip. For example, a cervical dysfunction can produce

symptoms throughout the upper extremity. The term referred is used to describe symptoms that have their origin at a site other than where the patient feels the symptoms (see Chapter 3). For example, pain due to osteoarthritis of the hip is often felt in the anterior groin and thigh. The term radicular is used to describe the distribution of symptoms associated with nerve root compression, in which the symptoms radiate from the source. For example, a patient who has a compressed spinal nerve in the cervical spine may feel the symptoms in the neck and throughout certain areas in the upper extremity. The concepts of referred and radicular symptoms are often difficult for a patient to understand, so it is important that the clinician provide an explanation so that the patient has a better understanding and can answer questions about symptoms they might otherwise have felt irrelevant.

Information about how the location of the symptoms has changed since the onset can indicate whether a condition is worsening or improving. In general, as a condition worsens, the pain distribution becomes more widespread and distal (peripheralized). As the condition improves, the symptoms tend to become more localized (centralized). A body chart may be used to record the location of symptoms (see Fig. 4-1).

CLINICAL PEARL

Symptoms that are distal and superficial are easier for the patient to specifically localize than those that are proximal and deep.

If the extremity appears to be the source of the symptoms, the clinician should attempt to reproduce the symptoms by loading the peripheral tissues. If this proves unsuccessful, a full investigation of the spinal structures must ensue.

Behavior of Symptoms

The presence of pain should not always be viewed negatively by the clinician. After all, its presence helps to determine the location of the injury, and its behavior aids the clinician in determining the stage of healing and the impact it has on the patient's function. For example, whether the pain is worsening, improving, or unchanging provides information on the effectiveness of an intervention. In addition, a gradual increase in the intensity of the symptoms over time may indicate to the clinician that the condition is worsening or that the condition is nonmusculoskeletal in nature (Table 4-4).[6,97]

Maitland[7] introduced the concept of the degree *of* irritability. An irritable structure has the following characteristics:

- A progressive increase in the severity *of* the pain or symptoms with movement or a specific posture. An ability to reproduce constant pain with a specific motion or posture indicates an irritable structure.
- Symptoms increased with minimal activity. An irritable structure is one that requires very little to increase the symptoms.
- Increased latent response *of* symptoms. Symptoms that do not resolve within a few minutes following a movement or posture indicate an irritable structure.

TABLE 4-4 Differentiation Between Musculoskeletal and Systemic Pain

Musculoskeletal Pain	Systemic Pain
Usually decreases with cessation of activity	Reduced by pressure
Generally lessens at night	Disturbs sleep
Aggravated with mechanical stress	Not aggravated by mechanical stress
Usually continuous or intermittent	Usually constant or in waves

Data from Meadows J. Orthopaedic Differential Diagnosis in Physical Therapy. New York, NY: McGraw-Hill; 1999.

According to McKenzie and May,[95] the intervention for the patient whose symptoms have a low degree of irritability, and which are gradually resolving, should focus only on education initially. However, if the improvement ceases, a mechanical intervention may then be necessary.[95]

The frequency and duration of the patient's symptoms can help the clinician to classify the injury according to its stage of healing: acute (inflammatory), subacute (migratory and proliferative), and chronic (remodeling) (Table 4-5) (see Chapter 2).

- Acute conditions: typically present for 7–10 days.
- Subacute conditions: typically present for 10 days to several weeks.
- Chronic conditions: typically present for more than several weeks.

In the case of a musculoskeletal injury that has been present without any formal intervention for a few months, there is a good possibility that adaptive shortening of the healing collagenous tissue has occurred, which may result in a failure to heal, and the persistence of symptoms.[95] The persistence of symptoms usually indicates a poorer prognosis, as it may indicate the presence of a chronic pain syndrome. Chronic pain syndromes have the potential to complicate the intervention process (see Chapters 2 and 5).[95]

If the frequency and duration of the patient's symptoms are reported to be increasing, it is likely the condition is worsening. Conversely, a decrease in the frequency and duration of the symptoms generally indicate that the condition is improving.

One of the simplest methods to quantify the intensity of pain is to use a 10-point visual analog scale (VAS). The VAS is a numerically continuous scale that requires the pain level be identified by making a mark on a 100-mm line, or by circling

TABLE 4-5 Stages of Healing

Stage	General Characteristics
Acute or inflammatory	Area is red, warm, swollen, and painful. Pain is present without any motion of involved area
Subacute or tissue formation (neovascularization)	Pain usually occurs with activity or motion of involved area
Chronic or remodeling	Pain usually occurs after the activity

TABLE 4-6 Patient Pain Evaluation Form

Name: _____

Date: _____ Signature: _____

Please use the three scales below to rate your pain over the past 24 hours. Use the upper line to describe your pain level right now. Use the other scales to rate your pain at its worst and best over the past 24 hours.

RATE YOUR PAIN: 0 = NO PAIN, 10 = EXTREMELY INTENSE

1.	Right now	0	1	2	3	4	5	6	7	8	9	10
2.	At its worst	0	1	2	3	4	5	6	7	8	9	10
3.	At its best	0	1	2	3	4	5	6	7	8	9	10

the appropriate number in a 1–10 series (Table 4-6).[98] The patient is asked to rate his or her present pain compared with the worst pain ever experienced, with 0 representing no pain, 1 representing pain that is minimally perceived, and 10 representing pain that requires immediate attention.[99]

If the behavior of the symptoms includes locking or giving way, the clinician must elicit further details about the causes of the hypomobility, the hypermobility, or the instability (see Chapter 2).

Aggravating and Easing Factors

Of particular importance are the patient's chief complaint and the relationship of that complaint to specific aggravating activities or postures, as these may point to the tissue of origin for symptoms. Questions must be asked to determine whether the pain is sufficient to prevent sleep or to wake the patient at night, and the effect that activities of daily living, work, sex, and so forth, have on the pain.

Musculoskeletal conditions are typically aggravated by movement and alleviated with rest. More specifically, musculotendinous structures may generate pain with either shortening or lengthening while noncontractile tissues may generate pain with lengthening.[15] If no activities or postures are reported to aggravate the symptoms, the clinician needs to probe for more information. For example, if a patient complains of back pain, the clinician needs to determine the effect that walking, bending, sleeping position, prolonged standing, and sitting have on the symptoms. Sitting or standing upright increases the lumbar lordosis and can aggravate symptoms in a patient with an anterior instability of the lumbar spine, spondylolisthesis, stenosis, or a lumbar zygapophyseal joint irritation. Sitting in a slouched posture typically aggravates symptoms of a lumbar disk protrusion or a sacroiliac joint dysfunction. Nonmechanical events that provoke the symptoms could indicate a nonmusculoskeletal source for the pain:[97]

- Eating. Pain that increases with eating may suggest gastrointestinal (GI) involvement.
- Stress. An increase in overall muscle tension prevents muscles from resting.
- Cyclical pain. Cyclical pain can often be related to systemic events (e.g., menstrual pain).

If aggravating movements or positions have been reported, they should be tested at the end of the tests and measures portion of the examination to avoid any overflow of symptoms, which could confuse the clinician.

CLINICAL PEARL

Any relieving factors reported by the patient can often provide sufficient information to assist the clinician with the intervention plan.

Nature of the Symptoms

Nature refers to the patient's description of symptoms.[15] It is important to remember that pain perception is highly subjective and is determined by a number of factors. The clinician must determine whether pain is the only symptom, or whether there are other symptoms that accompany the pain, such as bowel and bladder changes, tingling (paresthesia), radicular pain or numbness, weakness, and increased sweating.

- Bowel or bladder dysfunction. This finding usually indicates a compromise (compression) of the cauda equina.
- Paresthesia. Peripheral neuropathies can manifest as abnormal, frequently unpleasant sensations, which a patient may variously describe as numbness, pins and needles, and tingling.[100] When these sensations occur spontaneously without an external sensory stimulus, they are called paresthesias (Table 4-7).[100] Patients with paresthesias typically demonstrate a reduction in the perception of cutaneous and proprioceptive sensations. The seriousness of the paresthesia depends on its distribution. Although complaints of paresthesia can be the result of a relatively benign impingement of a peripheral nerve (see Chapter 3), the reasons for its presence can vary in severity and seriousness.
- Radicular pain. This type of pain is produced by nerve root irritation and is typically described as sharp or shooting. Any numbness that has a dermatomal pattern indicates spinal nerve root compression. Radiating pain refers to an increase in pain intensity and distribution. Radiating pain typically travels distally from the site of the injury.
- Weakness. Any weakness should be investigated by the clinician to determine whether it is the result of spinal nerve root compression, peripheral nerve lesion, disuse,

TABLE 4-7 Causes of Paresthesia

Paresthesia Location	Probable Cause
Lip (perioral)	Vertebral artery occlusion
Bilateral lower or bilateral upper extremities	Central protrusion of disk impinging on spine
All extremities simultaneously	Spinal cord compression
One-half of body	Cerebral hemisphere
Segmental (in dermatomal pattern)	Disk or nerve root
Glove-and-stocking distribution	Diabetes mellitus neuropathy and lead or mercury poisoning
Half of face and opposite half of body	Brain stem impairment

inhibition resulting from pain or swelling, injury to the contractile or inert tissues (muscle, tendon, bursa, etc.), or a more serious pathology such as a fracture (see section "Muscle Performance: Strength, Power, and Endurance" in the later discussion of tests and measures).

- Increased sweating. T is finding can have a myriad of causes, ranging from increased body temperature, as a result of exertion, fever, apprehension, and compromise, to the autonomic system. Night sweats are of particular concern because they often indicate the presence of a systemic problem.[101]

Quality of Symptoms

T e quality of the symptoms depends on the type of receptor being stimulated (see Chapter 3).

- Stimulation of the cutaneous A-δ nociceptors leads to pricking pain.[102]
- Stimulation of the cutaneous C nociceptors results in burning or dull pain.[103]
- Activation of the nociceptors in muscle by electrical stimulation produces aching pain.[104]
- Electrical stimulation of visceral nerves at low intensities results in vague sensations of fullness and nausea, but higher intensities cause a sensation of pain.[105]

CLINICAL PEARL

Because motor and sensory axons run in the same nerves, disorders of the peripheral nerves (neuropathies) usually affect both motor and sensory functions (see Chapter 2).

Motivational-affective circuits may also mimic pain states, most notably in patients with anxiety, neurotic depression, or hysteria.[106] T e mnemonic MADISON outlines the behavioral indicators that suggest motivational-affective pain[107,108]:

1. Multiple complaints, including complaints about unrelated body parts.
2. Authenticity claims in an attempt to convince the clinician that the symptoms exist.
3. Denial of the negative effect the pain is having on overall function.
4. Interpersonal variability, manifested by different complaints to different clinicians or support staff.
5. Singularity of symptoms, wherein the patient requests special consideration because of his or her type and level of pain.
6. Only you, whereby the clinician is placed at a special level of expertise.
7. Nothing works. T is is often a source of frustration and self-doubt on the part of the clinician.

A description of pain is commonly sought from the patient. Because pain is variable in its intensity and quality, describing the pain is often difficult for the patient. T e McGill Pain Questionnaire (MPQ)[109] was the first systematic attempt to use verbal descriptors to assess the quality of the patient's symptoms, and has been the most widely used instrument in pain research and practice (Table 4-8). T e MPQ is an inventory of 78 pain descriptors distributed across 20 subcategories (with 6 additional descriptors in the present pain index). T e subcategories are further grouped into three broad categories, termed sensory, a*ff*ective, and evaluative, respectively, in addition to a miscellaneous category. T e implication is that each word reflects a particular sensory quality of pain.

T e patient is asked to indicate on a body diagram the location of the pain and to rate his or her symptoms based on the 20 categories of verbal descriptors of pain.[110] T e 20 categories are ranked according to severity.[111] T e patient is then asked to describe how the pain changes with time (continuous, rhythmic, or brief) and how strong the pain is (mild, discomforting, distressing, horrible, or excruciating).

T e most commonly reported measure the MPQ instrument provides, the pain-rating index total, gives an estimate of overall pain intensity. T is measure, obtained by summing all the descriptors selected from the 20 subclasses, has a possible range of 0–78. Separate scores for each class may be obtained by summing the values associated with the words selected from subclasses that comprise that dimension. Scores for each of these dimensions vary in range from 0 to 42 for the sensory class, 0 to 14 for the affective class, and 0 to 5 for the evaluative class (see Table 4-8 for the Scoring Guide).

T e strength of the MPQ is its ability to distinguish patients with a sensory pain experience from those who have an affective pain experience. T e MPQ has been found to be sensitive to intervention effects[112] and to have a high test–retest reliability[109] and good construct validity.[113]

Symptom magnification, an exaggerated subjective response to symptoms in the absence of adequate objective findings, is an increasingly common occurrence in the clinic. T e patients who display this type of behavior are a difficult population to deal with. T e causes of symptom magnification can be categorized into two main patient types:

1. Patients with a psychosomatic overlay and those whose symptoms have a psychogenic cause.
2. Patients who are involved in litigation.

T e concept of malingering is discussed in Chapter 5.

TABLE 4-8 Modified McGill Pain Questionnaire

Patient's Name _____ Date _____

Directions: Many words can describe pain. Some of these words are listed below. If you are experiencing any pain, check (□) every word that describes your pain.

A.	Flickering	H.	Tingling	P.	Annoying
	Quivering		Itchy		Troublesome
	Pulsing		Smarting		Intense
	Throbbing		Stinging		Unbearable
	Beating	I.	Dull	Q.	Spreading
	Pounding		Sore		Radiating
B.	Jumping		Hurting		Penetrating
	Flashing		Aching		Piercing
	Shooting		Heavy	R.	Tight
C.	Pricking	J.	Tender		Numb
	Boring		Taut		Drawing
	Drilling		Rasping		Squeezing
	Stabbing		Splitting		Tearing
D.	Sharp	K.	Tiring	S.	Cool
	Cutting		Exhausting		Cold
	Lacerating	L.	Sickening		Freezing
E.	Pinching		Suffocating	T.	Nagging
	Pressing	M.	Fearful		Nauseating
	Gnawing		Frightful		Agonizing
	Cramping		Terrifying		Dreadful
	Crushing	N.	Punishing		Torturing
F.	Tugging		Grueling		
	Pulling		Cruel		
	Wrenching		Vicious		
G.	Hot		Killing		
	Burning	O.	Wretched		
	Scalding		Blinding		
	Searing				

KEY TO PAIN QUESTIONNAIRE

Group A: Suggests vascular disorder

Groups B–H: Suggests neurogenic disorder

Group I: Suggests musculoskeletal disorder

Groups J–T: Suggests emotional disorder

SCORING GUIDE: ADD UP TOTAL NUMBER OF CHECKS (□):

Total: 4–8 = NORMAL

8–10 = Focusing too much on pain

10–16 = May be helped more by a clinical psychologist than by a physical therapist

>16 = Unlikely to respond to therapy procedures

Patient Goals

The clinician should determine what level of physical activity is required by the patient. Specifically, what are the requirements for work and leisure, and sport? In addition, the clinician should ask the patient about his or her current level of activity and determine the type of activity, frequency, and intensity, and how the responses compare with the answers from the previous question. Finally, the clinician should ascertain what the patient's therapy goals are. For example, asking a simple question like "Are there any things you would like to do but are not doing because of your pain or injury?"

Imaging Studies

It is important for the clinician to determine whether the patient has undergone any imaging studies and, if so, the results of those studies. The role that imaging studies play in the examination and evaluation processes is outlined in Chapter 7. It is important to remember that, in general, imaging tests have

a high sensitivity (few false negatives) but low specificity (high false-positive rate), so are thus used in the clinical decision-making process to test a hypothesis, but should not be used in isolation.

Based on the history, there may be times when the extent of the remainder of the examination may have to be limited. T e decision to limit the examination is based on the presence of any subjective features that indicate the need for caution (see Systems Review). T ese features include[114]:

1. an irritable or severe disorder;
2. worsening symptoms;
3. subjective evidence of the potential involvement of vital structures, such as the vertebrobasilar system, the spinal cord or the central nervous system (CNS), or the spinal nerve roots;
4. symptoms that do not behave in a predictable manner.

Observation

Observational information forms the basis of the early clinical impression. It is, in essence, the beginning of the clinical search for patient consistency and reliability. Observation of the patient begins when the patient enters the clinic. As the clinician greets the patient and takes him or her to the treatment room, an initial observation is made. T is early observation can provide the clinician with information that includes, but is not limited to, how the patient holds the extremity, whether an antalgic gait is present, and how much discomfort appears to be present. T e more formal observation of each body area is included in each of the relevant chapters. Much can be learned from thorough observation[115]:

- How does the patient arise from a seated position to greet the clinician, easily or in a guarded manner?
- Does the patient look directly into the eyes of the clinician or look away? Is there a nervousness or fear present?
- Is there an exaggerated pain response, as demonstrated by facial expression and/or voiced complaints?
- Does the patient sit to the side with the majority of weight on one buttock while the opposite leg is extended, a position associated with a lumbar spinal nerve root syndrome?[116–118]
- In the case of an adult, is a spouse, or significant other, in attendance and does such a presence seem appropriate? If the presence appears inappropriate (signs of fear, questions always answered by the spouse/significant other, overly attentive spouse/significant other, etc.), some form of abuse occurring at home should be suspected.
- In the case of a child, is there any unexplained or excessive bruising, and does the parent or guardian appear to be answering for the child? T ese findings could indicate some form of abuse occurring at home.
- Does the patient require assistance in ambulation, transferring, or changing of clothing?
- Do the observation findings match the findings from the history?

T roughout the history, systems review, and tests and measures, collective observations form the basis for diagnostic deductions. Some of the observations made may be very subtle. For example, hoarseness of the voice could suggest laryngeal cancer, whereas a weakened, thickened, and lowered voice may indicate hypothyroidism.[119] Warm, moist hands felt during a handshake may indicate hyperthyroidism.[119] Cold, moist hands may indicate an anxious patient. Patients react differently to injury. Some patients may exaggerate the symptoms through facial expressions and gestures whereas others remain stoic. Patients may appear calm and pleasant, defensive, angry, apprehensive, or depressed. Anxious patients, or patients in severe pain, often appear restless. Clinicians must learn to adopt their approaches to these different reactions. For example, an anxious or apprehensive patient may require more reassurance than a calm and pleasant patient.

Much of the observation involves assessment of posture (see Chapter 6). Postural deviations negatively affecting the location of the center of gravity or center of mass in relation to the base of support may result in a patient complaining of pain and/or dysfunction when in sustained positions. Changes in the contours of the body shape or posture can be so specific that it often is possible to isolate the single muscle involved, the movements affected, and the related joint dysfunction from observation alone.[120] For example, a change in a soft tissue contour as compared to the other side could indicate muscle atrophy. T ese deviations and changes prompt a further musculoskeletal examination to determine the cause and potential management strategies. If there are any obvious deformities, the clinician must determine whether they are structural or functional:

- Structural: those deformities present at rest. For example, torticollis, and kyphosis.
- Functional: deformities that are the result of assumed postures and which disappear when the posture is changed. For example, functional scoliosis is due to a leg length discrepancy that disappears when the patient bends forward (see Chapter 27).

The patient's position of comfort can provide the clinician with valuable information. For example, patients with lateral recess spinal stenosis of the lumbar spine, congestive heart failure, or pulmonary disease often prefer the sitting position, whereas patients with pericarditis often sit and lean forward.[119] Patients with a posterior–lateral lumbar disk herniation often prefer to stand or lie rather than sit.

Systems Review

T e information from the history and the systems review serves as a guide for the clinician in determining which structures and systems require further investigation. T e systems review is the part of the examination that identifies possible health problems that require consultation with, or referral to, another healthcare provider (Table 4-9).[18] T e systems review consists of a limited examination of the anatomic and physiologic status of all systems (i.e., musculoskeletal, neurological, cardiovascular, pulmonary, integumentary, GI, urinary system,

TABLE 4-9 Signs and Symptoms Requiring Immediate Medical Referral

Signs/Symptoms	Common Cause
Angina pain not relieved in 20 minutes	Myocardial infarction
Angina pain with nausea, sweating, and profuse sweating	Myocardial infarction
Bowel or bladder incontinence and/or saddle anesthesia	Cauda equina lesion
Anaphylactic shock	Immunological allergy or disorder
Signs/symptoms of inadequate ventilation	Cardiopulmonary failure
Patient with diabetes who is confused, is lethargic, or exhibits changes in mental function	Diabetic coma
Patient with positive McBurney's point or rebound tenderness	Appendicitis or peritonitis
Sudden worsening of intermittent claudication	Thromboembolism
Throbbing chest, back, or abdominal pain that increases with exertion accompanied by a sensation of a heartbeat when lying down and palpable pulsating abdominal mass	Aortic aneurysm or abdominal aortic aneurysm

Data from Goodman CC, Snyder TEK. Differential Diagnosis in Physical Therapy. Philadelphia, PA: WB Saunders;1990; Stowell T, Cioffredi W, Greiner A, et al. Abdominal differential diagnosis in a patient referred to a physical therapy clinic for low back pain. J Orthop Sports Phys Ther. 2005:35;755–764.

and genitoreproductive).[18] The systems review includes the following components:[18]

- For the cardiovascular/pulmonary system, the assessment of heart rate, respiratory rate, blood pressure, and edema. There are four so-called vital signs that are standard in most medical settings: temperature, heart rate, blood pressure, and respiratory rate. Pain is considered by many to be a fifth vital sign.[121–130] The clinician should monitor at least heart rate and blood pressure in any person with a history of cardiovascular disease or pulmonary disease, or those at risk for heart disease.[131]
- *T*emperature. Body temperature is one indication of the metabolic state of an individual; measurements provide information concerning basal metabolic state, possible presence or absence of infection, and metabolic response to exercise.[132] "Normal" body temperature of the adult is 98.4°F (37°C). However, a temperature in the range of 96.5–99.4°F (35.8–37.4°C) is not at all uncommon. Fever or pyrexia is a temperature exceeding 100°F (37.7°C).[133] Hyperpyrexia refers to an extreme elevation of temperature above 41.1°C (or 106°F).[132] Hypothermia refers to an abnormally low temperature (below 35°C or 95°F). The temperature is generally taken by placing the bulb of a thermometer under the patient's tongue for 1–3 minutes, depending on the device. In most individuals, there is a diurnal (occurring everyday) variation in body temperature of 0.5–2°F. The lowest ebb is reached during sleep. Menstruating women have a well-known temperature pattern that reflects the effects of ovulation, with the temperature dropping slightly before menstruation, and then dropping further 24–36 hours prior to ovulation.[133] Coincident with ovulation, the temperature rises and remains at a somewhat higher level until just before the next menses. It is also worth noting that in adults older than 75 years of age, and in those who are immunocompromised (e.g., transplant recipients, corticosteroid users, persons with chronic renal insufficiency, or anyone taking excessive antipyretic medications), the fever response may be blunted or absent.[132]
- Heart rate. In most people, the pulse is an accurate measure of heart rate. The heart rate or pulse is taken to obtain information about the resting state of the cardiovascular system and the system's response to activity or exercise and recovery.[132] It is also used to assess patency of the specific arteries palpated, and the presence of any irregularities in the rhythm.[132] When the heart muscle contracts, blood is ejected into the aorta, and the aorta stretches. At this point, the wave of distention (pulse wave) is most pronounced, but relatively slow moving (3–5 m/s). As it travels toward the peripheral blood vessels, it gradually diminishes and becomes faster. In the large arterial branches, its velocity is 7–10 m/s; in the small arteries, it is 15–35 m/s. When taking a pulse, the fingers must be placed near the artery and pressed gently against a firm structure, usually a bone. The pulse can be taken at a number of points. The most accessible is usually the radial pulse, at the distal aspect of the radius. Sometimes, the pulse cannot be taken at the wrist and is taken at the elbow (brachial artery), at the neck against the carotid artery (carotid pulse), behind the knee (popliteal artery), or in the foot using the dorsalis pedis or posterior tibial arteries. The pulse rate can also be measured by listening directly to the heart beat, using a stethoscope. One should avoid using the thumb when taking a pulse, as it has its own pulse that can interfere with detecting the patient's pulse. The normal adult heart rate is 70 beats per minute (bpm), with a range of 60–80 bpm. A rate of greater than 100 bpm is referred to as tachycardia. Normal causes of tachycardia include anxiety, stress, pain, caffeine, dehydration, or exercise. A rate of less than 60 bpm is referred to as bradycardia. Athletes may normally have a resting heart rate lower than 60. The normal range of resting heart rate in children is between 80 and 120 bpm. The rate for a newborn is 120 bpm (normal range 70–170 bpm).

CLINICAL PEARL

There is normally a transient increase in pulse rate with inspiration, followed by a slowing down with expiration.[22]

- Respiratory rate. The normal chest expansion difference between the resting position and the fully inhaled position is 2–4 cm (females > males). The clinician should compare measurements of both the anterior–posterior diameter and the transverse diameter during rest and at full inhalation. Normal respiratory rate is between 8 and 14 per minute in adults and slightly quicker in children. The following breathing patterns are characteristic of disease:[133]
- Cheyne–Stokes respiration, characterized by a periodic, regular, sequentially increasing depth of respiration, occurs with serious cardiopulmonary or cerebral disorders.
- Biot's respiration, characterized by irregular spasmodic breathing and periods of apnea, is almost always associated with hypoventilation due to CNS disease.
- Kussmaul's respiration, characterized by deep, slow breathing, indicates acidosis, as the body attempts to blow off carbon dioxide.
- Apneustic breathing is an abnormal pattern of breathing characterized by a post-inspiratory pause. The usual cause of apneustic breathing is a pontine lesion.
- Paradoxical respiration is an abnormal pattern of breathing, in which the abdominal wall is sucked in during inspiration (it is usually pushed out). Paradoxical respiration is due to paralysis of the diaphragm.
- Blood pressure. Blood pressure is a measure of vascular resistance to blood flow.[132] The normal adult blood pressure can vary over a wide range. The assessment of blood pressure provides information about the effectiveness of the heart as a pump and the resistance to blood flow. It is measured in mm Hg and is recorded in two numbers. The systolic pressure is the pressure that is exerted on the brachial artery when the heart is contracting, and the diastolic pressure is the pressure exerted on the artery during the relaxation phase of the cardiac cycle.[132] The JNC 7 report released in May 2003 has added a new category of prehypertension and has established more aggressive guidelines for medical intervention of hypertension. The normal values for resting blood pressure in adults are:
  - normal: systolic blood pressure < 120 mm Hg and diastolic blood pressure < 80 mm Hg;
  - prehypertension: systolic blood pressure 120–139 mm Hg or diastolic blood pressure 80–90 mm Hg;
  - stage 1 hypertension: systolic blood pressure 140–159 mm Hg or diastolic blood pressure 90–99 mm Hg and;
  - stage 2 hypertension: systolic blood pressure ≥ 160 mm Hg or diastolic blood pressure ≥ 100 mm Hg.

The normal values for resting blood pressure in children are:

- systolic: birth to 1 month, 60–90 mm Hg; up to 3 years of age, 75–130 mm Hg; and over 3 years of age, 90–140 mm Hg;
- diastolic: birth to 1 month, 30–60 mm Hg; up to 3 years of age, 45–90 mm Hg; and over 3 years of age, 50–80 mm Hg.

Orthostatic hypotension is defined as a drop in systolic blood pressure when assuming an upright position. Orthostatic hypotension can occur as a side effect of antihypertensive medications (see Chapter 9), and in cases of low blood volume in patients who are postoperative or dehydrated, and in those with dysfunction of the autonomic nervous system, such as that which occurs with a spinal cord injury or post-cerebrovascular accident.[132] Activities that may increase the chance of orthostatic hypotension, such as application of heat modalities, hydrotherapy, pool therapy, moderate-to-vigorous exercise using the large muscles, sudden changes of position, and stationary standing, should be avoided in susceptible patients.[132] The normal systolic range generally increases with age. The pressure should be determined in both the arms. Causes of marked asymmetry in blood pressure of the arms include the following: errors in measurements, marked difference in arm size, thoracic outlet syndromes, embolic occlusion of an artery, dissection of an aorta, external arterial occlusion, coarctation of the aorta, and atheromatous occlusion.[133]

- Edema. Edema is an observable swelling from fluid accumulation in certain body tissues. Edema most commonly occurs in the feet and legs, where it is also referred to as peripheral edema. Swelling or edema may be localized at the site of the injury or diffused over a larger area. In general, the amount of swelling is related to the severity of the injury. However, in some cases, serious injuries produce very limited swelling, whereas, in others, minor injuries cause significant swelling. Edema occurs as a result of changes in the local circulation and an inability of the lymphatic system to maintain equilibrium. The swelling is the result of the accumulation of excess fluid under the skin, in the interstitial spaces or compartments within the tissues that are outside of the blood vessels. Most of the body's fluids that are found outside of the cells are normally stored in two spaces: the blood vessels (referred to as blood volume) and the interstitial spaces (referred to as interstitial fluid). Generally, the size of lymph nodes is dependent on the size of the drainage area. Usually, the closer the lymph node is to the spinal cord, the greater the size of the lymph node. The neck is the exception to the rule. In various diseases, excess fluid can accumulate in either one or both of the interstitial spaces or blood vessels. An edematous limb indicates a poor venous return. Pitting edema is characterized by an indentation of the skin after the pressure has been removed. A report of rapid joint swelling (within 2–4 hours) following a traumatic event may indicate bleeding into the joint. Swelling of a joint that is more gradual, occurring 8–24 hours following the trauma, is likely caused by an inflammatory process or synovial swelling.

The more serious reasons for swelling include fracture, tumor, congestive heart failure, and deep vein thrombosis.

- For the integumentary system, the assessment of skin integrity, skin color, and the presence of scar formation. T e integumentary system includes the skin, the hair, and the nails. T e examination of the integumentary system may reveal manifestations of systemic disorders. T e overall color of the skin should be noted. Cyanosis in the nails, the hands, and the feet may be a sign of a central (advanced lung disease, pulmonary edema, congenital heart disease, or low hemoglobin level) or peripheral (pulmonary edema, venous obstruction, or congestive heart failure) dysfunction.[132] Palpation of the skin, in general, should include assessment of temperature, texture, moistness, mobility, and turgor.[132] Skin temperature is best felt over large areas using the back of the clinician's hand. An assessment should be made as to whether this is localized or generalized warmth:[132]
  - Localized. May be seen in areas of the underlying inflammation or infection.
  - Generalized. May indicate fever or hyperthyroidism.

  Skin texture is described as smooth or rough (coarse). Skin mobility may be decreased in areas of edema or in scleroderma.
- For the musculoskeletal system, the gross assessment of symmetry, the range of motion, strength, weight, and height.
- For the neuromuscular system, a general assessment of gross coordinated movement (e.g., balance, locomotion, transfers, and transitions). In addition, the clinician observes for peripheral and cranial nerve integrity and notes any indication of neurological compromises such as tremors or facial tics.
- For communication ability, affect, cognition, language, and learning style, the clinician notes whether the patient's communication level is age appropriate; whether the patient is oriented to person, place, and time; and whether the emotional and behavioral responses appear to be appropriate to his or her circumstances. It is important to verify that the patient can communicate their needs. T e clinician should determine whether the patient has a good understanding of his or her condition, the planned intervention, and the prognosis. T e clinician should also determine the learning style that best suits the patient.

The Scanning Examination

T e Cyriax scanning (screening) examination (see Chapter 3) traditionally follows the history and is often incorporated as part of the systems review, especially if:

- T ere are symptoms when no history of trauma is present.
- T ere is no history to explain the signs and symptoms.
- T e signs and symptoms are unexplainable.

T e scanning examination should be carried out until the clinician is confident that there is no serious pathology present and is routinely carried out unless there is some good reason for postponing it (e.g., recent trauma, in which case a modified differential diagnostic examination is used).[4] T e upper quarter scanning examination (Table 3-11) is appropriate for upper thoracic, upper extremity, and cervical problems, whereas the lower quarter scanning examination (Table 3-12) is typically used for thoracic, lower extremity, and lumbosacral problems. T e preferred sequence of the scanning examination is outlined in Table 4-10.

TABLE 4-10 Typical Sequence of Upper- or Lower-Quarter Scanning Examinations

1. Initial observation: involves everything from initial entry of the patient, including gait, demeanor, standing and sitting postures, obvious deformities and postural defects, scars, radiation burns, creases, and birthmarks
2. Patient history
3. Scanning examination
4. Active range of motion
5. Passive overpressure
6. Resistive tests
7. Deep tendon reflexes
8. Sensation testing
9. Special tests

Negative scan

If, at the end of the scan, the clinician has determined that the patient's condition is appropriate for physical therapy but has not determined a diagnosis to treat the patient, the clinician needs to perform further testing

Positive scan (results in a diagnosis)

1. Specific interventions (traction, manual techniques, and specific exercises) can be given if the diagnosis is one that will benefit from physical therapy.
2. Patient is returned to physician for more tests if signs and symptoms are cause for concern.

T e tests of the Cyriax[134] upper or lower quarter scanning examination (Table 3-13) can be used to:

- Examine the patient's neurologic status. T e tests that comprise the scanning examination are designed to detect neurologic weakness, the patient's ability to perceive sensations, and the inhibition of the muscle stretch reflexes and other reflexes by the CNS, which would highlight the presence of a lesion to the central or peripheral nervous systems (see Chapter 3).
- Help determine whether the symptoms are being referred.
- Confirm or refute the physician's diagnosis.
- Help rule out any serious pathology, such as a fracture or a tumor.
- Assess the status of the contractile and inert tissues.[134]
- Contractile. T e term contractile tissue, as defined by Cyriax, is a bit of a misnomer, because the only true contractile tissue in the body is the muscle fiber. However, included under this term are the muscle belly, tendon, tenoperiosteal junction, submuscular/tendinous bursa, and bone (tendo-osseous junction), because all are stressed to some degree with a muscle contraction.
- Inert. Inert tissue, according to Cyriax, includes the joint capsule, the ligaments, the bursa, the articular surfaces of the joint, the synovium, the dura, the bone, and the fascia.

TABLE 4-11 Scan Findings and Interventions

Conditions	Findings	Protocol
Disk protrusion, prolapse, and extrusion	Severe pain	Gentle manual traction in progressive extension
Anterior–posterior instability	Flexion and extension reduction greater than rotation	Traction and/or traction manipulation in extension
Arthritis	Hot capsular pattern	PRICEMEM (protection, rest, ice, compression, elevation, medication, electrotherapeutics, and manual therapy)
Subluxation of segment	One direction restricted	Exercises in pain-free direction
Arthrosis of segment	All directions restricted	Exercises in pain-free direction

N.B.: The tendo-osseous junction and the bursae are placed in each of the subdivisions, owing to their close proximity to contractile tissue and their capacity to be compressed or stretched during movement.

- Generate a working hypothesis.

The entire scanning examination should take no more than a few minutes to complete.

If a diagnosis is rendered from the scan, an intervention may be initiated using the guidelines outlined in Table 4-11. The scan or the history, or both, also may have indicated to the clinician that the patient's condition is in the acute stage of healing. Although this is not a diagnosis in the true sense, it can be used for the purpose of the intervention plan.

Tests and Measures

The tests and the measures (Table 4-12) component of the examination, which serves as an adjunct to the history and the systems review, involves the physical examination of the patient. Before proceeding with the tests and measures, the clinician must obtain valid consent and a full explanation must be provided to the patient as to what procedures are to be performed and the reasons for these. The chosen tests used by the clinician must be based on the patient's history or the presentation. At times, a complete examination cannot be performed. For example, if the joint to be examined is too acutely inflamed, the clinician may defer some of the examinations to the subsequent visit.

The tests and the measures now currently used in physical therapy have been largely influenced by the work of a number of clinicians over the years, including Cyriax,[134–137] Maitland,[7,138] Grieve,[139] Kaltenborn,[5] Butler,[12] Sahrmann,[11] and McKenzie.[140]

CLINICAL PEARL

The physical examination must be modified based on the history; for example, the examination of an acutely injured patient differs greatly from that of a patient in less discomfort or distress. In addition, the examination of a child differs in some respects from that of an adult (see Chapter 30).

The traditional goals of the physical examination have been to determine the structure involved, reproduce the patient's symptoms, confirm or refute the working hypothesis, and establish an objective data baseline.[6,141] More recently, the focus of the examination has shifted to include the identification of impairments, functional limitations, disabilities, or changes in physical function and health status resulting from injury, disease, or other causes. This information is then used through the evaluation process to establish the diagnosis and the prognosis, and to determine the intervention.[18]

The physical examination must be supported by as much science as possible so that the decision about which test(s) to use during the examination should be based on the best available research evidence. According to Sackett et al.,[142] evidence-based practice (EBP) involves the integration of best research

TABLE 4-12 Tests and Measures

Aerobic capacity and endurance
Anthropometric characteristics
Arousal, attention, and cognition
Assistive and adaptive devices
Circulation (arterial, venous, and lymphatic)
Cranial and peripheral nerve integrity
Environmental, home, and work (job, school, and play) barriers
Ergonomics and body mechanics
Gait, locomotion, and balance
Integumentary integrity
Joint integrity and mobility
Motor function (motor control and learning)
Muscle performance (strength, power, and endurance)
Neuromotor development and sensory integration
Orthotic, protective, and supportive devices
Pain
Posture
Prosthetic requirements
Range of motion (including muscle length)
Reflex integrity
Self-care and home management (ADLs and IADLs)
Sensory integrity (including proprioception and kinesthesia)
Ventilation and respiration and gas exchange
Work, community, and leisure integration or reintegration

ADLs, activities of daily living; IADLs, instrumental activities of daily living.

evidence with clinical expertise and patient values. Delivery of high-quality health care that is evidence-based, cost-effective, individually tailored, and sustainable requires a coordinated strategy.[143] Knowledge translation (KT), a dynamic and iterative process that includes synthesis, dissemination, exchange and ethically sound application of knowledge,[144] is a process to facilitate the consideration of research evidence and clinical practice.[143] The KT concept was first introduced by the Canadian Institutes of Health Research (CIHR) in 2000, and has since spawned definitions from the World Health Organization (WHO) and the National Institute on Disability and Rehabilitation Research (NIDRR). The WHO defined KT as "the synthesis, exchange, and application of knowledge by relevant stakeholders to accelerate the benefits of global and local innovation in strengthening health systems and improving people's health,"[145] and the NIDRR defined it as "the multidimensional, active process of ensuring that new knowledge gained through the course of research ultimately improves the lives of people with disabilities, and furthers their participation in society."[146] The KT approach expands the clinician-focused EBP view as it is an interactive process characterized by effective exchanges between researchers who create new knowledge and those who implement it. The emphasis is on application and on consideration of the multiple factors that may influence whether the application is successful and sustained.[147] KT strategies have emerged as a potential solution to the challenges of consistently using research evidence to guide clinical practice and support an optimal change in clinical practice behaviors.[147] A number of frameworks have been developed to provide a template for consideration of the multiple key factors that influence whether the application is successful. Perhaps the most well-known is the knowledge-to-action (KTA) developed by Graham et al.,[148] which consists of a complex and dynamic process with boundaries that are fluid and permeable such that the following phases may occur consecutively or concurrently:

- Knowledge creation: the collection of promising principles and practices
- Adapting to local context: adapting the principles and practices
- Assessing barriers: assessing and addressing as many barriers as possible
- Selection, tailoring, and implementation of interventions: involves any necessary training or education
- Monitoring knowledge use/pilot implementation: observing
- Evaluation of content and process: receiving feedback
- Sustaining knowledge use: determining successes/weaknesses

The gathering of evidence must occur in a systematic, reproducible, and unbiased manner to select and interpret diagnostic tests and to assess potential interventions.[149] The EBP process generally occurs in five steps:[150]

- Formulating a clinical question including details about the patient type or problem, the intervention being considered, a comparison intervention, and the outcome measure to be used.
- Searching for the best evidence, which can include search on Ovid, EMBASE, PubMed, PEDro, or other medical search engine database, using the keywords from the clinical question.
- Critical appraisal of the evidence. In general, there are two types of clinical studies—those that analyze primary data and those that analyze secondary data.[151] Studies that collect and analyze primary data include case reports and series and case-controls, cross-sectional, cohort (both prospective and retrospective), and randomized controlled trials.[151] Analysis of secondary data occurs in systematic reviews or a meta-analysis. A systematic review is used to answer questions about the evidence supporting or refuting the effectiveness or efficacy of an intervention.[152] A systematic review may be extended to include a meta-analysis, a statistical procedure used to numerically summarize the included studies' treatment effect.[153] Thus, a meta-analysis can increase statistical power by providing a single, overall measure of the treatment effect, enhancing the clinical interpretation of findings across several studies.[152] Another way to broadly categorize studies is experimental, where an intervention is introduced to subjects, or observational, in which no active treatment is introduced to the subjects.[151]
- Applying the evidence to the patient.
- Evaluation of the outcome.

The choice of which tests to use should be based on pretest probabilities, which are used to assess the diagnostic possibility of a disorder. The results from these tests are then combined with value judgments to arrive at the correct diagnosis. Unfortunately, many tests and procedures used in physical therapy practice are not, as yet, evidence based. This is particularly true with the so-called special tests (see "Special Tests"). Indeed, many of the purportedly effective special tests listed in many orthopaedic texts exhibit such poor diagnostic accuracy that only 50% of patients who have a positive test result are found to have the condition that the test is supposed to detect.[149,154] Without EBP, clinicians fail to provide the consumer with scientific evidence regarding clinically effective and cost-effective practice. Throughout this text, wherever possible, the sources of evidence will be identified for each of the examination and intervention techniques described. However, in an ever-changing profession, it is ultimately the reader's responsibility to remain updated with practice recommendations and decide the appropriateness of the evidence for each of their patients in their own unique clinical setting.

Active Physiological Range of Motion of the Extremities

Active movements of the involved area are typically performed before passive movements. During the history, the clinician should have deduced the general motions or activities that aggravate or provoke the symptoms. Any movements that are known to be painful are performed last. The range of motion examination should be used to confirm the exact directions of motion that elicit the symptoms. The diagnosis of restricted movement in the extremities can usually be simplified by comparing both sides, provided that at least

TABLE 4-13 Active Ranges of Joint Motions

Joint	Action	Degrees of Motion
Shoulder	Flexion	0–170 to 180
	Extension	0–50 to 60
	Abduction	0–170 to 180
	Internal rotation	0–60 to 100
	External rotation	0–80 to 90
Elbow	Flexion	0–145
Forearm	Pronation	0–90
	Supination	0–90
Wrist	Flexion	0–90
	Extension	0–70
	Radial deviation	0–25
	Ulnar deviation	0–35
Hip	Flexion	0–115 to 120
	Extension	0–10 to 15
	Abduction	0–45
	Adduction	0–20 to 30
	Internal rotation	0–30 to 45
	External rotation	0–30 to 45
Knee	Flexion	0–120 to 130
Talocrural	Plantarflexion	0–50
	Dorsiflexion	0–20
Subtalar	Inversion	0–30
	Eversion	0–20

one side is symptom-free. Under normal circumstances, the normal (symptom-free) side is tested first as this allows the clinician to establish a baseline while also showing the patient what to expect. Active range of motion (AROM) testing may be deferred if small and unguarded motions provoke intense pain because this may indicate a high degree of joint irritability or other serious condition. T e normal AROM for each of the joints is depicted in Table 4-13.

AROM testing gives the clinician information about the following:

- T e quantity of available physiologic motion.
- T e presence of muscle substitutions.
- T e willingness of the patient to move.
- T e integrity of the contractile and the inert tissues.
- T e quality of motion. A painful arc during a range of motion, with or without a painful limitation of movement, indicates the presence of a derangement.[155] For example, there may be an arc of pain between 60 and 120 degrees of shoulder abduction, indicating an impingement of the structures under the acromion process or the coracoacromial ligament.
- Symptom reproduction. Depending on where in the range of motion the pain is experienced can provide the clinician information as to the stage of healing and the degree of tissue irritability. If the pain is experienced by the patient before the tissue limitation is felt, it is likely an acute injury or there is an active stage of a disease present. In this scenario, the tissues are likely highly irritable necessitating a gentle approach. If the pain experienced occurs concurrently with the tissue limitation, the condition is typically in the subacute stage of healing. If the pain is experienced after tissue limitation is met, the clinician can use more aggressive techniques such as stretching and joint mobilizations.
- T e pattern of motion restriction (e.g., capsular or noncapsular, opening or closing restriction—see later).

Full and pain-free AROM suggests normalcy for that movement, although it is important to remember that normal range of motion is not synonymous with normal motion.[156] Normal motion implies that the control of motion must also be present. T is control is a factor of muscle flexibility, joint stability, and central neurophysiologic mechanisms (see Chapter 3). T ese factors are highly specific in the body.[157] A loss of motion at one joint may not prevent the performance of a functional task, although it may result in the task being performed in an abnormal manner. For example, the act of walking can still be accomplished in the presence of a knee joint that has been fused into extension. Because the essential mechanisms of knee flexion during the stance period, and foot clearance in the swing period, are absent, the patient compensates for these losses by hiking the hip on the involved side, by side bending the lumbar spine to the uninvolved side, and through excessive motion of the foot.

Single motions in the cardinal planes are usually tested first. T ese tests are followed by dynamic and static testing. Dynamic testing involves repeated movements. Static testing involves sustaining a position. Sustained static positions may be used to help detect postural syndromes.[155] McKenzie advocates the use of repeated movements in specific directions in both the spine and the extremities. Repeated movements can give the clinician some valuable insight into the patient's condition:[155]

- Internal derangements tend to worsen with repeated motions.
- Symptoms of a postural dysfunction remain unchanged with repeated motions.
- Pain from a dysfunction syndrome is increased with tissue loading but ceases at rest.
- Repeated motions can indicate the irritability of the condition.
- Repeated motions can indicate to the clinician the direction of motion to be used as part of the intervention. If pain increases during repeated motion in a particular direction, exercising in that direction is not indicated. If pain only worsens in part of the range, repeated motion exercises can be used for the part of the range that is pain free, or that does not worsen the symptoms.
- Pain that is increased after the repeated motions may indicate a retriggering of the inflammatory response, and repeated motions in the opposite direction should be explored.

Combined motion testing may be used when the symptoms are not reproduced with the cardinal plane motions

(flexion, extension, abduction, etc.), the repeated motions, or the sustained positions. Compression and distraction also may be added to all of the active motion tests in an attempt to reproduce the symptoms.

Passive Physiological Range of Motion of the Extremities

Passive motions are movements performed by the clinician without the assistance of the patient. Passive range of motion (PROM) is performed in the anatomic range of motion for the joint and normally demonstrates slightly greater range of motion than active motion—the barrier to active motion should occur earlier in the range than the barrier to passive motion.

If the patient can complete the full active physiological range of motion easily, without presenting pain or other symptoms, then passive testing of that motion is usually unnecessary. However, if the active motion does not reproduce the patient's symptoms, because the patient is avoiding the painful part of the range, or the AROM appears incomplete, it is important that the clinician performs gentle, passive overpressure. Pain that occurs at the mid-end range of active and passive movement is suggestive of a capsular contraction or a scar tissue that has not been adequately remodeled.[155] Pain during passive overpressure is often due to the stretching, or pinching of noncontractile structures, or stretching of the contractile structures.[158] T us, PROM testing gives the clinician information about the integrity of the contractile and inert tissues, and with gentle overpressure, the end-*f*eel. Cyriax[134] introduced the concept of the end-feel, which is the quality of resistance encountered by the clinician at end range. T e point at which resistance is encountered is evaluated for quality and tenderness. Additional forces from the clinician are needed as the end range of a joint is reached, and the elastic limits are challenged. T is space termed the end-play zone requires a force of overpressure to be reached so that when that force is released, the joint springs back from its elastic limits. T e end-feel can indicate to the clinician the cause of the motion restriction (Tables 4-14 and 4-15).

TABLE 4-14 Normal End-Feels

Type	Cause	Characteristics and Examples
Bony	Produced by bone-to-bone approximation	Abrupt and unyielding; gives impression that further forcing will break something Examples: Normal: elbow extension Abnormal: cervical rotation (may indicate osteophyte)
Elastic	Produced by muscle–tendon unit; may occur with adaptive shortening	Stretches with elastic recoil and exhibits constant-length phenomenon; further forcing feels as if it will snap something Examples: Normal: wrist flexion with finger flexion, the straight-leg raise, and ankle dorsiflexion with the knee extended Abnormal: decreased dorsiflexion of the ankle with the knee flexed
Soft tissue approximation	Produced by contact of two muscle bulks on either side of a flexing joint where joint range exceeds other restraints	Very forgiving end-feel that gives impression that further normal motion is possible if enough force could be applied Examples: Normal: knee flexion and elbow flexion in extremely muscular subjects Abnormal: elbow flexion with obese subject
Capsular	Produced by capsule or ligaments	Various degrees of stretch without elasticity; stretch ability is dependent on thickness of tissue Strong capsular or extracapsular ligaments produce hard capsular end-feel, whereas thin capsule produces softer one Impression given to clinician is that if further force is applied, something will tear Examples: Normal: wrist flexion (soft), elbow flexion in supination (medium), and knee extension (hard) Abnormal: inappropriate stretch ability for specific joint; if too hard, may indicate hypomobility due to arthrosis; and if too soft, hypermobility

Data from Meadows JTS. Manual Therapy: Biomechanical Assessment and Treatment, Advanced Technique. Calgary: Swodeam Consulting, Inc.; 1995.

TABLE 4-15 Abnormal End-Feels

Type	Causes	Characteristics and Examples
Springy	Produced by articular surface rebounding from intraarticular meniscus or disk; impression is that if forced further, something will give way	Rebound sensation as if pushing off from a rubber pad Examples: Normal: none Abnormal: knee flexion or extension with displaced meniscus
Boggy	Produced by viscous fluid (blood) within joint	"Squishy" sensation as joint is moved toward its end range; further forcing feels as if it will burst joint Examples: Normal: none Abnormal: hemarthrosis at knee
Spasm	Produced by reflex and reactive muscle contraction in response to irritation of nociceptor, predominantly in articular structures and muscle; forcing it further feels as if nothing will give	Abrupt and "twangy" end to movement that is unyielding while the structure is being threatened but disappears when threat is removed (kicks back) With joint inflammation, it occurs early in range, especially toward close-packed position, to prevent further stress With irritable joint hypermobility, it occurs at end of what should be normal range, as it prevents excessive motion from further stimulating the nociceptor Spasm in grade II muscle tears becomes apparent as muscle is passively lengthened and is accompanied by a painful weakness of that muscle Note: Muscle guarding is not a true end-feel, as it involves co-contraction Examples: Normal: none Abnormal: significant traumatic arthritis, recent traumatic hypermobility, and grade II muscle tears
Empty	Produced solely by pain; frequently caused by serious and severe pathologic changes that do not affect joint or muscle and so do not produce spasm; demonstration of this end-feel is, with exception of acute subdeltoid bursitis, de facto evidence of serious pathology; further forcing simply increases pain to unacceptable levels	Limitation of motion has no tissue resistance component, and resistance is from patient being unable to tolerate further motion due to severe pain; it is not same feeling as voluntary guarding, but rather it feels as if patient is both resisting and trying to allow movement simultaneously Examples: Normal: none Abnormal: acute subdeltoid bursitis and sign of the buttock
Facilitation	Not truly an end-feel, as facilitated hypertonicity does not restrict motion; it can, however, be perceived near end range	Light resistance as from constant light muscle contraction throughout latter half of range that does not prevent end of range being reached; resistance is unaffected by rate of movement Examples: Normal: none Abnormal: spinal facilitation at any level

Data from Meadows JTS. Manual Therapy: Biomechanical Assessment and Treatment, Advanced Technique. Calgary: Swodeam Consulting, Inc.;1995.

CLINICAL PEARL

One study that looked at the intra- and interrater reliability of assessing end-feel, and pain and resistance sequence in subjects with painful shoulders and knees, found the end-feel to have good intrarater reliability, but unacceptable interrater reliability.[159]

Although some clinicians feel that overpressure should not be applied in the presence of pain, this is erroneous. Most, if not all, of the end-feels that suggest acute or serious pathology are to be found in the painful range, including spasm and the empty end-feel.

Assessing the end-feel is very important in joints that have only very small amounts of the normal range, such as those of the spine. The type of end-feel can help the clinician determine the presence of dysfunction. For example, a hard, capsular end-feel indicates a pericapsular hypomobility, whereas a jammed or a pathomechanical end-feel indicates a pathomechanical hypomobility. A normal end-feel would indicate a normal range whereas an abnormal end-feel would suggest an abnormal range, either hypomobile or hypermobile. An association between an increase in pain and abnormal pathologic end-feels compared with normal end-feels has been demonstrated.[160]

The intensity of the planned intervention is based on the type of tissue resistance to movement, and on the acuteness of the

TABLE 4-16	Abnormal Barriers to Motion and Recommended Manual Techniques	
Barrier	**End-feel**	**Technique**
Pain	Empty	None
Pain	Spasm	None
Pain	Capsular	Oscillations (I, IV)
Joint adhesions	Early capsular	Passive articular motion stretch (I–V)
Muscle adhesions	Early elastic	Passive physiologic motion stretch
Hypertonicity	Facilitation	Muscle energy (Hold/relax, etc.)
Bone	Bony	None

condition, which is demonstrated by the end-feel (Table 4-16).[134] This information may indicate whether the resistance is caused by pain, muscle, capsule ligament, disturbed mechanics of the joint, or a combination.

CLINICAL PEARL

According to Cyriax, if active and passive motions are limited or painful in the same direction, the lesion is in the inert tissue, whereas if the active and passive motions are limited or painful in the opposite direction, the lesion is in the contractile tissue.[134]

The quantity and quality of movement refer to the ability of the patient to achieve end-range without deviation from the intended movement plane.

Both the passive and active physiological ranges of motion can be measured using a goniometer (see Chapter 13), which has been shown to have a satisfactory level of intraobserver reliability.[161–163] Visual observation in experienced clinicians has been found to be equal to measurements by goniometry.[164] Although normative values for a range of motion exist, the symmetry between sides should be used to determine individual differences. Goniometric measurement of the joints is described in Chapter 13.

The recording of a range of motion varies. The American Medical Association recommends recording the range of motion on the basis of the neutral position of the joint being zero, with the degrees of motion increasing in the direction the joint moves from the zero starting point.[24] A plus sign (+) is used to indicate joint hyperextension and a minus sign (–) to indicate an extension lag. The method of recording chosen is not important, provided the clinician chooses a recognized method and documents it consistently with the same patient.

Capsular and Noncapsular Patterns of Restriction

Cyriax introduced the terms capsular and noncapsular patterns of restriction, which link impairment to pathology (Table 4-17). A capsular pattern of restriction is a limitation of pain and movement in a joint-specific ratio, which is usually present with arthritis, or following prolonged immobilization.[134] Thus, the PROM for that joint will be limited in a capsular pattern, and there will be decreased joint play movement. It is worth remembering that a consistent capsular pattern for a particular joint might not exist and that these patterns are based on empirical findings and tradition, rather than on research.[159,165]

A noncapsular pattern of restriction is a limitation in a joint in any pattern other than a capsular one and may indicate the presence of a joint derangement, a restriction of one part of the joint capsule, or an extraarticular lesion that obstructs joint motion.[134]

A positive finding for joint hypomobility would be a reduced range in a capsular or noncapsular pattern. The hypomobility can be painful, suggesting an acute sprain of a structure, or painless, suggesting a contracture or an adhesion of the tested structure. Significant degeneration of the articular cartilage presents with crepitus (joint noise) on movement when compression of the joint surfaces is maintained.

While an abnormal motion is typically described as being reduced, the abnormal motion may also be excessive (see Chapter 2). Excessive motion is often missed and is erroneously classified as normal motion. To help determine whether the motion is normal or excessive, PROM, in the form of passive overpressure, and the end-feel are assessed.

CLINICAL PEARL

Apprehension from the patient during AROM that limits a movement at near or full range suggests instability, whereas apprehension in the early part of the range suggests anxiety caused by pain.

Active Physiological Range of Motion of the Spine

Active physiologic intervertebral mobility, or active mobility, tests of the spine were originally designed by osteopaths to assess the ability of each spinal joint to move actively through its normal range of motion, by palpating over the transverse processes of a joint during the motion (see also Position Testing of the Spine). Theoretically, by palpating over the transverse processes, the clinician can indirectly assess the motions occurring at the zygapophyseal joints on either side of the intervertebral disk. However, the clinician must remember that, although it is convenient to describe the various motions of the spine occurring in a certain direction, these involve the integration of movements of a multi-joint complex.

The human zygapophyseal joints are capable of only two major motions: gliding upward and gliding downward. If these movements occur in the same direction, flexion or extension of the spine occurs, while if the movements occur in opposite directions, side flexion occurs.

Osteopaths use the terms opening and closing to describe flexion and extension motions, respectively, at the zygapophyseal joint. Under normal circumstances, an equal amount of gliding occurs at each zygapophyseal joint with these motions.

TABLE 4-17 Capsular Patterns of Restriction

Joint	Limitation of Motion (Passive Angular Motion)
Glenohumeral	External rotation > abduction > internal rotation (3:2:1)
Acromioclavicular	No true capsular pattern; possible loss of horizontal adduction and pain (and sometimes slight loss of end range) with each motion
Sternoclavicular	See acromioclavicular joint
Humeroulnar	Flexion > extension (±4:1)
Humeroradial	No true capsular pattern; possible equal limitation of pronation and supination
Superior radioulnar	No true capsular pattern; possible equal limitation of pronation and supination with pain at end ranges
Inferior radioulnar	No true capsular pattern; possible equal limitation of pronation and supination with pain at end ranges
Wrist (carpus)	Flexion = extension
Radiocarpal	See wrist (carpus)
Carpometacarpal	Flexion = extension
Midcarpal	Flexion = extension
Carpometacarpal 1	Retroposition
Carpometacarpals 2–5	Fan > fold
Metacarpophalangeal 2–5	Flexion > extension (±2:1)
Interphalangeal 2–5	
Proximal (PIP)	Flexion > extension (±2:1)
Distal (DIP)	Flexion > extension (±2:1)
Hip	Internal rotation > flexion > abduction = extension > other motions
Tibiofemoral	Flexion > extension (±5:1)
Superior tibiofibular	No capsular pattern; pain at end range of translatory movements
Talocrural	Plantar flexion > dorsiflexion
Talocalcaneal (subtalar)	Varus > valgus
Midtarsal	Inversion (plantar flexion, adduction, and supination)
Talonavicular calcaneocuboid	> Dorsiflexion
Metatarsophalangeal 1	Extension > flexion (±2:1)
Metatarsophalangeals 2–5	Flexion ≥ extension
Interphalangeals 2–5	
Proximal	Flexion ≥ extension
Distal	Flexion ≥ extension

Data from Cyriax J. Textbook of Orthopaedic Medicine, Diagnosis of Soft Tissue Lesions. 8th ed. London: Bailliere Tindall; 1982.

- During flexion, both zygapophyseal joints glide superiorly (open).
- During extension, both zygapophyseal joints glide inferiorly (close).
- During side flexion, one joint is gliding inferiorly (closing), while the other joint is gliding superiorly (opening). For example, during right-side flexion, the right joint is gliding inferiorly (closing), while the left joint is gliding superiorly (opening).

By combining flexion or extension movements with side flexion, a joint can be "opened" or "closed" to its limits. Thus, flexion and right-side flexion of a segment assesses the ability of the left joint to open maximally (flex), whereas extension and left-side flexion of a segment assesses the ability of the left joint to close maximally (extend).

There is a point that may be considered as the center of segmental rotation, about which all segmental motion must occur. In the case of a zygapophyseal joint impairment

(hypermobility or hypomobility), it is presumed that this center of rotation will be altered.

If one zygapophyseal joint is rendered hypomobile (i.e., the superior facet cannot move to the extreme of superior or inferior motion), then the pure motions of flexion and extension cannot occur. T is results in a relative asymmetric motion of the two superior facets, as the end of the range of flexion or extension, is approached (i.e., a side-flexion motion will occur). However, this side-flexion motion will not be about the normal center of segmental rotation. T e structure responsible for the loss of zygapophyseal joint motion, whether it is a muscle, disk protrusion, or the zygapophyseal joint itself, will become the new axis of vertebral motion, and a new component of rotation about a vertical axis, normally unattainable, will be introduced into the segmental motion. T e degree of this rotational deviation is dependent on the distance of the impairment from the original center of rotation.

Because the zygapophyseal joints in the spine are posterior to the axis of rotation, an obvious rotational change occurring between full flexion and full extension (in the position of a vertebral segment) is indicative of zygapophyseal joint motion impairment.

By observing any marked and obvious rotation of a vertebral segment occurring between the positions of full flexion and full extension, one may deduce the probable pathologic impairment.

CLINICAL PEARL

Active motion induced by the contraction of the muscles determines the so-called physiologic range of motion,[166] whereas passively performed movement causes stretching of noncontractile elements, such as ligaments, and determines the anatomic range of motion.

T e active mobility tests of the spine are described in the appropriate chapters.

Passive Physiological Range of Motion of the Spine

T e passive physiologic intervertebral mobility, or passive mobility, tests use the same principles as the active physiologic intervertebral mobility tests to assess the ability of each joint in the spine to be moved passively through its normal range of motion. During extension, the spinous processes should approximate whereas, during flexion, they should separate.

If the pain is reproduced, it is useful to associate the pain with the onset of tissue resistance to gain an appreciation of the acuteness of the problem. T e passive mobility tests of the spine are described in the appropriate chapters.

Mobility

Mobility can be viewed as a factor of range *of* motion, *fl*exibility, and accessory joint motion (see Chapter 13):

- T e term range *of* motion refers to the distance and direction a joint can move, and is measured using a goniometer.
- Flexibility refers to the passive extensibility of connective tissue that provides the ability to move a joint or series of joints through a full, nonrestricted, injury, and pain-free ROM. T e extensibility and habitual length of connective tissue are factors of the demands placed upon it (see Chapter 2). T ese demands produce changes in the viscoelastic properties and, thus, the length–tension relationship of a muscle or muscle group, resulting in an increase or a decrease in the length of those structures. A decrease in the length of the soft tissue structures, or adaptive shortening, is very common in postural dysfunctions. Although some types of flexibility (e.g., straight-leg raise) can be measured using a goniometer, most types are assessed using specific tests. A more subjective test for flexibility includes an examination of the end-feel, which can detect a loss of motion resulting from the excessive tension of the agonist muscle.
- Accessory joint motion. Accessory joint motion is the amount of the arthrokinematic glide that occurs at the joint surfaces, termed joint play (see Chapter 1).

T e examination of mobility is performed to determine if a particular structure, or group of structures, has sufficient movement to perform a desired activity. Decreased mobility can be produced by

- restricted accessory joint motion;
- tissue damage secondary to trauma;
- prolonged immobilization;
- disease;
- hypertonia. Hypertonic muscles that are superficial can be identified through observation and palpation. Observation will reveal the muscle to be raised, and light palpation will provide information about tension, as the muscle will feel hard and may stand out from those around it.

Mobility can be measured objectively using standardized tests, or a goniometer. Visual observation, which has been found to have a variability of 30% in patients with low back pain and sciatica, may also be used.[167]

Joint Integrity

Joint integrity testing can provide valuable information about the status of each joint and its capsule. Kaltenborn[5] introduced the concept of motion restriction of a joint based on its arthrokinematics. In order for a joint to function completely, both the osteokinematic and arthrokinematic motions have to occur normally (see Chapter 1). It, therefore, follows that if a joint is not functioning completely, either the physiologic range of motion is limited compared with the expected norm, or there is no PROM available between the physiologic barrier and the anatomic barrier. As previously mentioned, the assessment of the end-feel can help determine the cause of the restriction. In general, the physiologic motion is controlled by the contractile tissues, whereas the accessory motion is controlled by the integrity of the joint surfaces and the noncontractile (inert) tissues. T is guideline may change in the case of a joint that has undergone degenerative changes, which

can result in a decrease in the physiologic motions (capsular pattern of restriction). It is important that the intervention to restore the complete function of the joint is aimed at the specific cause.

Joint pain and dysfunction do not occur in isolation.[168,169] Various different measurement scales have been proposed for judging the amount of accessory joint motion present between two joint surfaces (see Chapter 10), most of which are based on a comparison with a comparable contralateral joint, using manually applied forces in a logical and precise manner.[170] In the extremities, these tests are referred to as passive articular mobility or joint glide tests. In the spine, these tests are referred to as the passive physiologic accessory intervertebral motion testing.

CLINICAL PEARL

In general, if the concave-on-convex glide of the joint surfaces is restricted, there is a contracture of the trailing portion of the capsule, whereas if the convex-on-concave glide of the joint surfaces is restricted, there is an inability of the moving surface to glide into the contracted portion of the capsule.

The passive articular mobility tests involve the clinician assessing the arthrokinematic, or accessory, motions using joint glides, and determining whether the glide is hypomobile, normal, or hypermobile (see Chapter 2) .[5–7]

Accessory motions are involuntary motions. With few exceptions, muscles cannot restrict the glides of a joint, especially if the glides are tested in the open-packed position of a peripheral joint and, at the end of available range, in the spinal joints.

Thus, if the clinician assesses the accessory motion of the joint by performing a joint glide, information about the integrity of the inert structures will be given. There are two scenarios:

1. The joint glide is unrestricted. An unrestricted joint glide indicates two differing conclusions:
   a. The integrity of both the joint surface and the periarticular tissue is good. If the joint surface and the periarticular structures are intact, the patient's loss of motion must be the result of a contractile tissue. The intervention for this type involves soft tissue mobilization techniques designed to change the length of a contractile tissue.
   b. The joint glide is unrestricted but excessive. This is very difficult to detect, but if present, may indicate a pathological hypermobility or instability, or it may be normal for the individual. In these cases, the end-feel can provide some useful information. The intervention for this type concentrates on stabilizing techniques designed to give secondary support to the joint through muscle action.
2. The joint glide is restricted. If the joint glide is restricted, the joint surface and the periarticular tissues are implicated as the cause of the patient's loss of motion, although as previously mentioned, the contractile tissues cannot definitively be ruled out. The intervention for this type of finding initially involves a specific joint mobilization to restore the glide. Once the joint glide is restored following these mobilizations, the osteokinematic motion can be assessed again. If it is still reduced, the contractile tissues are likely to be at fault. Distraction and compression can be used to help differentiate the cause of the restriction.
   a. Distraction. Distraction is a force imparted passively by the clinician that results in a distraction of the joint surfaces. It is not synonymous with traction (see Chapter 1). If the distraction is limited, a contracture of connective tissue should be suspected.

      If the distraction increases the pain, it may indicate a tear of connective tissue (e.g., joint capsule) and may be associated with increased range.

      If the distraction eases the pain, it may indicate an involvement of the joint surface.
   b. Compression. Compression is the opposite force to distraction and involves an approximation of the joint surfaces (see Chapter 1).

      If the compression increases the pain, a loose body or an internal derangement of the joint may be present. If the compression decreases the pain, it may implicate the joint capsule.

      Thus, by assessing these joint motions, the clinician can determine the

      - cause of a limitation in a joint's physiologic range of motion;
      - the end-feel response of the tissues;
      - stage of healing;
      - the integrity of the support structures (e.g., ligaments) of a joint (e.g.,, the integrity of the anterior cruciate ligament is tested with the Lachman test).

Based on the information gleaned from the joint glide/accessory motion assessment, the clinician can make a clinical decision as to which intervention to use. If the joint glide is felt to be restricted, and there is no indication of a bony end-feel or severe irritability, joint mobilization techniques are used. If the joint glide is found to be unrestricted, the clinician may decide to employ a technique that increases the extensibility of the surrounding connective tissues, such as muscle energy, because abnormal shortness of these connective tissues, including the ligaments, the joint capsule, and the periarticular tissues, can restrict joint mobility.

CLINICAL PEARL

Caution must be used when basing clinical judgments solely on the results of accessory motion testing, because few studies have examined the validity and reliability of accessory motion testing of the spine or extremities, and little is known about the validity of these tests for most inferences.[170] A study of the predicted value of positive and negative test results, in addition to the sensitivity and specificity of the various tests, would be of value.[170]

Position Testing in the Spine

The position tests are osteopathic screening tests used to compare the relative position of a specific zygapophyseal

joint(s) with the joint(s) below (see appropriate chapters). As with all screening tests, position testing is valuable in focusing the attention of the clinician to a specific area but is not appropriate for making a definitive statement concerning the movement status of the segment. However, when combined with the results of the passive and active movement testing, position tests help to form a working hypothesis.

Muscle Performance: Strength, Power, and Endurance

Strength measures the power with which musculotendinous units act across a bone-joint lever-arm system to actively generate motion, or passively resist movement against gravity and variable resistance.[24]

According to Cyriax, pain with a contraction generally indicates an injury to the contractile tissue or joint.[134] T is suspicion can be confirmed by combining the findings from the type of symptom, the symptom duration, the symptom distribution, and the end-feel (Table 4-18). Cyriax reasoned that if you isolate and then apply tension to a structure, you can make a conclusion as to the integrity of that structure.[134] His work also introduced the concept of tissue reactivity. Tissue reactivity is the manner in which different stresses and movements can alter the clinical signs and symptoms. T is knowledge can be used to gauge any subtle changes to the patient's condition.[171]

In addition to examining the integrity of the contractile and inert structures, strength testing may be used to examine the integrity of the key muscles (see Chapter 3). Pain with muscle testing may indicate a muscle injury, a joint injury, or a combination of both. Pain that occurs consistently with resistance, at whatever the length of the muscle, may indicate a tear of the muscle belly. T e weakness elicited with muscle testing must be differentiated between weakness throughout the range of motion (pathological weakness) and weakness that only occurs in certain positions (positional weakness). According to Cyriax,[134,136] strength testing can provide the clinician with the following findings:

- A weak and painless contraction may indicate palsy or a complete rupture of the muscle–tendon unit. T e motor disorder associated with peripheral neuropathy is first manifested by weakness and a diminished or absent tendon reflex (see Chapter 3).[100]
- A strong and painless contraction indicates a normal finding.
- A weak and painful contraction. A study by Franklin [172] indicated that the conditions related to this finding need to include not only serious pathology, such as a significant muscle tear or a tumor, but relatively minor muscle damage and inflammation such as that induced by eccentric isokinetic exercise.[158]
- A strong and painful contraction indicates a grade I contractile lesion.

Pain that does not occur during the test, but occurs upon the release of the contraction, is thought to have an articular source, produced by the joint glide that occurs following the release of tension.

CLINICAL PEARL

Pain that occurs with resistance, accompanied by pain at the opposite end of the passive range, indicates muscle impairment.

T e degree of certainty regarding the findings just described depends on a combination of the length of the muscle tested, and the force applied. To fully test the integrity of the muscle–tendon unit, a maximum contraction must be performed in the fully lengthened position of the muscle–tendon unit. Although this position fully tests the muscle–tendon unit, there are some problems with testing in this manner:

- T e joint and its surrounding inert tissues are in a more vulnerable position and could be the source of the pain.
- It is difficult to differentiate between damage to the contractile tissue of varying severity. T e degree of significance with the findings in resistive testing depends on the position of the muscle and the force applied (Table 4-19). For example, pain reproduced with a minimal contraction in the rest position for the muscle is more strongly suggestive of a contractile lesion than pain reproduced with a maximal contraction in the lengthened position for the muscle.
- As a muscle lengthens, it reaches a point of passive insufficiency, where it is not capable of generating its maximum force output (see Chapter 1).

If the same muscle is tested on the opposite side, using the same testing procedure, the concern about the length of the muscle is removed, because the focus of the test is to provide a

TABLE 4-18 Differential Diagnosis of Contractile, Inert, and Neural Tissue Injury

	Contractile Tissue	Inert Tissue	Neural Tissue
Pain	Cramping, dull, and ache	Dull–sharp	Burning and lancinating
Paresthesia	No	No	Yes
Duration	Intermittent	Intermittent	Intermittent–constant
Dermatomal distribution	No	No	Yes
Peripheral nerve sensory distribution	No	No	Yes (if peripheral nerve involved)
End-feel	Muscle spasm	Boggy and hard capsular	Stretch

TABLE 4-19	Strength Testing Related to Joint Position and Muscle Length
Muscle Length	**Rationale**
Fully lengthened	Muscle in position of passive insuf ciency Tightens the inert component of the muscle Tests for muscle tears (tendoperiosteal tears) while using minimal force
Mid-range	Muscle in strongest position Tests overall power of muscle
Fully shortened	Muscle in its weakest position Used for the detection of palsies, especially if coupled with an eccentric contraction

comparison with the same muscle on the opposite side, rather than to assess the absolute force output.

To assess strength, strength values using manual muscle testing (MMT) have traditionally been used between similar muscle groups on opposite extremities, or antagonistic ratios. T is information is then used to determine whether a patient was fully rehabilitated. It should be noted that there is considerable variability in the amount of resistance that normal muscles can hold against. T e application of resistance throughout the arc of motion (make test or active resistance test) in addition to resistance applied at only one point in the arc of motion (break test), which is used more often, can help in judging the strength of a muscle.[158] T e various techniques for assessing muscle strength using MMT are described in Chapter 12.

CLINICAL PEARL

Perhaps the most obvious problem of using the "break" test method during MMT is that the tests may demonstrate substantial ceiling effects that depend on the characteristics of the clinician.[173] For example, small clinicians may find it dif cult to "break" muscle contractions, so they may tend to underestimate weakness when compared to large clinicians.[174]

During all testing, stabilization of the body part on which the muscle originates, in addition to careful avoidance of substitution by other muscle groups, are emphasized. Substitute motions are compensatory movement patterns caused by muscle action of a stronger adjacent agonist muscle, or a muscle group that normally serves as a stabilizer. Substitutions by other muscle groups during testing indicate the presence of weakness. It does not, however, tell the clinician the cause of the weakness. Proper alignment is determined by the direction of the muscle fibers and the line of pull of the muscle to be tested (see Chapter 12). T e alignment or position of the patient or the limb with respect to gravity may also be important based on the grade anticipated.

CLINICAL PEARL

MMT has been shown to be less sensitive in detecting strength deficits in stronger muscles than in weaker muscles.[158]

Several scales have been devised to assess muscle strength. For example, Janda[175] used a 0–5 scale with the following descriptions:

- Grade 5: N (normal). A normal, very strong muscle with a full range of movement and one that is able to overcome considerable resistance. T is does not mean that the muscle is normal in all circumstances (e.g., when at the onset of fatigue or in a state of exhaustion). If the clinician is having difficulty differentiating between a grade 4 and a grade 5, the eccentric "break" method of muscle testing may be used. T is procedure starts as an isometric contraction, but then the clinician applies sufficient force to cause an eccentric contraction or a "break" in the patient's isometric contraction.
- Grade 4: G (good). A muscle with good strength and a full range of movement, and one that is able to overcome moderate resistance. T e subjectivity involved in a grade 4 score is one of the major criticisms of MMT as the grading requires the clinician to assign an ordinal number to a subjective evaluation of resistance offered by the patient.
- Grade 3: F (*fair*). A muscle that can move through its complete range of movement against gravity but only if no additional resistance is applied. If the muscle strength is less than grade 3, then the methods advocated in muscle testing manuals must be used.[158]
- Grade 2: P (poor). A very weak muscle that is only able to move through its complete range of motion if the force of gravity is eliminated.
- Grade 1: *T* (trace). A muscle with evidence of slight contractility but demonstrates no effective movement.
- Grade 0. A muscle with no evidence of any contractility.

T e grading systems for MMT produce ordinal data with unequal rankings between grades. For example, the grades 5 (normal) and 4 (good) typically encompass a large range of a muscle's strength, while the grades of 3 (fair), 2 (poor), and 1 (trace) include a much narrower range.[158] If the popular methods to grade muscles are analyzed, the frailties and similarities become obvious. If the muscle strength is less than grade 3, these testing grades are useful, but it is the grades of 3 and higher that produce the most confusion. Some of the confusion arises from the descriptions of maximal, moderate, and minimal, or considerable, which removes much of the objectivity from the tests.

CLINICAL PEARL

Studies have demonstrated that reliability in MMT depends on the specific muscle being examined. For example, Florence et al.[176] found high reliability in the proximal muscles as opposed to the distal muscles, and Barr et al.[177] found the upper body muscles to be more reliably tested than the lower body ones.[178]

Strength testing must elicit a maximum contraction of the muscle being tested if it is to be deemed a valid test. T e following strategies ensure that this occurs:

1. Placing the joint that the muscle to be tested crosses, in (or close to) its open-packed position. T is strategy helps

protect the joint from excessive compressive forces, and the surrounding inert structures from excessive tension.

2. Placing the muscle to be tested in a shortened position. T is puts the muscle in an ineffective physiologic position and has the effect of increasing motor neuron activity.
3. Using gravity-minimized positions. T is strategy avoids the effect of the weight of the moving body segment on force measurements. For example, to test the strength of the hip abductors, the patient is positioned in supine so that the muscle action pulls in a horizontal plane relative to the ground.[158]
4. Having the patient per*f*orm an eccentric muscle contraction by using the command "Don't let me move you." Because the tension at each cross-bridge and the number of active cross-bridges is greater during an eccentric contraction (see Chapter 1), the maximum eccentric muscle tension developed is greater with an eccentric contraction than with a concentric one.
5. Breaking the contraction. It is important to break the patient's muscle contraction, in order to ensure that the patient is making a maximal effort and that the full power of the muscle is being tested. Although force values determined with make and break tests are highly correlated, break tests usually result in greater force values than make tests,[179,180] so they should not be used interchangeably.
6. Holding the contraction *f*or at least 5 seconds. Weakness resulting from nerve palsy has a distinct fatigability. T e muscle demonstrates poor endurance because usually it is only able to sustain a maximum muscle contraction for about 2–3 seconds before complete failure occurs. T is strategy is based on the theories behind muscle recruitment, wherein a normal muscle, while performing a maximum contraction, uses only a portion of its motor units, keeping the remainder in reserve to help maintain the contraction (see Chapter 1). A palsied muscle, with its fewer functioning motor units, has very few, if any, motor units in reserve. If a muscle appears to be weaker than normal, further investigation is required, as follows:
   a. T e test is repeated three times. Muscle weakness resulting from disuse will be consistently weak and should not become weaker with several repeated contractions. In contrast, a palsied muscle becomes weaker with each contraction.
   b. Another muscle that shares the same innervation is tested. Knowledge of both spinal and peripheral nerve innervation will aid the clinician in determining which muscle to select (see Chapter 3).
7. Comparing *f*indings with the uninvolved side. One study found no statistically significant difference in force between the dominant and nondominant lower extremities but did find the difference between the dominant and nondominant upper extremities.[181] Sapega[182] recommends that the difference in muscle force between sides of greater than 20% probably indicates an abnormality, while the difference of 10–20% possibly indicates an abnormality.

As always, these tests cannot be evaluated in isolation but have to be integrated into a total clinical profile, before drawing any conclusion about the patient's condition.

CLINICAL PEARL

MMT is an ordinal level of measurement[182] and has been found to have both inter- and intrarater reliability, especially when the scale is expanded to include plus or minus a half or a full grade.[69,183,184] Training to standardized testing positions, stabilization, and grading criteria resulted in higher agreement and correlation coef cients between testers.

Although the grading of muscle strength has its role in the clinic, and the ability to isolate the various muscles is very important in determining the source of nerve palsy, specific grading of individual muscles does not give the clinician much information on the ability of the structure to perform functional tasks. In addition, measurements of isometric muscle force are specific to a point or small range in the joint range excursion and, thus, cannot be used to predict dynamic force capabilities.[185–187]

CLINICAL PEARL

Muscle function testing should address the production and control of motion in functional activities. Although there is general agreement about the role of the trunk and pelvic musculature in normal functioning of the vertebral column, protection against pain, and recurrence of low back disorders,[140,188,189] more research is needed to determine the role of functional strength in the extremities. Part of the functional assessment includes an assessment of those muscles that are prone to weakness, which can provide the clinician with the following information:[190]

- The strength of individual muscles or muscle groups that form a functional unit.
- Nature, range, and quality of simple movement patterns.
- The relationship between the strength and the flexibility of a muscle or muscle group.
- The ability of the whole body to perform a task.

More recently, the use of quantitative muscle testing (QMT) has been recommended to assess strength, as it produces interval data that describe force production. QMT methods include:

- T e use of handheld dynamometers. Although more costly and time consuming than MMT, handheld dynamometry can be used to improve objectivity and sensitivity. Patients are typically asked to push against the dynamometer with a maximal isometric contraction (make test), or hold a position until the clinician and the dynamometer overpower the muscle producing an eccentric contraction (break test).[158] Normative force values for particular muscle groups by patient age and gender have been reported, with some authors including regression equations that take into account body weight and height.[191]

CLINICAL PEARL

Depending on the study, handheld dynamometers have demonstrated good to excellent intratester reliability and poor to excellent intertester reliability.[192–196]

- The use of an isokinetic dynamometer. This is a stationary, electromechanical device that controls the velocity of the moving body segment by resisting and measuring the patient's effort so that the body segment cannot accelerate beyond a preset angular velocity.[158] Isokinetic dynamometers measure torque and range of motion as a function of time, and can provide an analysis of the ratio between the eccentric contraction and concentric contraction of a muscle at various positions and speeds.[197] This ratio is aptly named the eccentric/concentric ratio.[198] The ratio is calculated by dividing the eccentric strength value by the concentric strength value. Various authors[199,200] have demonstrated that the upper limit of this ratio is 2.0 and that lower ratios indicate pathology.[198,201] Alternatively, the same recommendations for MMT advocated by Sapega[182] can be used: a difference in muscle force between sides of greater than 20% probably indicates abnormality, while the difference of 10–20% possibly indicates abnormality. To ensure the validity of isokinetic dynamometry measurements, calibration of equipment is necessary and should be performed each day of testing, at the same speed and damp setting during the testing.[202]

One of the major criticisms of muscle testing is the over estimation of strength when a muscle is weak as identified by QMT, compared to the same muscle being graded as normal by MMT, such that a theoretical percentage score based on MMT is likely to grossly overestimate the strength of a patient.[178] For example, Beasley[203] showed that 50% of knee extensor strength needed to be lost before MMT was able to identify weakness.

Studies that compare the reliability of MMT and QMT often come to the conclusion that MMT may be consistent and reliable, but it is unable to detect subtle differences in strength.[174,204] Thus, although MMT results are more consistent, the variation produced by QMT can appreciate differences in strength undetectable in MMT.[178]

Regardless of the type of muscle testing used, the procedure is innately subjective and depends on the subject's ability to exert a maximal contraction. This ability can be negatively impacted by such factors as pain, poor comprehension, motivation, cooperation, fatigue, and fear.

CLINICAL PEARL

Voluntary muscle strength testing will remain somewhat subjective until a precise way of measuring muscle contraction is generally available.[24] This is particularly true when determining normal and good values.

Functional Testing

Within the WHO-ICF model, activity is the execution of a task or action, and participation is defined as involvement in life affairs. Measurement of activity and participation limitations can be completed using one of the following methods:[15]

- Questionnaire-based measurements. These measurements typically involve the use of pencil and paper forms to collect information about the patient's physical or mental well-being in terms of limitations at the levels of activity and participation. Measures of responsiveness have commonly been reported as statistically significant change scores, which are useful in establishing the threshold of change needed beyond measurement error.[205] These minimal clinically important differences (MCIDs) in performance measures have become commonly used outcome measures (see also MDC in "Outcomes" section). Responsiveness, as investigated with the MCID, indicates whether a patient experiences a beneficial change following treatment that would mandate a change in patient management, in the absence of troublesome side effects, excessive costs, and inconveniences.[205,206] It is theorized that the reporting of MCID provides a more definite response of improvement thereby reducing the chance for error potentially associated with minimal improvement scores.[207]
- Function-based measurements. These instruments, often referred to as functional performance measures, measure the ability to demonstrate the skillful and efficient assumption, maintenance, modification, and control of voluntary postures and movement patterns.[18] Functional performance measures, which typically involve a set of proxy movements that mimic a certain function, or the critical elements of that function, have often been criticized, as detailed testing of their measurement properties has not been extensively reported.[205]
- Physical performance measurements. These measurements are used for the athletic population to measure muscular strength, power, and endurance (see later).

Prior to initiating an intervention, it is important for the clinician to determine what functional factors are important to the patient, and what functions are necessary for the patient to perform work-related, recreational, or social activities. It is worth remembering that insurance companies typically reimburse based on intervention goals that improve work-related and functional abilities, and not on those goals that enhance a patient's ability to perform recreational or athletic pursuits.

A number of variables affect function. These include age, gender, physical capacity (strength, power, flexibility, dexterity, agility, speed, muscular endurance, cardiovascular endurance, coordination, and skill), healing status (phase of healing, weight-bearing status, precautions/contraindications, and comorbidities), and psychological profile (motivation, fear, and coping mechanisms).[208]

Functional testing is a complex and multifactorial process in which the clinician makes a determination about the patient's level of functional independence based on principles of physiology, biomechanics, and motor behavior[208]:

- Physiology. Relevant physiological issues include the functions of body structures and systems, the extent of the injury, and the patient's healing status, energy systems, adaptation, and overall fitness level.
- Biomechanics. Biomechanical considerations include functional anatomy, direction/planes of motion and stress, kinematics (time, distance, position, displacement, velocity), and kinetics (force, torque, mass, acceleration, inertia, momentum).

- Motor behavior. Motor behavior issues include proprioception, perception, transfer, practice, learning, control, coordination, and performance.

Physical Performance

Four categories of physical performance tests have been identified[209]:

1. Movement
2. Balance
3. Hop/jump
4. Agility

The first two categories tend to be the focus in the majority of early rehabilitation protocols, whereas the last two tend to be used with those patients who plan to return to sports or a high level of physical activity. Each of these categories is now described.

Movement. This type of test evaluates a patient's ability to perform a specific motor pattern. The movement patterns chosen may often replicate common tasks or movements that are performed by the individual on a regular basis as part of his occupation, activity, or sport. For example, moving from the standing position to a sitting position. The criteria for simple patterns are that the movement[120,175]

- is performed exactly in the desired direction;
- is smooth and of a constant speed;
- follows the shortest and most efficient path;
- is performed in its full range.

The criteria for more complex movement patterns are as follows[120]:

- Synchronization between the primary movers in the distal regions with those more proximal.
- Smooth propagation of motion from one region of the body to another.
- Absence of inefficient movement patterns or muscle recruitment.
- Optimal relationships between the speed of motion initiated in one region and the speed of motion in other regions.

Mass movement patterns involve combined motions of the joints within the kinetic chain, depending on the desired motion.[210] For example, a mass pattern of the lower extremity could involve hip, knee, and ankle dorsiflexion, with the rotation and abduction–adduction component varying. Advanced movement patterns involve such combinations as hip extension, knee flexion, and plantar flexion, or hip flexion, knee extension, and dorsiflexion—motions that occur with normal gait.[210]

Balance. This is type of test assesses the patient's ability to demonstrate postural control and balance using either static balance tests or dynamic balance tests (see Chapter 3).

The Functional Movements Screen (FMS) is a relatively new assessment tool that attempts to address the quality of multiple movement factors, including balance, with the goal of predicting general risk of musculoskeletal conditions and injuries.[211–214] The original intent of the FMS was to identify functional movement deficits and asymmetries that may be predictive of general conditions and injuries, with the ultimate goal of being able to modify the identified movement deficits through individualized exercise prescription.[215] Thus, specific exercises and activities are avoided until the required movement competency is achieved. The FMS consists of seven fundamental movement component tests (Table 4-20).

- In-line lunge (Fig. 4-2)
- Hurdle step (Fig. 4-3)
- Deep squat (Fig. 4-4)
- Quadruped rotary stability (Fig. 4-5)
- Active straight-leg raise (Fig. 4-6)
- Shoulder mobility (Fig. 4-7)
- Trunk stability push-up (Fig. 4-8)

For the component tests that are scored for both the right and left sides, the lowest score is used when calculating the FMS composite score. Each of these movement component tests is scored on a scale of 0–3, with the sum creating a component score ranging from 0 to 21 points. It has been suggested that a composite score that is less than or equal to 14 on the FMS may suggest higher injury risk, but that a score greater than 14 does not rule out future injury risk.[216] Unfortunately, as yet, interpretation of FMS scores is limited by the scant evidence in widely accessible journals. For example, Hartigan et al.[217] concluded that one of the components of the FMS, the in-line lunge, was not related to balance, power, or speed. However, other studies have advocated its use.[218–220]

Hop. This is type of test, which assesses the ability of an individual to absorb impact on the lower extremity, and to often change direction, is typically used to identify side to side differences between the dynamic function of the lower extremities. In general, hop tests are quantified in either distance or time. Single-leg hop tests are commonly used for return to sport assessment as they mimic lower extremity functional demands that challenge stability: generation of power, acceleration and deceleration of body weight, dynamic control of triplanar forces, and maintenance of postural stability.[221] Performance during hop tests that measures distance is commonly standardized to the length of the limb or expressed as the limb symmetry index (LSI).[222] The LSI is a percentage value of one limb versus the other and is calculated by comparing the performance of the involved and uninvolved limb (LSI = involved/uninvolved*100% for the distance measures and LSI = uninvolved/involved*100% for the timed hop).[223] It has been universally accepted that normal LSI is between ≥85%[223] and ≥90%.[224]

The most commonly used single-leg hop tests include:

- Single hop *for* distance test. This test measures the distance traveled in an anterior direction using a single, unilateral hop. The patient is asked to stand on one limb and to hop as far forward as possible, landing on the same limb, and to maintain the landing for a minimum of 2 seconds while the toe measurement (to the nearest centimeter) is recorded. Weakness of the hip girdle musculature may result in poor propulsion, poor performance absorption, and poor control of the frontal plane landing mechanics.[222]

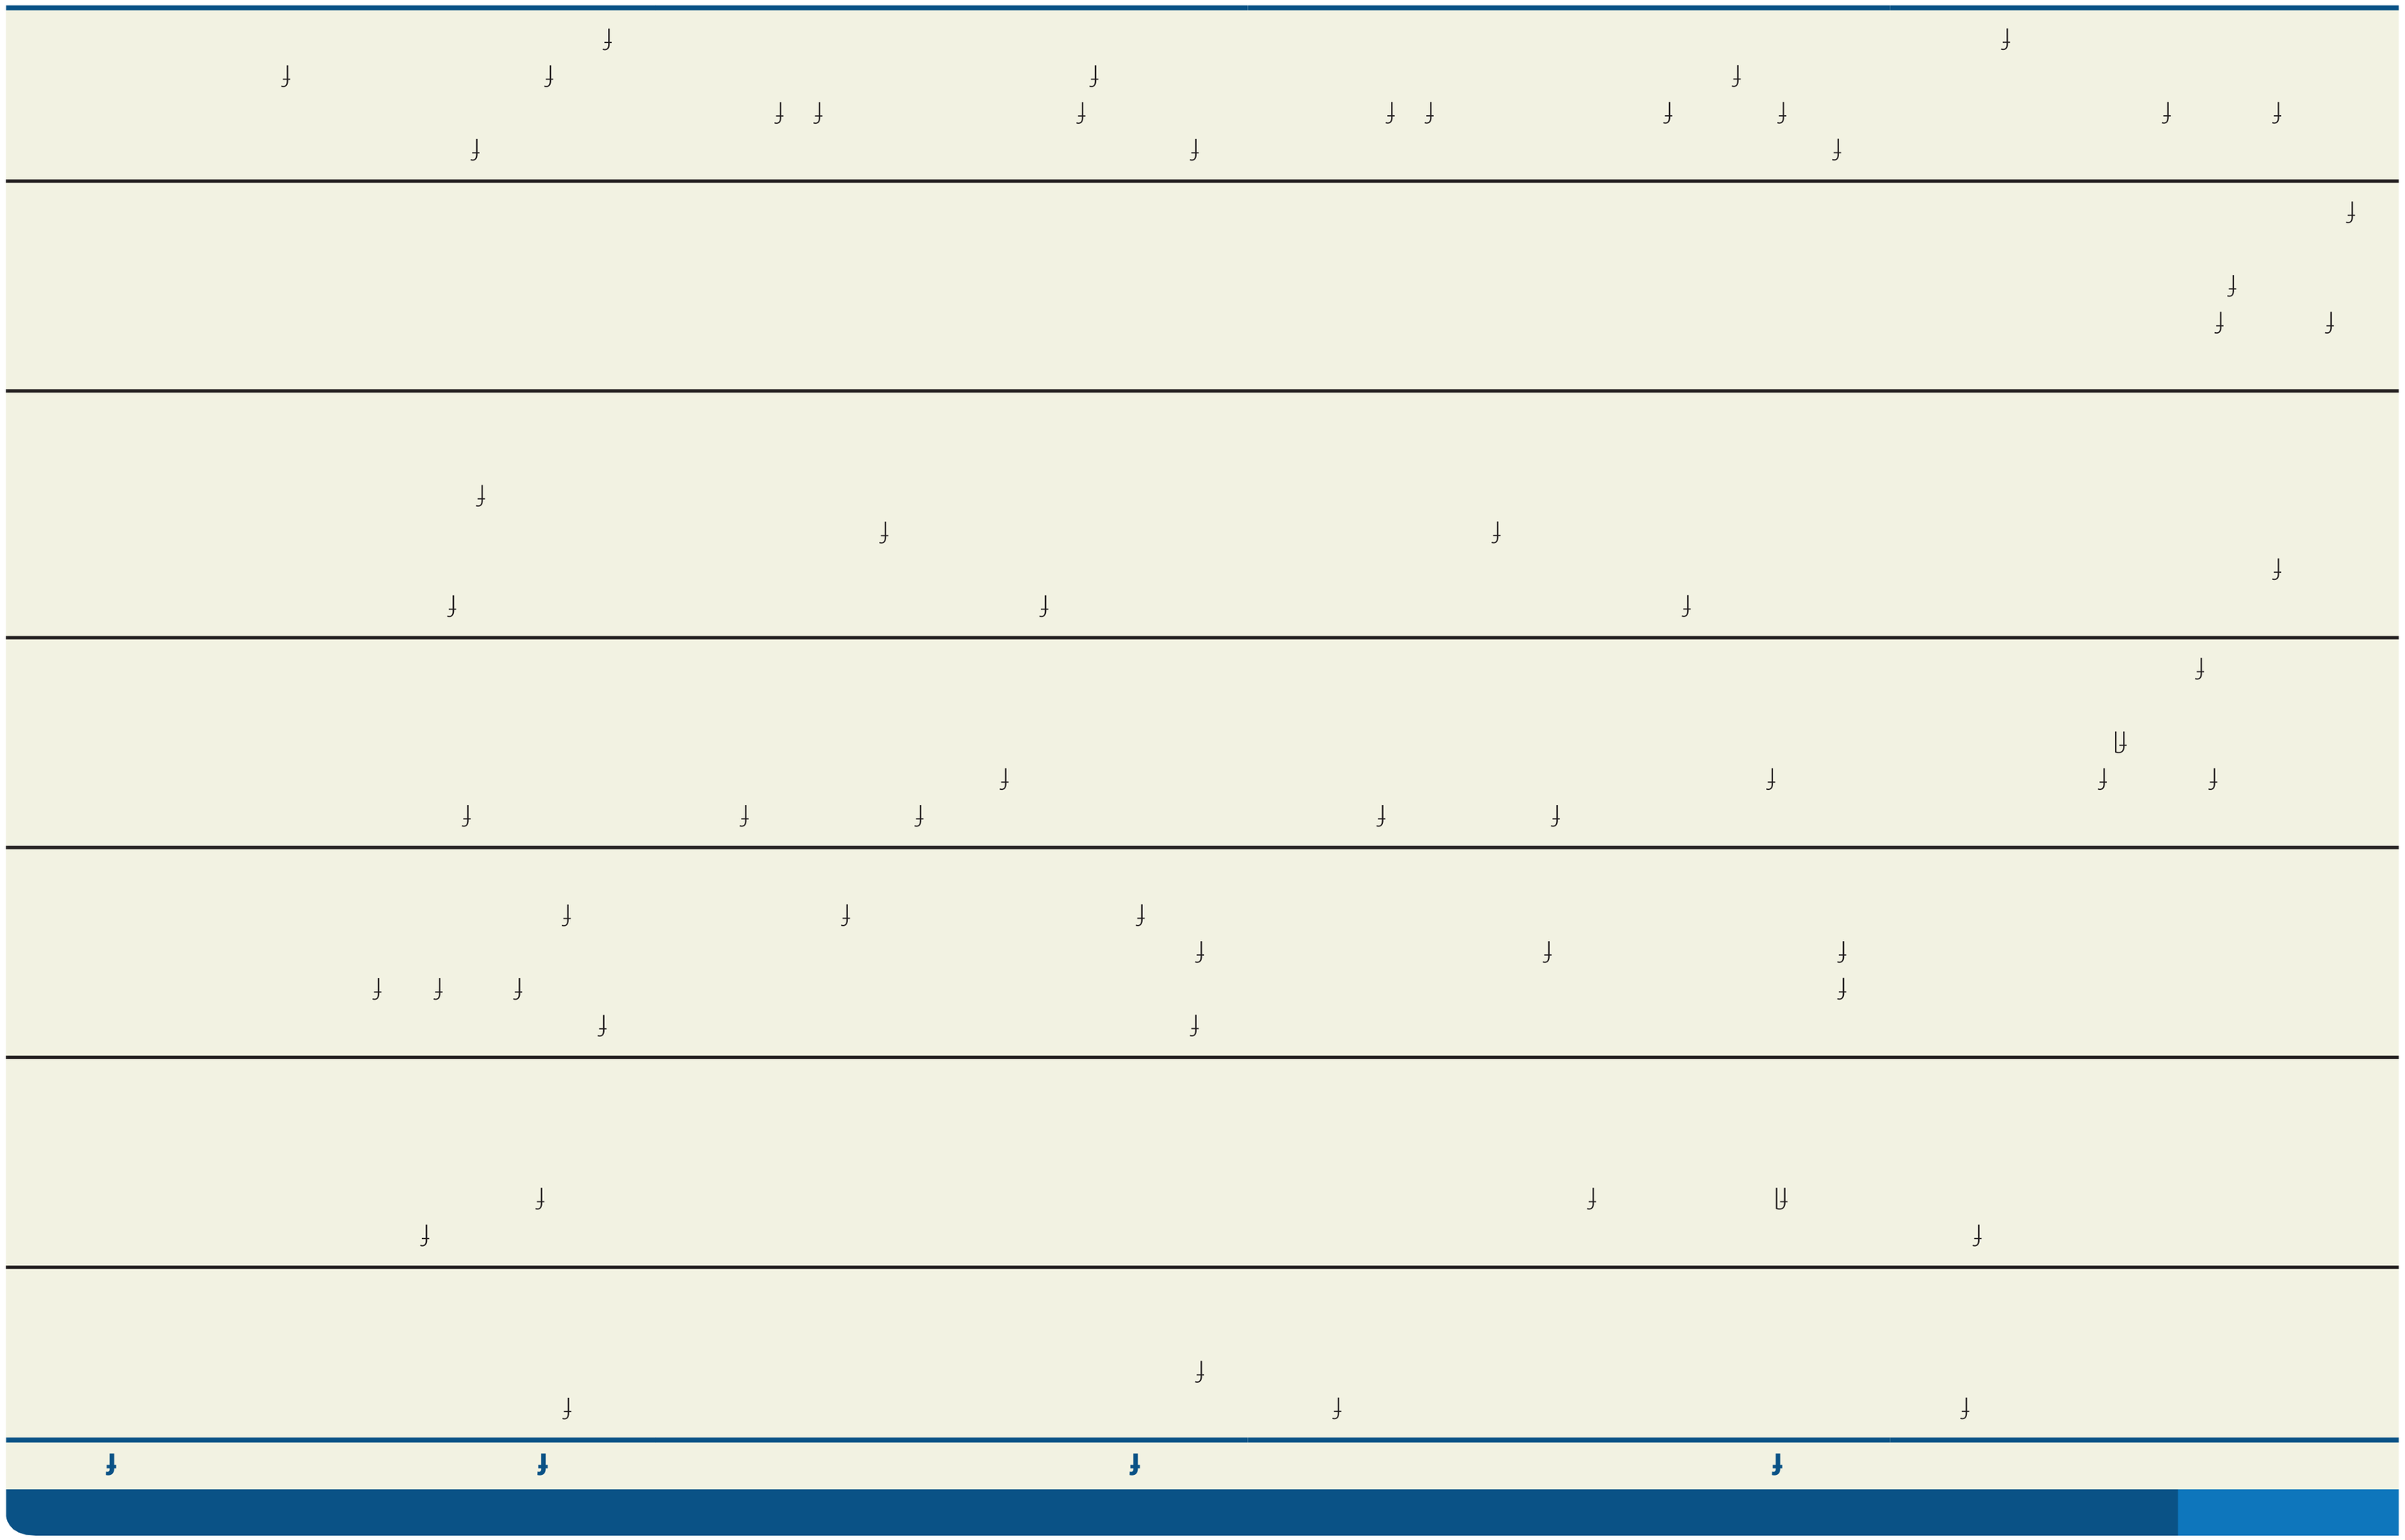

FIGURE 4-2 In-line lunge.

- 6-m timed hop test. T is test measures the time required for an individual to hop unilaterally for a distance of 6 m. T e patient is asked to perform large one-leg hops in series over the 6 m, which is timed to the nearest one-tenth of a second.

FIGURE 4-3 Hurdle step.

FIGURE 4-4 Deep squat.

- *T*riple hop *f*or distance test. T e patient is asked to perform three hops as far as possible, landing on the same leg and maintaining the landing for a minimum of 2 seconds while the toe measurement (to the nearest centimeter) is recorded. T e distances of the two legs may then

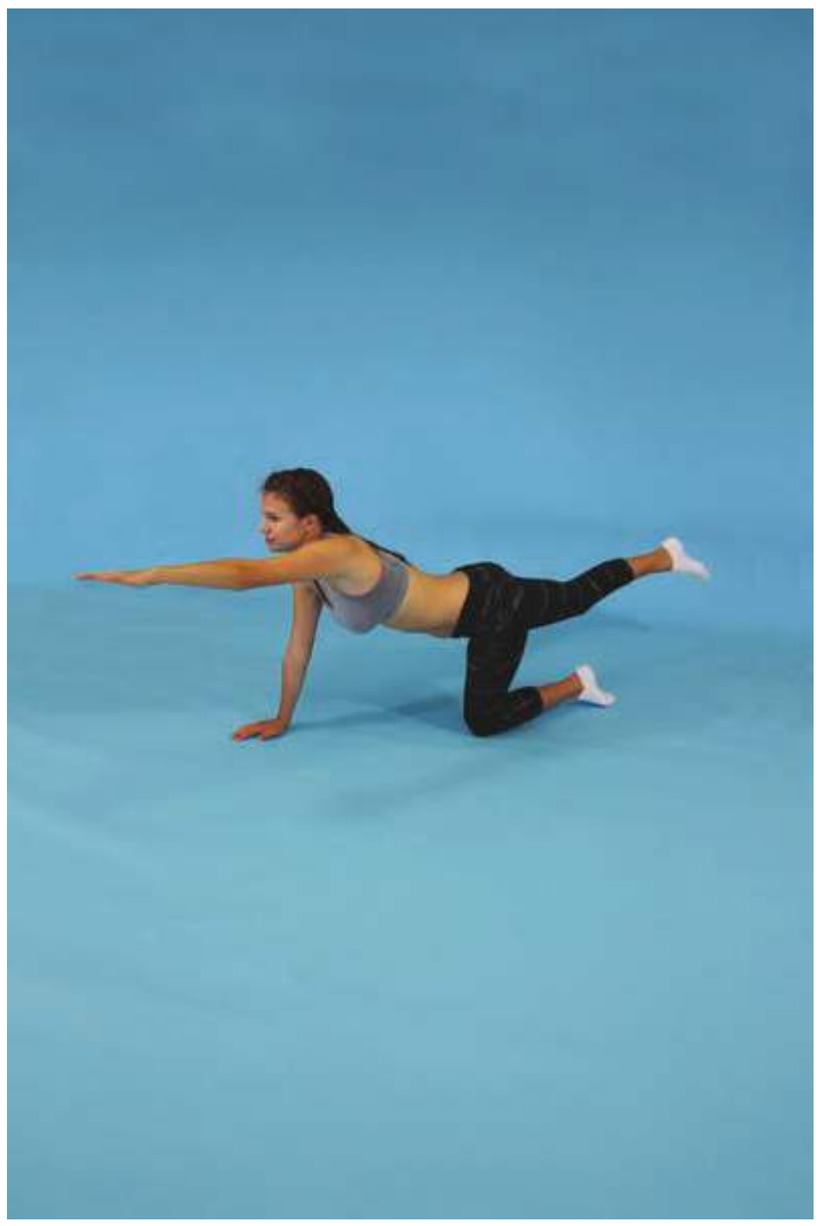

FIGURE 4-5 Quadruped rotary stability.

FIGURE 4-6 Active straight-leg raise.

be compared. This test has been shown to be a strong predictor of isokinetic strength of the hamstrings and quadriceps,[225] and as a self-reported functional outcome score for the knee.[226]

- 6-m timed crossover hop test. The patient is asked to perform three lateral hops as far as possible crossing over a 15-cm wide strip marking on each hop and to maintain landing after the third hop for 2 seconds. The first of the three hops is lateral with respect to the direction of the crossover (measured to the nearest centimeter).
- Side hop test. This test measures the amount of time it takes an individual to hop laterally back and forth on a single limb over a 30-cm distance for 10 repetitions.[227] Healthy controls have demonstrated a mean of 8.20 seconds for females and 7.36 seconds for males.[227]
- Figure-8 hop test. This test requires the individual to hop on a single limb twice around the course of two cones set 5 m apart.[228] An LSI $\leq$ 0.81 seconds has been established as the acceptable difference between size to discriminate normal function.[227]
- Square hop test. To perform this test, the individual stands on a single limb in the center of a 40 × 40 cm square and is then asked to hop as fast as possible out, then back in to the center of the square for each corresponding side of the square, before switching legs (a total of eight hops to complete a cycle around the square).[228] The time required to complete five cycles is recorded.

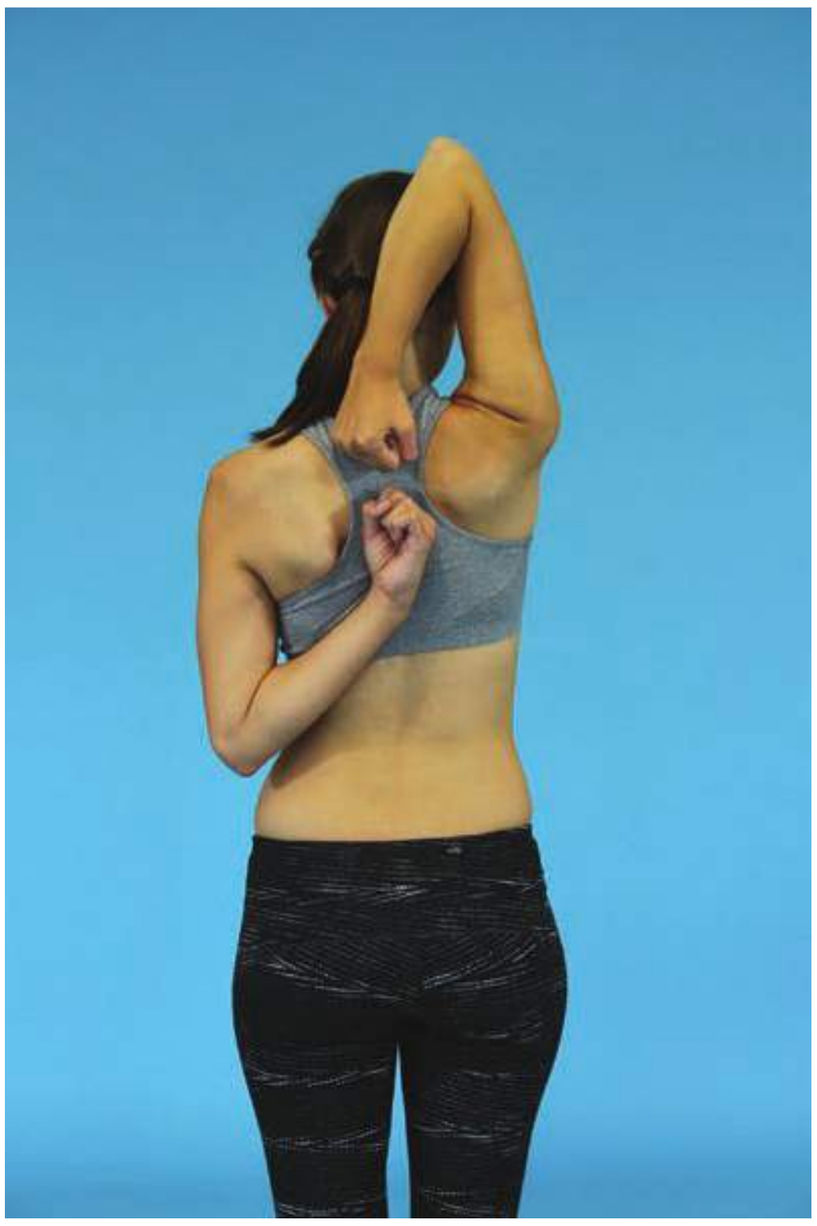

FIGURE 4-7 Shoulder mobility.

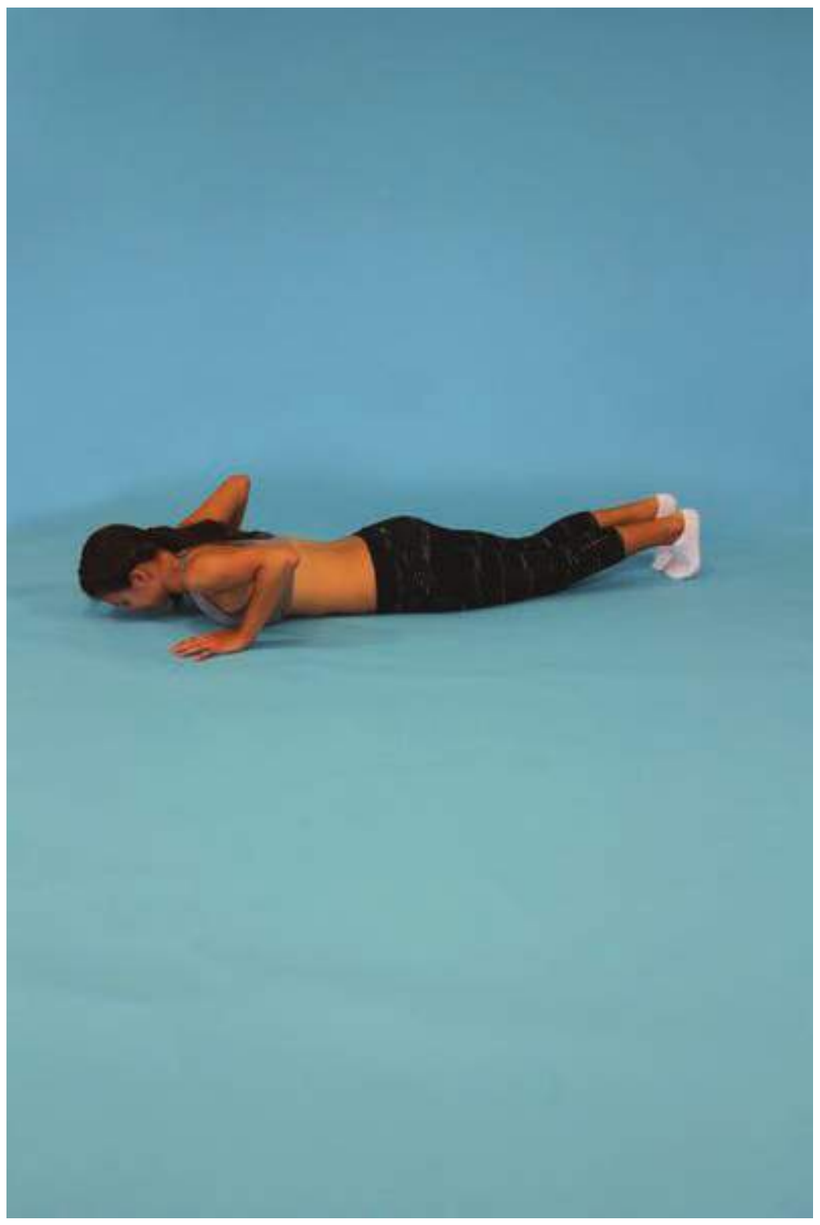

FIGURE 4-8 Trunk stability push-up.

Agility. These tests, commonly referred to as jump tests or field agility tests, are bipedal locomotive tests that require an individual to run in a predetermined pattern often involving cutting, pivoting, and changing direction to simulate sport-specific movements. Jump tests are performed bilaterally so, unlike hop tests, cannot be compared to the opposite side for analysis.[229] Examples of commonly used jump tests include:[222]

- The vertical jump test. This test, which allows the individual to squat to a depth of his or her choice just prior to takeoff, measures the vertical displacement of the center of mass determined by an individual's vertical jump value.

- T e squat jump test. T is test, unlike the vertical jump test, is performed from a static start position.
- T e drop jump test. T e individual steps from a 40 cm box, lands with both feet, then quickly performs a maximum vertical leap.

Numerous field agility tests have been used in the literature:[222]

- T e *T*-test. T is test requires forward and backward runs and lateral shuf es in both directions.
- Modified agility test (MAT). T is test, which is designed to highlight limb asymmetry, requires the individual to perform cutting and shuf ing to only one side. T e MAT is a timed test in which the individual performs 15 m of forward and backward running, side shuf ing, and cutting. T e patterns are then repeated on the other side to allow for a comparison of asymmetry between the two sides.

Self-Report Measures

Self-efficacy, which describes a person's own belief that he or she can successfully execute behavior in order to meet a desired outcome, plays a critical role in the management of neuromusculoskeletal conditions. Strong self-efficacy has been found to predict positive treatment outcomes, and a better prognosis,[230] whereas weak self-efficacy predicts long-term disability.[231] T e most common method for assessing self-efficacy is by a self-report questionnaire.[232] Self-report outcome instruments fall into one of four categories: generic, disease-specific, region-specific, and patient-specific. Self-report measures involve the patient rating his or her performance during activities such as walking, stair climbing, or sporting activity based on the ability to perform a task, difficulty with the task, help needed for the task, and pain during performance of the task.

- Generic. Generic instruments assess the global well-being of the patient and are useful in comparing groups of subjects with a wide range of conditions.
- Disease-specific. Disease-specific instruments determine the impact a disease/dysfunction has on the patient.[151] As a result of this focus on a disease state, the likelihood of increased responsiveness is higher. Some examples of the primary focus of these instruments include populations (rheumatoid arthritis), symptoms (back pain), and function (activities of daily living).[151] For example, the Fear Avoidance Beliefs Questionnaire (FABQ),[233] which was originally designed to help measure how much fear and avoidance impacted a patient with low back pain, thereby helping to identify those patients for whom psychosocial interventions may be beneficial (Table 4-21). However, the scale can be modified to apply to patients with other types of chronic pain as only two items mention the word "back." T e scoring for the FABQ is outlined in Table 4-22. T e disadvantage of a disease-specific outcome is that general information is lost.
- Region-specific. Region-specific instruments contain items that are specific to a particular area of the body and useful in assessing the effect of disease processes on that region. Examples of region-specific instruments include the Western Ontario and McMaster Universities Osteoarthritis index (WOMAC),[234] and the Hip Disability and Osteoarthritis Outcome Score (HOOS).[235]
- Patient-specific. Patient-specific instruments allow individuals to create items that assess issues they feel are important. T ese instruments are useful in analyzing the same individual over an extended period of time, but may not allow comparison to other subjects all patients. For example, the Patient-Specific Functional Scale (PSFS)[236] is designed to assess functional change, primarily in a patient presenting with a musculoskeletal disorder (see "Outcomes" section).

It is generally recommended that when evaluating patient outcomes, both a disease-specific and generic outcome instrument should be used.[151]

T roughout this text, numerous self-report measurement tools are outlined in each of the appropriate chapters.

TABLE 4-21 FABQ

Instructions: Here are some of the things that other patients have told us about their pain. For each statement, please score it from 0 to 6 to say how many physical activities such as bending, lifting, walking, or driving affect or would affect your back pain.

Statements

1. My pain is caused by physical activity.
2. Physical activity makes my pain worse.
3. Physical activity might harm my back.
4. I should not do physical activities that (might) make my pain worse.
5. I cannot do physical activities that (might) make my pain worse.

The following statements are about how your normal work affects or would affect your back pain:

6. My pain was caused by my work or by an accident at work.
7. My work aggravated my pain.
8. I have a claim for compensation for my pain.
9. My work is too heavy for me.
10. My work makes or would make my pain worse.
11. My work might harm my back.
12. I should not do my normal work with my present pain.
13. I cannot do my normal work with my present pain.
14. I cannot do my normal work till my pain is treated.
15. I do not think that I will be back to my normal work within 3 months.
16. I do not think that I will ever be able to go back to that work.

Data from Waddell G, Newton M, Henderson I, et al. A Fear-Avoidance Beliefs Questionnaire (FABQ) and the role of fear-avoidance beliefs in chronic low back pain and disability. Pain. 1993:52;157–1568.

Aerobic Capacity and Endurance

Aerobic capacity endurance is the ability to perform work or participate in activity over time, using the body's oxygen uptake, delivery, and energy-release mechanisms (see Chapter 15).[18] Clinical indications for the use of the tests and measures for this category are based on the findings from the history and systems

TABLE 4-22 FABQ Scoring[a]

Response	Points
Completely disagree	0
	1
	2
Unsure	3
	4
	5
Completely agree	6
Fear-avoidance beliefs about work (scale 1) = (points for item 6) + (points for item 7) + (points for item 9) + (points for item 10) + (points for item 11) + (points for item 12) + (points for item 15)	
Fear-avoidance beliefs about physical activity (scale 2) = (points for item 2) + (points for item 3) + (points for item 4) + (points for item 5)	
Items not in scale 1 or 2: 1 8 13 14 16	
Interpretation: ▯ minimal scale scores: 0 ▯ maximum scale 1 score: 42 (7 items) ▯ maximum scale 2 score: 24 (4 items) ▯ The higher the scale scores the greater the degree of fear and avoidance beliefs shown by the patient	
Performance: ▯ Internal consistency (alpha) 0.88 for scale 1 and 0.77 for scale 2	

[a]Data from Waddell G, Newton M, Henderson I, et al. A Fear-Avoidance Beliefs Questionnaire (FABQ) and the role of fear-avoidance beliefs in chronic low back pain and disability. Pain. 1993;52;157–168.

review. T ese indications include, but are not limited to, pathology, pathophysiology, and impairment to the[18]:

- cardiovascular system (e.g., abnormal heart rate, rhythm, and blood pressure);
- endocrine/metabolic system (e.g., osteoporosis);
- multiple systems (e.g., trauma and systemic disease);
- neuromuscular system (e.g., generalized muscle weakness and decreased endurance);
- pulmonary system (e.g., abnormal respiratory pattern, rate, and rhythm).

T e aerobic capacity and endurance of a patient can be measured using standardized exercise test protocols (e.g., ergometry, step tests, time or distance walk or run tests, and treadmill tests) and the patient's response to such tests (see Chapter 15).[18]

Anthropometric Characteristics

Anthropometric characteristics are traits that describe body dimensions, such as height, weight, girth, and body fat composition.[18] T e use of an anthropometric examination and the subsequent measurements varies. Clearly, if a noticeable amount of effusion or swelling is present, these measurements serve as an important baseline from which to judge the effectiveness of the intervention.

Circulation

Circulation is defined by T e Guide as the movement of blood through organs and tissues to both deliver oxygen and remove carbon dioxide and cellular byproducts.[18] Circulation also involves the passive movement of lymph through channels. T e examination of the circulation includes an examination of those cardiovascular signs not tested in the aerobic capacity and endurance portion, and the anthropometric characteristics portion of the examination, including the patient's physiologic response to position change, an inspection of the nail beds, capillary refill, and monitoring of the pulses of the extremities.

In general, the posterior (dorsal) pedis pulse is used in the lower extremities to assess the patency of the lower extremity vessels, whereas the radial pulse is used for the upper extremities.

Work, Environmental, and Home Barriers (Job, School, and Play)

Work, environmental, and home barriers are the physical impediments that keep patients from functioning optimally in their surroundings.[18]

Ergonomics and Body Mechanics

Ergonomics is the relationship between the worker; the work that is done; the actions, tasks, or activities inherent in that work (job, school, and play); and the environment in which the work (job, school, and play) is performed.[18] Body mechanics are the interrelationships of the muscles and joints, as they maintain or adjust posture in response to forces placed on or generated by the body.

It is not within the scope of this text to detail the scientific and engineering principles related to ergonomics, and the numerous tests used to quantify these measures. Ergonomics, as it relates to posture, is discussed in Chapter 6 and within the related chapters.

Gait, Locomotion, and Balance

Gait analysis is an important component of the examination process (see Chapter 6) and should not be reserved only for those patients with lower extremity dysfunction. Although the act of walking is often taken for granted, normal and reciprocal gait requires a finely tuned series of reflexes.[237] T e examination of gait is performed to highlight any breakdown within these reflexes, including imbalances of flexibility or strength, or compensatory motions.[238] T e analysis of gait is described in Chapter 6.

Gait, like posture, varies between individuals, and a gait that differs from normal is not necessarily pathologic.

Balance is an essential component of sport participation and for activities of daily living (see Chapter 3). During the history, the patient may describe symptoms of dizziness, lightheadedness, a sense of impending faint, or poor balance. Nausea and vomiting are common complaints in balance disorders. T e assessment of balance is discussed in Chapter 3.

Orthotic, Adaptive, Protective, and Assistive Devices

T ese devices are implements and equipment used to support or protect weak or ineffective joints or muscles and serve to enhance performance.[18] Examples of such devices include canes, crutches, walkers, reachers, and ankle foot orthoses.

Posture

Posture describes the relative positions of different joints at any given moment.[97] T e postural examination gives an overall view of the patient's muscle function in both chronic and acute pain states. T e examination enables the clinician to differentiate between possible provocative causes, such as structural variations, altered joint mechanics, muscle imbalances, and the residual effects of pathology. T e assessment of posture is detailed in Chapter 6 and in the relevant chapters.

Work (Job, School, and Play), Community, and Leisure Integration and Reintegration

In short, this category refers to the process of assuming or resuming roles and functions.

Self-care and Home Management (Including Activities of Daily Living and Instrumental Activities of Daily Living)

T is portion of the examination addresses the patient's perception of his or her condition, namely issues regarding the patient's perception of their functional level and quality of life.

Palpation

Palpation is a fundamental skill used throughout the examination. Both Gerwin et al.[239] and Njooand and van der Does[240] found that training and experience are essential in performing reliable palpation tests. Hoppenfeld[241] advocates an approach to palpation that is organized by region. Under this system, the palpation of bony structures occurs separately from the palpation of the soft tissues. While this may be helpful to the clinician, time constraints often dictate that the two are examined concurrently. Palpation, which can play a central role in the performance of several manual therapy techniques,[242] is performed to[243,244]

- check for any vasomotor changes such as an increase in skin temperature that might suggest an inflammatory process.
- localize specific sites of swelling.
- determine the presence of muscle tremors, and/or fasciculations.
- identify specific anatomic structures and their relationship to one another.
- identify sites of point tenderness. Hyperalgic skin zones can be detected using skin drag, which consists of moving the pads of the fingertips over the surface of the skin and attempting to sense resistance or drag.
- identify soft tissue texture changes or myofascial restriction. Normal tissue is soft and mobile and moves equally in all directions. Abnormal tissue may feel hard, sensitive, or somewhat crunchy or stringy.[245]
- locate changes in muscle tone resulting from trigger points, muscle spasm, hypertonicity, or hypotonicity. However, a study by Hsieh et al.[246] found that among non-expert physicians, physiatric or chiropractic, trigger point palpation is not reliable for detecting taut band and local twitch response, and only marginally reliable for referred pain after training. T e most useful diagnostic test to detect these changes is to create a fold in the tissue and to stretch it.[247] T e tissue should be soft and supple, and there should be no resistance to the stretch.
- determine circulatory status by checking distal pulses.
- detect changes in the moisture of the skin.
- locate any deformity that may be suggestive of a fracture, severe muscle or tendon lesion, or vascular compromise.

T e pertinent palpation techniques for each of the joints are described in the relevant chapters.

Special Tests

Special tests for each area are dependent on the special needs and structure being tested. Numerous tests exist for each joint. With a few notable exceptions, the reliability of most orthopedic testing is either poor or unproven. T erefore, the clinician is wise to avoid overreliance on labeling a specific test as positive or negative.[248] Rather, the patient's response to provocative maneuvers should be carefully noted and be used to provide a framework within which the clinician builds a complete picture of the clinical entity.[248] In addition, the clinician should use more than one examination maneuver to make the diagnosis. One study[249] reported improved sensitivity, specificity, and positive predictive value of the utilization of combinations of tests rather than using tests in isolation.

T e special tests are only performed if there is some indication that they would be helpful in arriving at a diagnosis. T e tests help confirm or implicate a particular structure and may also provide information as to the degree of tissue damage.

In the joints of the spine, examples of special tests include directional stress tests (posterior–anterior pressures and anterior, posterior, and rotational stressing), joint quadrant testing, vascular tests, and repeated movement testing. Examples of special tests in the peripheral joints include ligament stress tests (i.e., Lachman for the anterior cruciate ligament), articular stress testing (valgus stress applied at the elbow), and glenohumeral impingement tests. Special tests can be categorized according to intent:

- Provocative tests. Provocative tests include those that are designed to put stress on an involved structure and reproduce the pain that has brought the patient into the clinic while ruling out the involvement of other structures. Although palpation fits the criteria as a provocative test, its importance to the examination warrants its own section. Examples of other provocative tests include the Spurling's test (cervical foraminal encroachment test) to detect a potential cervical radiculopathy, the thoracic

outlet tests, the neurodynamic mobilizations tests (e.g., the straight-leg raise—see Chapter 11) that assess for neural adhesions and nerve root problems, and the selective tissue tension tests designed by Cyriax.[137] T ese tests, which by their very nature are designed to reproduce the patient's symptoms, should be used judiciously, and only after consultation with the patient to describe the reasons for the testing.

- Clearing tests. T e purpose of the clearing tests is to remove a structure or region as a potential source of the patient's problem. T e clearing tests are typically used when a patient presents with symptoms in either the lower extremities or upper extremities. For example, in a patient complaining of shoulder pain, the clinician must determine if the symptoms are local or are referred. To help in this decision-making process, the cervical spine must be "cleared" so it can be ruled out as a potential source. T is can be done through a combination of neck side bending, rotation, and extension in an effort to reproduce the symptoms. If the symptoms are not reproduced with these maneuvers, the cervical spine is unlikely to be an obvious source of the symptoms. Because the cervical spine has the potential to refer pain throughout the entire upper extremity, it is always a worthy consideration as a cause of symptoms in the shoulder, the elbow, the wrist and the hand. Similarly, because the lumbar spine and the sacroiliac joint have the potential to refer symptoms into the lower extremities, they should always be considered in cases of hip, knee, and ankle and foot symptoms. In addition, neighboring joints should always be considered as potential causes of symptoms until cleared.

T e special tests for each of the joints are described in the various chapters of this book, with emphasis placed on those that are evidence based. T e interpretation of the findings from the special tests depends on the skill and experience of the clinician, as well as the degree of familiarity with the tests. While special tests are associated with false-positive and false-negative results, a positive test finding in conjunction with other aspects of the examination is highly suggestive of pathology.[158]

Reflex and Sensory Testing

Reflex and sensory testing is covered in Chapter 3. T e neurological examination is only carried out if the clinician feels the nervous system is involved, or if the clinician is unsure as to whether there is any neurological involvement.

Neuromeningeal Mobility Tests

T e neurodynamic mobility tests, described in Chapter 11, examine for the presence of any abnormalities of the dura, both centrally and peripherally. T ese tests are used if a dural adhesion or irritation is suspected. T e tests employ a sequential and progressive stretch to the dura until the patient's symptoms are reproduced.[12] T eoretically, if the dura is scarred, or inflamed, a lack of extensibility with stretching occurs. Because the sinuvertebral nerve innervates the dural sleeve, the pain caused by an inflamed dura is felt by the patient at multi-segmental levels and is described as having an ache-like quality. If the patient experiences sharp or stabbing pain during the test, a more serious underlying condition should be suspected.

Evaluation

Physical therapists are responsible for thoroughly examining each patient and then either treating the patient according to established guidelines or referring the patient to a more appropriate healthcare provider.[250] Once the examination is complete, the clinician should be able to add and subtract the various findings, determine the accuracy of the working hypothesis, and make an evaluation, which involves developing the diagnosis, the prognosis, and the realistic POC.[251] According to Grieve,[139] an evaluation is the level of judgment necessary to make sense of the findings, in order to identify a relationship between the symptoms reported and the signs of disturbed function. T us, while the evaluation is used to determine the diagnosis, the prognosis, and the POC, it is the diagnosis that guides the intervention.

After determining an initial working hypothesis, the clinician must make a fundamental decision based on the following:[15]

- Refer the patient out for additional consultation and treatment,
- Initiate physical therapy intervention or continue the physical therapy examination, or
- Initiate both a physical therapy intervention and referral.

CLINICAL PEARL

The diagnosis and prognosis are critical to shaping the final POC. A physical therapy diagnosis refers to the cluster of signs and symptoms, syndromes, or categories and is used to guide the physical therapist in determining the most appropriate intervention strategy for each patient.[252]

Clinical Decision Making

Patients may be referred to physical therapy with a nonspecific diagnosis, an incorrect diagnosis, or no diagnosis at all.[253] Information derived from the history, physical examination, and other investigations is used to revise prior beliefs about the likelihood of a given diagnosis or outcome by a magnitude proportional to the relative strength of that information.[254] T e application of such methods, particular within a diagnostic context, has been termed probabilistic reasoning.[255,256] Within a probabilistic framework, perfect predictions are not anticipated, and error is knowingly accepted.[257] T us, the goal of probabilistic reasoning is not to predict outcomes with certainty but, rather, to generate predictions that are more often "less wrong" than those generated by other methods.[256]

A diagnosis can only be made when all potential causes for the signs and symptoms have been ruled out, so the clinician should resist the urge to categorize a condition based on a small number of findings. T e best indicator of the correctness of a

diagnosis is the quality of the hypothesis considered, because if the appropriate diagnosis is not considered from the start, any subsequent inquiries will be misdirected.[258] Ultimately, given the role of physical therapists as movement specialists, task analysis should form the basis of the diagnosis.[259] Once impairments have been highlighted; a determination can be made as to the reason for those impairments, and the relationship between the impairments and the patient's functional limitations or disabilities.

Decision making encompasses the selection of tests during the examination process, interpretation of data from the detailed history and examination, establishment of the diagnosis, estimation of the prognosis, determination of intervention strategies, sequence of therapeutic procedures, and establishment of discharge criteria.[252] The decision-making process is a multifaceted fluid process which combines tacit knowledge with accumulated clinical experience.[260] The experienced clinician is able to recognize patterns and extrapolate information from them using forward reasoning, to develop an accurate working hypothesis.[261] This is can be accomplished through an estimate of the proportional contribution of tissue pathology and impairment clusters to the patient's functional limitations.[262] Many physical therapists are taught to direct their orthopedic evaluation toward classifying patients based on a pathoanatomic model, such as "signs and symptoms consistent with rotator cuff tear." The rationale behind such approach is that by using the same labels and language as the referring physicians, communication will be enhanced.[263] However, as physical therapists treat movement-related impairments rather than structural anatomical abnormalities, such labeling creates a disconnect between the diagnostic and treatment processes.[263] Thus, by changing the focus of the label to the human movement system, the diagnosis changes to a pathokinesiologic model, where the diagnostic process focuses on identification of characteristic movement impairments.[263,264] Such a label, with its focus on the patterns or clusters of movement impairments, provides a better guide to the intervention and the setting of goals. There may be cases when providing a diagnostic label can be combined with the relevant movement impairment. For example, shoulder mobility deficit associated with capsular contracture helps differentiate a similar clinical presentation in the case of glenohumeral osteoarthritis.[263]

Using this information, the clinician puts a value on examination findings, by considering relevant environmental, social, cultural, psychological, medical, and physical findings, and clusters the information into recognizable, understandable, or identifiable diagnoses, dysfunctions, or classification syndromes.[262] According to Kahney,[265] the expert seems to do less problem solving than the novice because the former has already stored solutions to many of the clinical problems previously encountered.[266]

One of the problems for the clinician is how to attach relevance to all of the information gleaned from the examination. This judgment process can be viewed as a continuum. At one end of the continuum is the novice who uses very clear-cut signposts, while at the other end there is the experienced clinician who has a vast bank of clinical experiences from which to draw.[266] An expert is able to see meaningful relationships, possess enhanced memory, is skilled in qualitative analysis, and has well-developed reflection skills.[260] This is combination of skills allows the expert to systematically organize the information to make efficient and effective clinical decisions.

What differentiates diagnosis by the physical therapist from diagnosis by the physician is not the process itself, but the phenomena being observed and clarified.[267] Sackett et al.[149] proposed three strategies of clinical diagnosis:

- Pattern recognition. This is is characterized by the clinician's instantaneous realization that the patient conforms to a previously learned pattern of disease.
- History and physical examination. This is method requires the clinician to consider all hypotheses of the potential etiology.
- Hypothetico-deductive method. In this method, the clinician identifies early clues and formulates a short list of potential diagnoses.

The clinician's knowledge base is critical to the evaluation process.[258] Experienced clinicians appear to have a superior organization of knowledge, and they use a combination of hypothetico-deductive reasoning and pattern recognition to derive the correct diagnosis or working hypothesis.[258]

A number of frameworks have been applied to clinical practice for guiding clinical decision making and providing structure to the healthcare process.[268,269] While the early frameworks were based on disablement models, the more recent models have focused on enablement perspectives using algorithms. An algorithm is a systematic process involving a finite number of steps that produces the solution to a problem. Algorithms used in healthcare allow for clinical decisions and adjustments to be made during the clinical reasoning and decision-making process because they are not prescriptive or protocol driven.[260] The most commonly used algorithm in physical therapy is the hypothesis-oriented algorithm *f*or clinicians (HOAC) designed by Rothstein and Echternach.[270] The HOAC is designed to guide the clinician through the evaluation to the intervention planning with a logical sequence of activities, and requires the clinician to generate working hypotheses early in the examination process, the latter of which is a strategy often used by expert clinicians.

When integrating evidence into clinical decision making, an understanding of how to appraise the quality of the evidence offered by clinical studies is important. One of the major problems in evaluating studies is that the volume of literature makes it difficult for the busy clinician to obtain and analyze all of the evidence necessary to guide the clinical decision-making process.[67] The other problem involves deciding whether the results from the literature are definite enough to indicate an effect other than chance. Judging the strength of the evidence becomes an important part of the decision-making process. Clinical prediction rules (CPRs) function to produce estimates of the likelihood of a target diagnosis, prognosis, or treatment outcome that, in turn, informed clinical decision making.[271] A CPR is initially derived using multivariable statistical procedures to identify which aspects of a patient's presentation are independently related to a certain diagnosis or outcome.[272] The tool then undergoes a process of validation, whereby it is applied to new groups of patients in different settings to evaluate its ability to accurately predict

that same diagnosis/outcome.[272] Validated CPRs subsequently undergo impact analysis, by which they are tested to determine whether their clinical application leads to improved patient outcomes or efficiencies in resource consumption.[272]

CLINICAL PEARL

- CPRs, a common application of probabilistic reasoning in health care, are tools designed to assist clinicians in decision making when caring for patients. For example, Flynn et al.[273] designed a CPR to identify patients with low back pain more likely to benefit from lumbopelvic thrust manipulation. The study identified that the probability of success from this intervention increased from 45% to 95% when four or more factors were present, including precise estimates of the tool sensitivity and specificity. These data were then used to help calculate more precise estimates of the post-test probability of a fall in patients who were either positive or negative on the CPR.[256] It is important to remember that a CPR that has not undergone validation is not recommended for use in practice as it may reflect chance statistical associations or be specific to the patient sample or setting from which it was derived.[272,274]
- Clinical practice guidelines (CPGs), as their name suggests, are a method by which diagnostic labels are used to direct treatment, guide best practice, and inform prognosis.
- Clinimetrics.[15] A variety of test properties are used to determine the adequacy of a given test, and these test characteristics are collectively called clinimetric properties. Clinimetric properties include two sets of quantitative estimates:
  1. Validity, reliability, and responsiveness (see text).
  2. Feasibility of the test. Feasibility considers the practical constraints of completing and interpreting a test. Factors that impact feasibility include comfort and convenience for the patient and clinician.

The standard for the assessment of the usefulness of a test or intervention is the clinical trial, that is, a prospective study assessing the effect and value of a test or intervention against a control in human subjects.[275] Unfortunately, many of the experimental studies that deal with physical therapy topics are not clinical trials, because there is no control to judge the efficacy of the test or intervention, and there are no tests or interventions from which to draw comparisons.[276]

CLINICAL PEARL

Feasibility and pilot studies are preliminary studies conducted specifically for the purposes of establishing whether or not a full trial will be feasible to conduct, and that all the necessary components of a trial will work properly together.[277] In essence, feasibility studies are used to help develop trial interventions or outcome measures, whereas pilot studies replicate in miniature, a planned full-size randomized clinical trial.[278,279]

The best evidence for making decisions about interventions comes from randomized controlled trials, systematic reviews, and evidence-based CPGs (Table 4-23).[280] The ideal clinical trial includes a blinded, randomized design and a control group. A randomized clinical trial (RCT) is conducted to compare two (or more) treatments, or treatment to a control or comparison group.[277] It may be possible to discriminate between high- and low-quality trials by asking three simple questions:[280]

1. Were subjects randomly allocated to conditions? Random allocation implies that a nonsystematic, unpredictable procedure was used to allocate subjects to conditions.
2. Was there blinding of assessors and patients? Blinding of assessors and patients minimizes the risk of the placebo effect and the "Hawthorne effect," an experimental artifact that is of no clinical utility, where patients report better outcomes than they really experience because they perceive that this is what is expected from them.[281]
3. Was there an adequate follow-up? Ideally, all subjects who enter the trial should subsequently be followed up to avoid bias. In practice, this rarely happens. As a general rule, losses to follow-up of less than 10% avoid serious bias, but losses to follow-up of more than 20% cause potential for serious bias.

CLINICAL PEARL

Long thought of as a psychological response, placebo (in Latin, "I shall please") and its negative converse nocebo (in Latin, "I shall harm") are real psychobiological responses to healthcare interactions.[282] Placebo and nocebo phenomena are influenced by clinician behavior, which affects both the patient's and the clinician's experiences and meets at the point when the clinician's wish to do good equals the patient's desire to be helped.[282] This phenomenon, coupled with therapeutic interventions, is where the art and science of medicine work together—a mixture of the clinician framing a positive therapeutic experience and the use of evidence-based interventions.[283]

Numerous physical therapy tests exist that are designed to help the clinician rule out some of the many possible diagnoses. Regardless of which test is chosen, the test must be performed reliably by the clinician in order for the test to be a valuable guide.

Reliability. Reliability describes the extent to which a test or measurement is free from error. It is the repeatability of the measurement between clinicians, between groups of patients, over time.[15] A test is considered reliable if it produces precise, accurate, and reproducible information.[67] Two types of reliability are often described:

- Intrarater. Determines whether the same single examiner can repeat the test consistently.
- Interrater. Determines whether two or more examiners can repeat a test consistently.

Reliability is quantitatively expressed by way of an index of agreement, with the simplest index being the percentage

TABLE 4-23 Randomized Controlled Trials, Systematic Reviews, and Clinical Practice Guidelines

Randomized controlled trials (RCTs)	Involve experiments on people. Less exposed to bias. Ensures comparability of groups. Typically, volunteers agree to be randomly allocated to groups receiving one of the following: ▯ Treatment and no treatment ▯ Standard treatment and standard treatment plus a new treatment ▯ Two alternate treatments The common feature is that the experimental group receives the treatment of interest and the control group does not. At the end of the trial, outcomes of subjects in each group are determined—the difference in outcomes between groups provides an estimate of the size of the treatment effect.
Systematic reviews	Reviews of the literature conducted in a way that is designed to minimize bias. Can be used to assess the effects of health interventions, the accuracy of diagnostic tests, or the prognosis for a particular condition. Usually involve criteria to determine which studies will be considered, the search strategy used to locate studies, the methods for assessing the quality of the studies, and the process used to synthesize the findings of individual studies. Particularly useful for busy clinicians who may be unable to access all the relevant trials in an area and may otherwise need to rely upon their own incomplete surveys of relevant trials.
Clinical practice guidelines	Recommendations for management of a particular clinical condition. Involve compilation of evidence concerning needs and expectations of recipients of care, the accuracy of diagnostic tests, and effects of therapy and prognosis. Usually necessitates the conduct of one or sometimes several systematic reviews. May be presented as clinical decision algorithms. Can provide a useful framework upon which clinicians can build clinical practice.

Data from Maher CG, Herbert RD, Moseley AM, et al. Critical appraisal of randomized trials, systematic reviews of randomized trials and clinical practice guidelines. In: Boyling JD, Jull GA, eds. Grieve's Modern Manual Therapy: The Vertebral Column. Philadelphia, PA: Churchill Livingstone; 2004:603–614; Petticrew M. Systematic reviews from astronomy to zoology: myths and misconceptions. BMJ. 2001;322;98–101.

agreement value. The statistical coefficients most commonly used to characterize the reliability of the tests and measures are the intraclass correlation coefficient (ICC) and the kappa statistic (κ), both of which are based on statistical models[284]:

- The ICC is a reliability coefficient calculated with variance estimates obtained through an analysis *of* variance (Table 4-24).[285] The advantage of the ICC over correlation coefficients is that it does not require the same number of raters per subject, and it can be used by two or more raters or ratings.[285]
- The κ statistic is a chance-corrected index of agreement that overcomes the problem of chance agreement when used with nominal and ordinal data.[286] With nominal data, the κ statistic, is applied after the percentage agreement between testers has been determined. However, with higher scale data, it tends to underestimate reliability.[287] Theoretically, the κ statistic can be negative if an agreement is worse than chance. Practically, in clinical reliability studies, the κ statistic usually varies between 0.00 and 1.00.[287] The κ statistic does not differentiate among disagreements; it assumes that all disagreements are of equal significance.[287]
- Standard error *of* measurement (SEM). The SEM reflects the reliability of the response when the test is performed many times and is an indication of how much change there might be when the test is repeated.[287] If the SEM is small, then the test is stable with minimal variability between tests[287].

Validity. The validity of a test is defined as the degree to which the test measures what it purports to be measuring, and how well it correctly classifies individuals with or without a particular disease.[68–70] A test is considered to have diagnostic accuracy if it has the ability to discriminate between patients with and without a specific disorder.[288] There are several types of test validity that should be considered when evaluating for inclusion in the physical therapy examination:[15]

- Construct validity. This type of validity represents the level of agreement between a measurement and the idea

TABLE 4-24 Intraclass Correlation Coefficient Benchmark Values

Value	Description
<0.75	Poor-to-moderate agreement
>0.75	Good agreement
>90	Reasonable agreement for clinical measurements

Data from Portney L, Watkins MP. Foundations *of* Clinical Research: Applications to Practice. Norwalk, CT: Appleton & Lange; 1993.

it purports to measure. To establish adequate construct validity of a measurement, the measurement should provide similar results as other measurements that are intended to measure the same variable. In addition, the measurement should provide different results from other measurements of theoretically different ideas. Convergent validity is the agreement between two different measurements of the same variable. Divergent validity is the extent to which two measurements of theoretically separate ideas are unrelated.

- Content validity. This type of validity is the extent to which a measurement reflects the idea (content) that it prepares to measure. Measurements with high content validity demonstrate a more accurate representation of the variable being measured.
- Criterion related validity. This type of validity is an estimate of the extent to which the test can substitute for another test, which may be a gold-standard test or a test of a related variable. Criterion related validity is commonly assessed as concurrent validity and predicted validity where concurrent validity is the measure of association between two measurements taken at the same time, and where predictability is an estimate of the ability of a measurement to forecast a future measurement or outcome.
- Face validity. This type of validity is an approximation that a measurement appears to reflect the variable that the measurement is intended to estimate. For example, palpation of the hand and wrist is considered to have high face validity, because locations for palpation reflect the typical locations of anatomical structures.

In order to determine if a test is both reliable and valid, the test must be examined in a research study and, preferably, multiple studies.

Validity is directly related to the notion of sensitivity and specificity. The sensitivity and specificity of any physical test to discriminate relevant dysfunction must be appreciated to make meaningful decisions.[289] Sensitivity is the ability of the test to pick up what it is testing for, and specificity is the ability of the test to reject what it is not testing for.

- Sensitivity represents the proportion of patients with a disorder who test positive. A test that can correctly identify every person who has the disorder has a sensitivity of 1.0. SnNout is an acronym for when the sensitivity of a symptom or sign is high, a negative response rules out the target disorder. Thus, a so-called highly sensitive test helps rule out a disorder. The positive predictive value is the proportion of patients with positive test results who are correctly diagnosed. Responsiveness is the characteristic of sensitivity to true change or difference between measurements. Measurement changes may be relevant within the same patient over time; measurement differences may be clinically important between subjects with and without a certain pathology.[15]
- Specificity is the proportion of the study population without the disorder that test negative.[290] A test that can correctly identify every person who does not have the target disorder has a specificity of 1.0. SpPin is an acronym for when specificity is extremely high, a positive test result rules in the target disorder. Thus, a so-called highly specific test helps rule in a disorder or condition. The negative predictive value is the proportion of patients with negative test results who are correctly diagnosed.

CLINICAL PEARL

Interpretation of sensitivity and specificity values is easiest when their values are high.[254] A test with a very high sensitivity, but low specificity, and vice versa, is of little value, and the acceptable levels are generally set at between 50% (unacceptable test) and 100% (perfect test), with an arbitrary cutoff at about 80%.[290]

Once the specificity and sensitivity of the test are established, the predictive value of a positive test versus a negative test can be determined if the prevalence of the disease/dysfunction is known. For example, when the prevalence of the disease increases, a patient with a positive test is more likely to have the disease (a false negative is less likely). A negative result of a highly sensitive test will probably rule out a common disease, whereas if the disease is rare, the test must be much more specific for it to be clinically useful.

CLINICAL PEARL

Collectively, estimates of validity, reliability, and responsiveness may be called psychometric properties.[15]

The likelihood ratio (LR) is the index measurement that combines sensitivity and specificity values and can be used to gauge the performance of a diagnostic test, as it indicates how much a given diagnostic test result will lower or raise the pretest probability of the target disorder.[290,291]

CLINICAL PEARL

Diagnostic tests are used for the purpose of discovery, confirmation, and exclusion.[292] Tests for discovery and exclusion must have high sensitivity for detection whereas confirmation tests require high specificity.[293]

Four measures contribute to sensitivity and specificity (Table 4-25):

- *T*rue positive. The test indicates that the patient has the disease or the dysfunction, and this is confirmed by the gold standard test.

TABLE 4-25 2 × 2 Table

		Disease/Outcome	
		Present	**Absent**
Test	Positive (+)	a (true +ve)	b (false +ve)
	Negative (−)	c (false −ve)	d (true −ve)

- False positive. The clinical test indicates that the disease or the dysfunction is present, but this is not confirmed by the gold standard test.
- False negative. The clinical test indicates the absence of the disorder, but the gold standard test shows that the disease or dysfunction is present.
- True negative. The clinical and the gold standard test agree that the disease or dysfunction is absent.

These values are used to calculate the statistical measures of accuracy, sensitivity, specificity, negative and positive predictive values, and negative and positive LRs, as indicated in Table 4-26. Another way to summarize diagnostic test performance using Table 4-25 is via the diagnostic odds ratio (DOR): DOR = true/false = (a∗d)/(b∗c). The DOR of a test is the ratio of the odds of positivity in disease relative to the odds of positivity in the non-diseased. The value of a DOR ranges from 0 to infinity, with higher values indicating better discriminatory test performance. A value of 1 means that a test does not discriminate between those patients with the disorder and those without.

CLINICAL PEARL

The DOR value rises steeply when sensitivity or specificity becomes near perfect.

The quality assessment of studies of diagnostic accuracy (QUADAS)[294] is an evidence-based quality assessment tool currently recommended for use in systematic reviews of diagnostic accuracy studies (DAS). The aim of DAS is to determine how good a particular test is at detecting the target condition. DAS allow the calculation of various statistics that provide an indication of "test performance"—how good the index test is at detecting the target condition. These statistics include sensitivity, specificity, positive and negative predictive values, positive and negative LRs, and diagnostics odds ratios. The QUADAS tool is a list of 14 questions which should each be answered "yes," "no," or "unclear" (Table 4-27). A score of 10 or greater of "yes" answers is indicative of a higher-quality study, whereas a score of less than 10 "yes" answers suggests a poorly designed study. Throughout this text, the QUADAS score is used (if known) to evaluate the various physical therapy examination tests.

Prognosis and Plan of Care

The prognosis is the predicted optimal level of function that the patient will attain within a certain time frame. This information helps guide the intensity, duration, and frequency of the intervention and aids in justifying the intervention. Prognostic studies have become identified as a research priority as healthcare providers attempt to differentiate between patients with a more favorable prognosis and those with a poor prognosis.[295] The goal is to either identify baseline characteristics that are associated with a specific outcome at a given point or determine those characteristics that tend to have a good prognosis regardless of treatment provided.[296,297] These determinations will allow for a more intensive approach to patients with a poor general prognosis, and a less intensive approach to those who are inclined to improve regardless of intervention.[296]

The prognosis represents a synthesis, based on an understanding of the extent of pathology, premorbid conditions, the ability of surrounding tissue structures to compensate in the short- or long-term, the healing processes of the various tissues, the patient's age, foundational knowledge, theory,

TABLE 4-26 Definition and Calculation of Statistical Measures

Statistical Measure	Definition	Calculation
Accuracy	The proportion of people who were correctly identified as either having or not having the disease or dysfunction	(TP + TN)/(TP + FP + FN + TN)
Sensitivity	The proportion of people who have the disease or dysfunction and who test positive	TP/(TP + FN)
Specificity	The proportion of people who do not have the disease or dysfunction and who test negative	TN/(FP + TN)
Positive predictive value	The proportion of people who test positive and who have the disease or dysfunction	TP/(TP + FP)
Negative predictive value	The proportion of people who test negative and who do not have the disease or dysfunction	TN/(FN + TN)
Positive LR	How likely a positive test result is in people who have the disease or dysfunction as compared to how likely it is in those who do not have the disease or dysfunction	Sensitivity/(1 − specificity)
Negative LR	How likely a negative test result is in people who have the disease or dysfunction as compared to how likely it is in those who do not have the disease or dysfunction	(1 − sensitivity)/specificity

TP, true positive; TN, true negative; FP, false positive; FN, false negative.
Data from Fritz JM, Wainner RS. Examining diagnostic tests: an evidence-based perspective. Phys Ther. 2001, 81:1546–1564; Powell JW, Huijbregts PA. Concurrent criterion-related validity of acromioclavicular joint physical examination tests: a systematic review. J Man Manip Ther. 2006:14;E19–E29.

Item		Yes	No	Unclear
1.	Was the spectrum of patients representative of the type of patient who will receive the test?	( )	( )	( )
2.	Were selection criteria clearly described?	( )	( )	( )
3.	Is the reference standard likely to correctly classify the target condition?	( )	( )	( )
4.	Is the time period between reference standard and index test short enough to be reasonably sure that the target condition did not change between the two tests?	( )	( )	( )
5.	Did the whole sample or a random selection of the sample, receive verification using a reference standard of diagnosis?	( )	( )	( )
6.	Did patients receive the same reference standard regardless of the index test result?	( )	( )	( )
7.	Was the reference standard independent of the index test (i.e., the index test did not form part of the reference standard)?	( )	( )	( )
8.	Was the execution of the index test described in sufficient detail to permit replication of the test?	( )	( )	( )
9.	Was the execution of the reference standard described in sufficient detail to permit its replication?	( )	( )	( )
10.	Were the index test results interpreted without knowledge of the results of the reference standard?	( )	( )	( )
11.	Were the reference standard results interpreted without knowledge of the results of the index test?	( )	( )	( )
12.	Were the same clinical data available when test results were interpreted as would be available when the test is used in practice?	( )	( )	( )
13.	Were uninterpretable/intermediate test results reported?	( )	( )	( )
14.	Were withdrawals from the study explained?	( )	( )	( )

[a]Data from Whiting P, Rutjes AW, Reitsma JB, et al. The development of QUADAS: a tool for the quality assessment of studies of diagnostic accuracy included in systematic reviews. BMC Med Res Methodol. 2003, 3:25.

evidence, experience, and examination findings, and takes into account the patient's social, emotional, and motivational status.[259,262] A number of studies have demonstrated a significant relationship between patient expectations and outcomes,[298–303] including one by Bishop et al.[304] which reported that more than 80% of patients expected that manual therapy to the cervical spine would provide relief of symptoms, prevention of disability, and improvement of activity level and sleep. Another study[298] noted that low or negative expectations before treatment affected outcome 6 months after treatment. It would seem apparent that a physical therapist can consciously or unconsciously shape patient expectations, and thus influence outcomes, through placebo (positive) or nocebo (negative) pathways.[283]

The patient's aspirations and patient-identified problems, together with those problems identified by the clinician, determine the focus of the goals.[259] The patient and clinician should come to an agreement regarding the most important problems, around which care should be focused, and together establish relevant goals.[259] Ideally, in each patient encounter, the clinician should strive to discover the patient's expectation and then deliver and exceed it to the extent that it doesn't cause more harm.[283]

Patient education and patient responsibility become extremely important in determining the prognosis. Typically the goal of a rehabilitation program is to return the patient/athlete to the pre-injury level using the patient's uninjured side as the gold standard. This may sometimes be inadequate as in most cases the clinician does not know what the pre-injury level actually was. Instead, the goal of every rehabilitation program should be to obtain an enhanced and improved level of whole body functional ability.[305] In addition, the rehabilitation program should identify, address, and correct all specific predisposing factors that may lead to another injury by addressing the physical, biomechanical, environmental, and psychological factors of the whole person during the rehabilitation process.[305]

The POC is organized around the patient's goals. The physical therapist's POC consists of consultation, education, and intervention. Procedural interventions are covered in Chapter 8.

Patient Participation in Planning. The patient's aspirations and patient-identified problems, together with those problems

identified by the clinician, determine the focus of the goals.[259] The patient and clinician should come to an agreement regarding the most important problems, around which care should be focused, and together establish relevant goals.[259] Patient education and patient responsibility become extremely important in determining the prognosis.

Anticipated Goals and Expected Outcomes. This includes the predicted positive effects on the:

- Disorder or condition
- Dysfunction
- Functional limitations and disabilities
- Prevention of future occurrences
- Health, fitness, and wellness of the patient
- Patient/client Satisfaction

The intervention is typically guided by short-term (anticipated goals) and long-term (expected outcomes) goals, which are dynamic in nature, being altered as the patient's condition changes, and strategies with which to achieve those goals based on the stages of healing.

CLINICAL PEARL

The most successful intervention programs are those that are custom designed from a blend of clinical experience and scientific data, with the level of improvement achieved being related to goal setting and the attainment of those goals.

The following information must be included within the POC based on the anticipated goals.

- Frequency of treatments, including how often the patient will be seen per day or per week.
- What interventions the patient will receive, including the use of any modalities, therapeutic exercise, and any specialized equipment.
- Plans for discharge, including patient and family education, equipment needs, and referral to other services as appropriate.
- The documented goals should be listed in order of priority with the most important or more vital functional activities listed first.
- Short-term (anticipated) goals. Short-term goals are the interim steps along the way to achieving the long-term goals. The purposes of the short-term goals include:
  - To set the priorities of the intervention.
  - To direct the intervention based on the specific needs and problems of the patient.
  - To provide a mechanism to measure the effectiveness of the intervention.
  - To communicate with other healthcare professionals.
  - To provide an explanation of the rationale behind the goal to third-party payers.

The timeframe for short-term goals can be based on the next time the patient will be seen.

CLINICAL PEARL

Examples of short-term goals based on the facility (with and without using abbreviations):

- Acute-care: Indep. walker amb. on level surfaces 50% PWB on RLE for 50 ft w/i 3 d. The patient will ambulate independently with a walker for 50 feet with 50% partial weight bearing of the right lower extremity within three days.
- Outpatient orthopedic clinic: Pt. will ↑ R knee √ AROM to 0–90° within 2 d. to assist with amb. The patient will increase right knee flexion active range of motion to 0–90 degrees within two days to assist with ambulation.

- Long-term (expected outcomes) goals. Long-term goals are the final product of a therapeutic intervention. The purposes of long-term goals are the same as those for short-term goals. Long-term goals typically use functional terms rather than such items as degrees of range of motion, or grades of muscle strength. Examples of typical long-term goals would include:
  - The patient will be independent with transfers on/off toilet, supine-sit, and sit-stand and with ambulation for 100 ft using an assistive device at time of discharge.
  - The patient will be independent with ambulation on level and uneven surfaces and stair negotiation without assistive device at time of discharge.

Coordination, Communication, and Documentation

Coordination

The physical therapist is responsible for the coordination of physical therapy care and services.

Communication

Communication with all of the individuals involved in a patient's care is typically provided either verbally or through written documentation. Much about becoming a clinician relates to an ability to communicate with the patient, the patient's family, and the other members of the healthcare team. It is important to remember that listening is often more critical than speaking. Special attention needs to be paid to cultural diversity and to nonverbal communication such as:

- Facial expression. The facial expression should be one of interest and concern.
- Voice volume. The voice volume should be at a level that is sufficient for the patient to hear. Avoid speaking loudly when possible, especially to those who are hard of hearing.
- Posture. An upright and attentive posture is preferable.
- Touch. Any touch, based on respect for the patient's cultural preferences and personal boundaries, used should be confident and firm.
- Gestures. Gestures should be limited to those describing a particular activity.

- Physical closeness. Comfort with physical closeness varies according to culture. In the United States, a distance of 18 in to 4 ft is considered normal for a professional distance.
- Eye contact. Maintaining eye contact enhances trust and demonstrates attentiveness.
- Eye level. Whenever possible, the clinician should alter his or her position so that the eye level between patient and clinician is the same. For example, if the patient is sitting, the clinician should assume a sitting position.

T e appearance of the clinician can convey an air of professionalism. Most institutions have a dress code.

CLINICAL PEARL

Learn to be a good listener by:

- Looking at the person who is talking and give him or her your full attention
- Making appropriate eye contact
- Showing understanding by summarizing and asking for confirmation
- Letting the speaker finish the point they were making
- Showing interest
- Being respectful

Communication between the clinician and the patient begins when the clinician first meets the patient and continues throughout any future sessions. Communication involves interacting with the patient using terms he or she can understand. T e introduction to the patient should be handled in a professional yet empathetic tone. Listening with empathy involves understanding the ideas being communicated and the emotion behind the ideas. Particularly important aspects of empathy are the recognition of patients' rights, potential cultural differences, typical responses to loss, and the perceived role of spirituality in health and wellness to the patient.

CLINICAL PEARL

A patient's privacy and dignity should be maintained at all times. Privacy includes the patient's personal space. Whenever appropriate, the clinician should ask permission from the patient before carrying out an action (moving the patient's belongings off the bedside table, sitting down, etc.)

Given the nature of the physical therapy profession, physical therapists interact frequently with people with disabilities. When writing or speaking about people with disabilities, it is important to put the person first. Group designations such as "the blind" or "the disabled" are inappropriate because they do not reflect the individuality, equality or dignity of people with disabilities. Similarly, words like "normal person" imply that the person with a disability is not normal, whereas "person without a disability" is descriptive but not negative. Etiquette considered appropriate when interacting with people with disabilities is based primarily on respect and courtesy. Outlined below are tips to help when communicating with persons with disabilities provided by the Office of Disability Employment Policy; the Media Project, Research and Training Center on Independent Living, University of Kansas, Lawrence, KS; and the National Center for Access Unlimited, Chicago, IL.

General Tips. When introduced to a person with a disability, it is appropriate to offer to shake hands. People with limited hand use or who wear an artificial limb can usually shake hands (shaking hands with the left hand is an acceptable greeting). If you offer assistance to a person with a disability, wait until the offer is accepted, then listen to or ask for instructions. Address people who have disabilities by their first names only when extending the same familiarity to all others.

Communicating with Individuals who are Blind, or Visually Impaired. T e clinician should speak to the individual when he or she is approached, and speak in a normal tone of voice. When conversing in a group, the clinician should remember to identify themselves and the person to whom he or she is speaking. T e clinician should not attempt to lead the individual without first asking; allow the person to hold your arm and control her or his own movements. Direct action should be given using descriptive words giving the person verbal information that is visually obvious to individuals who can see. For example, if you are approaching a series of steps, mention how many steps. If you are offering a seat, gently place the individual's hand on the back or arm of the chair so that the person can locate the seat. At the end of the session, the clinician should tell the individual that he or she is leaving.

Communicating with Individuals who are Deaf or Hard of Hearing. T e clinician should gain the patient's attention before starting a conversation (e.g., tap the person gently on the shoulder or arm), and then look directly at the individual, face the light, speak clearly, in a normal tone of voice, and keep the hands from obstructing the mouth. Short, simple sentences should be used. If the patient uses a sign language interpreter, the clinician should speak directly to the person, not the interpreter. If the clinician places a phone call, he or she should let the phone ring longer than usual. If a Text Telephone (TTY) is not available, the clinician should dial 711 to reach the national telecommunications relay service, which will facilitate the call.

Communicating with Individuals with Mobility Impairments. Whenever possible, the clinician should position himself or herself at the wheelchair user's eye level without leaning on the wheelchair or any other assistive device. Never patronize people who use wheelchairs by patting them on the head or shoulder. Do not assume that an individual in a wheelchair wants to be pushed—ask first.

Communicating with Individuals with Speech Impairments. If the clinician does not understand something the patient said, he or she should not pretend that they did but should ask the individual to repeat what he or she said and then repeat it back. To help the patient, the clinician should try to ask questions which require only short answers or a nod of the head. T e clinician should not speak for the individual or attempt to finish her or his sentences. If the clinician is

having difficulty understanding the individual, writing should be considered as an alternative means of communicating, but only after asking the individual if this is acceptable.

Communicating with Individuals with Cognitive Disabilities. Whenever possible, the clinician and patient should communicate in a quiet or private location, and should be prepared to repeat what is said, orally or in writing. It is important that the clinician be patient, flexible and supportive, and the clinician should wait for the individual to accept the offer of assistance; do not "over-assist" or be patronizing.

At the end of the first visit and at subsequent visits, the clinician should ask if there are any questions.

Documentation

Documentation in health care includes any entry into the patient/client record. T is documentation, considered a legal document, becomes a part of the patient's medical record. T e SOAP (Subjective, Objective, Assessment, Plan) note format has traditionally been used to document the examination and intervention process.

- Subjective: information about the condition from the patient or family member.
- Objective: measurement a clinician obtains during the physical examination.
- Assessment: analysis of problems including the long and short-term goals.
- Plan: a specific intervention plan for the identified problem(s).

T e purposes of documentation are as follows:[306]

- To document what the clinician does to manage the individual patient's case.
- To record examination findings, patient status, intervention provided, and the patient's response to treatment.
- To communicate with all other members of the healthcare team—this helps provide consistency among the services provided. T is includes communication between the physical therapist and the physical therapist assistant.
- To provide information to third-party payers, such as Medicare and other insurance companies who make decisions about reimbursement based on the quality and completeness of the physical therapy note.
- To help the physical therapist organize his/her thought processes involved in patient care.
- To be used for quality assurance and improvement purposes and for issues such as discharge planning.
- To serve as a source of data for quality assurance, peer and utilization review, and research.

Patient-Related Instruction

Patient education is an important component of the POC. T ere are probably as many ways to teach as there are to learn. T e clinician needs to be aware that people may have very different preferences for how, when, where, and how often they learn (see Chapter 8).

Outcomes

T e assessment of change in a patient's symptoms and function over time is essential to both clinical practice and research.[307] Outcomes measurement is a process that describes a systematic method to gauge the effectiveness and efficiency of an intervention in daily clinical practice.[308] Effectiveness in this context refers to the outcome of an intervention during the rigors of ordinary and customary care delivery.[308] T e efficiency of an intervention is a factor of utilization (e.g., number of outpatient visits, length of inpatient stay) with the costs of care and outcome. T e trend in using outcome measures in the decision-making process is consistent with the evidence-based approach (EBP) and represents the final step in the evaluation of clinical performance.[18,309] T e clinician should be able to evaluate and choose the appropriate outcome measure for a specific patient population since the caliber of information that an outcome measurement provides is a function of the sophistication, predictability, and accuracy of the tools or instruments used.[310] Measurement instruments must be able to detect a change when it has occurred and to remain stable when a change has not occurred.[311] T e better the sophistication, predictability, and accuracy of the measurement tool, the less chance there is for errors in measurement that make it difficult to ascertain whether true progress has occurred. In an effort to counteract the potential for these measurement errors, the term minimal detectable change (MDC) has been introduced. T e MDC is defined as the minimal amount of change that exceeds measurement error.[311] T e MDC is a statistical measure of meaningful change and is related to an instrument's reliability.[311] Although various methods for calculating the MDC have been proposed; a consensus has yet to be reached as to what is the optimal method.[312] Unfortunately, statistically significant change using the MDC may not indicate that the change is clinically relevant. T e minimally clinically important difference (MCID) is a measure of clinical relevance and indicates the amount of change in scale points that must occur before the change may be considered meaningful.[313] T e sensitivity of the MCID is represented by the number of patients the outcome measure correctly identifies as having changed an important amount divided by all of the patients who truly changed an important amount.[314] T e specificity of the MCID is represented by the number of patients the outcome measure correctly identifies as not having changed an important amount divided by all of the patients who truly did not change an important amount.[314] Although, it is tempting to make the assumption that the minimum level of statistical change (MDC) would be less than or equal to the MCID, the relationship between the MDC and the MCID scores is yet to be determined.[313]

Part of the problem in designing an outcome measurement tool is that function is highly individual, with multiple levels of difficulty and a high degree of specificity. In addition to the clinical and statistical measures, the success of an intervention is based on the perspective of the stakeholder.[311,315] For example, to the patient, success may be considered as the relief of symptoms. To the payers of health care, a successful

outcome is likely viewed as one that involved cost-efficient patient management.[311] Clinicians tend to define good outcomes as the learning of long-term management strategies, relief of symptoms, and improved function.[315]

Differential Diagnosis

CHAPTER 5

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Understand the importance of differential diagnosis.
2. Recognize some of the signs and symptoms that indicate the presence of a serious pathology.
3. Discuss the concept of malingering.
4. Describe why certain signs and symptoms (red flags) require medical referral.
5. Describe the various infective diseases and inflammatory disorders that the orthopaedic clinician may encounter.
6. Describe the various neoplastic and metabolic diseases that can impact the orthopaedic patient.
7. Discuss the differences between fibromyalgia and myofascial pain syndrome.
8. List the various systemic or medical pathologies that can mimic musculoskeletal pathology in the various body regions.

OVERVIEW

An important component of the Vision 2020 statement set forth by the American Physical Therapy Association (APTA) is achieving direct access.[1] With the majority of U.S. states now permitting direct access to physical therapists, many physical therapists now have the primary responsibility for being the gatekeepers of health care and for making medical referrals. In light of the APTA's movement toward realizing "Vision 2020," an operational definition of autonomous practice and the related term autonomous physical therapist practitioner is defined by the APTA's Board as follows:

- "Autonomous physical therapist practice is practice characterized by independent, self-determined professional judgment and action."
- "An autonomous physical therapist practitioner within the scope of practice defined by the 'Guide to Physical Therapist Practice' provides physical therapy services to patients who have direct and unrestricted access to their services, and may refer as appropriate to other healthcare providers and other professionals and for diagnostic tests."[2]

Through the history and physical examination, physical therapists diagnose and classify different types of information for use in their clinical reasoning and intervention.[3] The Guide clearly articulates the physical therapist's responsibility to recognize when a consultation with, or referral to, another healthcare provider is necessary.[4] This responsibility requires that the clinician have a high level of knowledge, including an understanding of the concepts of medical screening and differential diagnosis. The results of a number of studies have demonstrated that physical therapists can provide safe and effective care for patients with musculoskeletal conditions in a direct access setting.[5–7] Indeed, in a study by Childs et al.,[8] physical therapists demonstrated higher levels of knowledge in managing musculoskeletal conditions than medical students, physician interns and residents, and most physician specialists except for orthopaedists. In addition, physical therapist students enrolled in educational programs conferring the doctoral degree achieved higher scores than their peers enrolled in programs conferring the master's degree.[8] Furthermore, licensed physical therapists who were board certified achieved higher scores and pass rates than their colleagues who were not board certified.[8]

In an effort to aid the differential diagnosis of musculoskeletal conditions commonly encountered by physical therapists, screening tools have been designed to help recognize potential serious disorders (red or yellow flags).[9]

- Red-flag findings are symptoms or conditions that may require immediate attention and supersede physical therapy being the primary provider of service (Table 5-1), as they are typically indicative of nonmechanical (nonneuromusculoskeletal) conditions or pathologies of visceral origin.
- Yellow-flag findings are potential confounding variables that may be cautionary warnings regarding the patient's condition, and that require further investigation. Examples include dizziness, abnormal sensation patterns, fainting, progressive weakness, and circulatory or skin changes.

Stith et al.[10] describe the red-flag findings found within the patient's history, which indicate a need for a referral to

TABLE 5-1 Red-Flag Findings

History	Possible Condition
Constant and severe pain, especially at night	Neoplasm and acute neuromusculoskeletal injury
Unexplained weight loss	Neoplasm
Loss of appetite	Neoplasm
Unusual fatigue	Neoplasm and thyroid dysfunction
Visual disturbances (blurriness or loss of vision)	Neoplasm or neurologic dysfunction
Frequent or severe headaches	Neoplasm or neurologic dysfunction
Arm pain lasting > 2–3 mo	Neoplasm or neurologic dysfunction
Persistent root pain	Neoplasm or neurologic dysfunction
Radicular pain with coughing	Neoplasm or neurologic dysfunction
Pain worsening after 1 mo	Neoplasm
Paralysis	Neoplasm or neurologic dysfunction
Trunk and limb paresthesia	Neoplasm or neurologic dysfunction
Bilateral nerve root signs and symptoms	Neoplasm, spinal cord compression, and vertebrobasilar ischemia
Signs worse than symptoms	Neoplasm
Difficulty with balance and coordination	Spinal cord or CNS lesion
Fever or night sweats	Common findings in systemic infection and many diseases
Frequent nausea or vomiting	Common findings in many diseases, particularly of the gastrointestinal system
Dizziness	Upper cervical impairment, vertebrobasilar ischemia, craniovertebral ligament tear, inner ear dysfunction, CNS involvement, and cardiovascular dysfunction
Shortness of breath	Cardiovascular and/or pulmonary dysfunction and asthma
Quadrilateral paresthesia	Spinal cord compression (cervical myelopathy) and vertebrobasilar ischemia

CNS, central nervous system.

Data from Meadows J. A Rationale and Complete Approach to the Sub-Acute Post-MVA Cervical Patient. Calgary, AB: Swodeam Consulting; 1995.

the physician. The presence of any of the following findings during the patient history, systems review, and/or scanning examination (see Chapters 3 and 4) may indicate serious pathology requiring medical referral:

- Fevers, chills, or night sweats. These signs and symptoms are almost always associated with a systemic disorder such as an infection.[11]
- Recent unexplained weight changes. An unexplained weight gain could be caused by congestive heart failure, hypothyroidism, or cancer.[12] An unexplained weight loss could be the result of a gastrointestinal disorder, hyperthyroidism, cancer, or diabetes.[12]
- Malaise or fatigue. These complaints, which can help determine the general health of the patient, may be associated with a systemic disease.[11]
- Unexplained nausea or vomiting. This is never a good symptom or sign.[11]
- Unilateral, bilateral, or quadrilateral paresthesias. The distribution of neurologic symptoms can give the clinician clues as to the structures involved. Quadrilateral paresthesia always indicates the presence of central nervous system (CNS) involvement.
- Shortness of breath. Shortness of breath can indicate a myriad of conditions. These can range from anxiety and asthma to a serious cardiac or pulmonary dysfunction.[11]
- Dizziness. The differential diagnosis of dizziness can be quite challenging. Patients often use the word "dizziness" to refer to feelings of lightheadedness, various sensations of body orientation, blurry vision, or weakness in the legs.
- Nystagmus. Nystagmus is characterized by a rhythmic movement of the eyes, with an abnormal shifting away from fixation and rapid return.[13] Failure of any one of the main control mechanisms for maintaining steady gaze fixation (the vestibuloocular reflex and a gaze-holding system) results in a disruption of steady fixation (see Chapter 3).
- Bowel or bladder dysfunction. Bowel and bladder dysfunction may indicate compromise of the cauda equina. Cauda equina syndrome is associated with compression of the spinal nerve roots that supply neurologic function

to the bladder and bowel. A massive disk herniation may cause spinal cord or cauda equina compression. One of the early signs of cauda equina compromise is the inability to urinate while sitting down, because of the increased levels of pressure. The most common sensory deficit occurs over the buttocks, posterior–superior thighs, and perianal regions (the so-called saddle anesthesia), with a sensitivity of approximately 0.75.[14] Anal sphincter tone is diminished in 60–80% of cases.[14,15] Rapid diagnosis and surgical decompression of this abnormality is essential to prevent permanent neurologic dysfunction.

- Severe pain. An insidious onset of severe pain with no specific mechanism of injury.
- Pain at night that awakens the patient from a deep sleep, usually at the same time every night, and which is unrelated to a movement. This finding may indicate the presence of a tumor.
- Painful weakness. The presence of a painful weakness almost always indicates serious pathology, including but not limited to a complete rupture of contractile tissue or nerve palsy.
- A gradual increase in the intensity of the pain. This symptom typically indicates that the condition is worsening, especially if it continues during rest.
- Radiculopathy. Neurologic symptoms associated with more than two lumbar levels or more than one cervical level. With the exception of central protrusions or a disk lesion at L4 through L5, disk protrusions typically only affect one spinal nerve root. Multiple-level involvement could suggest the presence of a tumor or other growth, or it may indicate symptom magnification. The presence or absence of objective findings should help determine the cause.

Performing a medical screen is an inherent step in making a diagnosis for the purpose of deciding whether a patient referral is warranted, but the medical screen performed by the physical therapist is not synonymous with differential diagnosis. Differential diagnosis involves the ability to quickly differentiate problems of a serious nature from those that are not, using the history and physical examination. Problems of a serious nature include, but are not limited to, visceral diseases, cancer, infections, fractures, and vascular disorders. The purpose of the medical screen is to confirm (or rule out) the need for physical therapy intervention; the appropriateness of the referral; whether there are any red-flag findings, red-flag risk factors, or clusters of red-flag signs and/or symptoms; and whether the patient's condition falls into one of the categories of conditions outlined in the Guide.[16] Boissonnault and Bass[17] noted that screening for medical disease includes communicating with a physician regarding a list or pattern of signs and symptoms that have caused concern but not to suggest the presence of a specific disease.[3]

In clinical practice, physical therapists commonly use a combination of red-flag findings, the scanning examination, and the systems review to detect medical diseases. The combined results provide the physical therapist with a method to gather and evaluate examination data, pose and solve problems, infer, hypothesize, and make clinical judgments, such as the need for a patient/client referral.[16]

Systemic dysfunction or disease can present with seemingly bizarre symptoms. These symptoms can prove to be very confusing to the inexperienced clinician. Complicating the scenario is that certain patients who are pursuing litigation can also present with equally bizarre symptoms. These patients may be subdivided into two groups:

1. Those patients with a legitimate injury and cause for litigation who genuinely want to improve.
2. Those patients who are merely motivated by the lure of the litigation settlement and who have no intention of showing signs of improvement until their case is settled. Termed malingerers, these patients are a frustrating group for clinicians to deal with, because, like the nonorganic patient type, they display exaggerated complaints of pain, tenderness, and suffering.

Malingering is defined as the intentional production of false symptoms or the exaggeration of symptoms that truly exist.[18] These symptoms may be physical or psychological but have, in common, the intention of achieving a certain goal. Any individual involved in litigation, whether the result of a motor vehicle accident, work injury, or accident, has the potential for malingering.[19] Malingering can be thought of as synonymous with faking, lying, or fraud, and it represents a frequently unrecognized and mismanaged medical diagnosis.[18] Unfortunately, due to the similarity between malingerers and nonorganic patients, this deception often causes a significant, negative response from the clinician toward malingerers and nonorganic patients alike.

It is most important that the clinician addresses any suspected deception in a structured and unemotional manner and that interactions with the patient be performed in a problem-oriented, constructive, and helpful fashion.[18]

CLINICAL PEARL

The diagnosis of malingering should be made based on the production of actions in the attainment of a known goal, without elaboration of those actions based on the negative emotional response of the clinician.[18]

With very few exceptions, patients in significant pain look and feel miserable, move extremely slowly, and present with consistent findings during the examination. In contrast, malingerers present with severe symptoms and exaggerated responses during the examination, but can often be observed to be in no apparent distress at other times. This is particularly true if the malingering patient is observed in an environment outside of the clinic.

However, it cannot be stressed enough that all patients should be given the benefit of the doubt until the clinician, with a high degree of confidence, can rule out an organic cause for the pain.

A number of clinical signs and symptoms can alert the clinician to the possibility of a patient who is malingering. These include:

- subjective complaints of paresthesia with only stocking-glove anesthesia (conditions including diabetic neuropathy and the T4 syndrome must be ruled out);
- inappropriate scoring on the Oswestry Low Back Disability Questionnaire (Table 5-2), Neck Disability Index (Table 5-3), and McGill Pain Questionnaire (see Chapter 4);
- muscle stretch reflexes inconsistent with the presenting problem or symptoms;

TABLE 5-2 Oswestry Low Back Disability Questionnaire

PLEASE READ: This questionnaire is designed to enable us to understand how much your low back pain has affected your ability to manage your everyday activities. Please answer each section by marking the ONE BOX that most applies to you. We realize that you feel that more than one statement may relate to your problem, but please just mark the one box that most closely describes your problem at this point in time.

Name:

Date:

Section 1—Pain Intensity

- □ The pain comes and goes and is very mild
- □ The pain is mild and does not vary much
- □ The pain comes and goes and is moderate
- □ The pain is moderate and does not vary much
- □ The pain comes and goes and is severe
- □ The pain is severe and does not vary much

Section 2—Personal Care

- □ I have no pain when I wash or dress
- □ I do not normally change my way of washing and dressing even though it causes some pain
- □ I have had to change the way I wash and dress because these activities increase my pain
- □ Because of pain I am unable to do some washing and dressing without help
- □ Because of pain I am unable to do most washing and dressing without help
- □ Because of pain I am unable to do any washing and dressing without help

Section 3—Lifting (Skip *if* you have not attempted lifting since the onset *of* your back pain.)

- □ Can lift heavy weights without increasing my pain
- □ Can lift heavy weights but it increases my pain
- □ Pain prevents me from lifting heavy weights off the floor
- □ Pain prevents me from lifting heavy weights off the floor but I can manage if they are conveniently positioned, e.g., on a table
- □ Pain prevents me from lifting heavy weights but I can manage light to medium weights if they are conveniently positioned
- □ I can only lift very light weight at the most

Section 4—Walking

- □ I have no pain when I walk
- □ I have some pain when I walk but it does not prevent me from walking normal distances
- □ Pain prevents me from walking long distances
- □ Pain prevents me from walking intermediate distances
- □ Pain prevents me from walking short distances
- □ Pain prevents me from walking at all

Section 5–Sitting

- □ Sitting does not cause me any pain
- □ I can sit as long as I need to, provided I have my choice of chair
- □ Pain prevents me from sitting more than 1 h
- □ Pain prevents me from sitting more than ½ h
- □ Pain prevents me from sitting more than 10 min
- □ Pain prevents me from sitting at all

Section 6—Standing

- □ Standing does not cause me any pain
- □ I have some pain when I stand but it does not increase with time
- □ Pain prevents me from standing more than 1 h
- □ Pain prevents me from standing more than ½ h
- □ Pain prevents me from standing more than 10 min
- □ Pain prevents me from standing at all

Section 7—Sleeping

- □ I have no pain when I lie in bed
- □ I have some pain when I lie in bed but it does not prevent me from sleeping well
- □ Because of pain my sleep is reduced by 25%
- □ Because of pain my sleep is reduced by 50%
- □ Because of pain my sleep is reduced by 75%
- □ Pain prevents me from sleeping at all

Section 8—Sex Life (if applicable)

- □ My sex life is normal and causes no pain
- □ My sex life is normal but increases my pain
- □ My sex life is nearly normal but is very painful
- □ My sex life is severely restricted
- □ My sex life is nearly absent because of pain
- □ Pain prevents any sex life at all

Section 9—Social Life

- □ My social life is normal and causes no pain
- □ My social life is normal but increases my pain
- □ Pain has no significant effect on my social life, apart from limiting my more energetic interests (sports, etc.)
- □ Pain has restricted my social life and I do not go out often
- □ Pain has restricted social life to my home
- □ I have no social life because of pain

Section 10—Traveling

- □ I have no pain when I travel
- □ I have some pain when I travel but none of my usual forms of travel make it worse
- □ Traveling increases my pain but has not required that I seek alternative forms of travel
- □ I have had to change the way I travel because my usual form of travel increases my pain
- □ Pain has restricted all forms of travel
- □ I can only travel while lying down

- cogwheel motion of muscles during strength testing for weakness; and
- the ability of the patient to complete a straight-leg raise in a supine position, but demonstrating difficulty in performing the equivalent range (knee extension) in a seated position.

CLINICAL PEARL

Whatever the reasoning or motivation behind the malingering patient, the success rate from the clinician's viewpoint will be low, and so it is well worth recognizing these individuals from the outset.

TABLE 5-3 Neck Disability Index

This questionnaire has been designed to give the doctor information as to how your neck pain has affected your ability to manage in everyday life. Please answer every section and mark in each section only the ONE BOX that applies to you. We realize you may consider that two of the statements in any one section relate to you, but please just mark the box that most closely describes your problem.

Section 1—Pain Intensity
- □ I have no pain at the moment
- □ The pain is very mild at the moment
- □ The pain is moderate at the moment
- □ The pain is fairly severe at the moment
- □ The pain is the worst imaginable at the moment

Section 2—Personal Care (Washing, Dressing, etc.)
- □ I can look after myself normally without causing extra pain
- □ I can look after myself normally but it causes extra pain
- □ It is painful to look after myself and I am slow and careful
- □ I need some help but manage most of my personal care
- □ I need help every day in most aspects of self-care
- □ I do not get dressed, I wash with dif culty and stay in bed

Section 3—Lifting
- □ I can lift heavy weights without extra pain
- □ I can lift heavy weights but it gives extra pain
- □ Pain prevents me from lifting heavy weights off the floor, but I can manage if they are conveniently positioned, for example, on a table
- □ Pain prevents me from lifting heavy weights, but I can manage light to medium weights if they are conveniently positioned
- □ I can lift very light weights
- □ I cannot lift or carry anything at all

Section 4—Reading
- □ I can read as much as I want to with no pain in my neck
- □ I can read as much as I want to with slight pain in my neck
- □ I can read as much as I want with moderate pain in my neck
- □ I can't read as much as I want because of moderate pain in my neck
- □ I can hardly read at all because of severe pain in my neck
- □ I cannot read at all

Section 5–Headaches
- □ I have no headaches at all
- □ I have slight headaches which come infrequently
- □ I have moderate headaches which come infrequently
- □ I have moderate headaches which come frequently
- □ I have severe headaches which come frequently
- □ I have headaches almost all the time

Section 6—Concentration
- □ I can concentrate fully when I want to with no dif culty
- □ I can concentrate fully when I want to with slight dif culty
- □ I have a fair degree of dif culty in concentrating when I want to
- □ I have a lot of dif culty in concentrating when I want to
- □ I have a great deal of dif culty in concentrating when I want to
- □ I cannot concentrate at all

Section 7—Work
- □ I can do as much work as I want to
- □ I can only do my usual work, but no more
- □ I can do most of my usual work, but no more
- □ I cannot do my usual work
- □ I can hardly do any work at all
- □ I can't do any work at all

Section 8—Driving
- □ I can drive my car without any neck pain
- □ I can drive my car as long as I want with slight pain in my neck
- □ I can drive my car as long as I want because of moderate pain in my neck
- □ I can't drive my car as long as I want because of moderate pain in my neck
- □ I can hardly drive at all because of severe pain in my neck
- □ I can't drive my car at all

Section 9—Sleeping
- □ I have no trouble sleeping
- □ My sleep is slightly disturbed (less than 1 h sleepless)
- □ My sleep is mildly disturbed (1–2 h sleepless)
- □ My sleep is moderately disturbed (2–3 h sleepless)
- □ My sleep is greatly disturbed (3–5 h sleepless)
- □ My sleep is completely disturbed (5–7 h sleepless)

Section 10—Recreation
- □ I am able to engage in all my recreation activities with no neck pain at all
- □ I am able to engage in all my recreation activities, with some pain in my neck
- □ I am able to engage in most, but not all of my usual recreation activities because of pain in my neck
- □ I am able to engage in a few of my usual recreation activities because of pain in my neck
- □ I can hardly do any recreation activities because of pain in my neck
- □ I can't do any recreation activities at all

Note: For the Oswestry Low Back Disability and the Neck Disability Index each of the 10 items is scored from 0-5. The maximum score is therefore 50. The obtained score can be multiplied by 2 to produce a percentage score. Occasionally, a respondent will not complete one question or another. The average of all other items is then added to the completed items. The amount of disability can be determined using the following:

0–4 = no disability; 5–14 = mild; 15–24 = moderate; 25–34 = severe; above 34 = complete.

In contrast to the malingering patient, is the patient that presents with psychogenic symptoms. T is type of patient tends to exhibit an exaggeration of the symptoms in the absence of objective findings. Psychogenic symptoms are common in patients with anxiety, depression, or hysteria, making it important for the clinician to determine the level of psychological stress in a patient who demonstrates symptom magnification. Waddell et al.[20] have proposed a number of characteristics of this illness behavior (Table 5-4).

TABLE 5-4 Waddell Test for Nonorganic Physical Signs

Test	Inappropriate Response
Tenderness	Superficial, nonanatomic to light touch
Simulation	
Axial loading	Axial loading on standing patient's skull produces low back pain
Rotation	Passive, simultaneous rotation of shoulders and pelvis produces low back pain
Distraction	Discrepancy between findings on supine and seated straight leg raising
Regional disturbances	
Weakness	Giving way (Cogwheel) weakness
Sensory	Nondermatomal sensory loss
Overreaction	Disproportionate facial expression, verbalization, or tremor during examination

Data from Waddell G, McCulloch JA, Kummel E, et al. Nonorganic physical signs in low-back pain. Spine. 1980;5:117–125.

TABLE 5-5 Beighton Criteria for Generalized Joint Hypermobility

Finding	Score (Points)
Forward flexion of the trunk with knees fully extended so that the palms of the hand rest flat on the floor—one point	1 point
Hyperextension of the elbows beyond 10 degrees	1 point for each elbow
Hyperextension of the knees beyond 10 degrees	1 point for each knee
Passive apposition of the thumbs to the flexor aspect of the forearm	1 point for each hand
Passive dorsiflexion of the little fingers beyond 90 degrees	1 point for each hand

Data from Beighton P, Solomon L, Soskolne CL. 'Articular Mobility in an African Population.' Ann Rheum Dis. 1973;32413–418.

INHERITED DISEASES

Ehlers–Danlos Syndrome

Ehlers–Danlos syndrome (EDS) is an inherited heterogeneous connective tissue disorder characterized by varying degrees of skin hyperextensibility, joint hypomobility, joint dislocations, musculoskeletal pain, and vascular fragility.[21] Inheritance is autosomal dominant, autosomal recessive, or X-linked. There are six major types:[21,22]

- Classical. This type is characterized by the presence of skin hyperextensibility with atrophic scars in individuals with joint hypomobility.
- Hypermobility. This type is characterized by hypermobile joints and some degree of skin hyperextensibility. This type is associated with the most debilitating musculoskeletal manifestations, and joint pain is reported by 100% of patients.
- Vascular. This type is characterized by fragile viscera and, therefore, has the most serious consequences.
- Kyphoscoliosis. This type is characterized by severe hypotonia and scoliosis.
- Arthrochalasia. This type is characterized by severe hypermobility and joint dislocations.
- Dermatosparaxis. This type is characterized by fragile, sagging, and redundant skin.

The diagnosis of this condition begins with a complete history. The typical history with EDS includes reports of joint dislocations, subluxations, pain, easy bruising, easy bleeding, or poor wound healing.[21] The physical examination includes an evaluation of range of motion. Joint hypermobility is assessed using the Beighton criteria scale (Table 5-5), where a maximum score of 9 points is possible, and a score of > 4 defines hypermobility.[23] The skin is assessed for its consistency, the presence of dystrophic scars, striae, brown discoloration (secondary to hemosiderin deposition at areas of repetitive trauma and bruising), and hyperextensibility.[21]

Physical therapy can be used to enhance musculotendinous strength, neuromuscular coordination, and joint proprioception to maximize function, minimize symptoms, and improve joint stability.[21]

INFECTIVE DISEASES

Osteomyelitis

Osteomyelitis is an acute or chronic inflammatory process of the bone and its marrow secondary to infection with pyogenic organisms or other sources of infection, such as tuberculosis, or specific fungal infections (mycotic osteomyelitis), parasitic infections (Hydatid disease), viral infections, or syphilitic infections (Charcot arthropathy). The following are the two primary categories of acute osteomyelitis:

- Hematogenous osteomyelitis. It is an infection caused by bacterial seeding from the blood. The most common site is the rapidly growing and highly vascular metaphysis of growing bones.
- Direct or contiguous inoculation. This type of osteomyelitis is caused by direct contact with the tissue and bacteria during surgery, a penetrating wound, or as a result of poor dental hygiene.

Disease states known to predispose patients to osteomyelitis include diabetes mellitus, sickle-cell disease, acquired immune deficiency syndrome, IV drug abuse, alcoholism, chronic steroid use, immunosuppression, and chronic joint disease. Clinical signs and symptoms associated with osteomyelitis include fever (approximately 50% of cases), fatigue, edema, erythema, tenderness, and reduction in the use of the extremity.

CLINICAL PEARL

The most common clinical finding in patients with osteomyelitis is a constant pain with marked tenderness over the involved bone.

NEUROLOGIC DISORDERS

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), commonly referred to as Lou Gehrig's disease, is a neurodegenerative progressive disorder that causes rapid loss of motor neurons in the brain and spinal cord, leading to paralysis and death. Diagnosis is based solely on clinical data. T e diagnosis of ALS depends upon the recognition of a characteristic constellation of symptoms and signs and supportive electrophysiological findings. For clinically definite ALS diagnosis, UMN and LMN signs in bulbar and two spinal regions or in three spinal regions are required. T e LMN weakness and muscle atrophy involves both peripheral nerve and myotomal distributions. T e clinical hallmark of ALS is the coexistence of muscle atrophy, weakness, fasciculations, and cramps (caused by LMN degeneration), together with hyperactive or inappropriately brisk muscle stretch reflexes, pyramidal tract signs, and increased muscle tone (due to corticospinal tract involvement).[24] Muscle cramps are often already present before other symptoms develop. Most patients present with asymmetrical, distal weakness of the arm or leg. T e symptoms usually progress first in the affected extremity and then gradually spread to adjacent muscle groups and remote ipsilateral or contralateral regions. Although disability is usually limited in the early stages, ALS progresses relentlessly. Most patients are ultimately unable to walk, care for themselves, speak, and swallow.[24] However, there is usually no clinical involvement of parts of the CNS other than the motor pathways.[24]

Respiratory weakness due to high cervical (phrenic nerve, C4) and thoracic spinal cord involvement is the most common cause of death in ALS, often in conjunction with aspiration pneumonia.[24]

Guillain–Barré Syndrome

Guillain–Barré syndrome (GBS) is challenging to identify because of its multitude of presentations and manifestations. GBS may be defined as a postinfectious, acute, paralytic peripheral neuropathy. It can affect any age group although there is a peak incidence in young adults. GBS appears to be an inflammatory or immune-mediated condition.

T e majority of patients describe an antecedent febrile illness. Upper respiratory infections are seen in 50% of cases and are caused by a variety of viruses. T e illness is usually an acute respiratory or gastrointestinal condition that lasts for several days and then resolves. T is is followed in 1–2 weeks by the development of a progressive ascending weakness or paralysis, which is usually symmetric. T e progression of the weakness or paralysis can be gradual (1–3 weeks) or rapid (1–2 days). T e patient reports difficulty or instability with walking, arising from a chair, and ascending or descending stairs. Associated signs and symptoms include cranial nerve involvement (facial weakness), paresthesias, sensory deficits, difficulty in breathing, diminished muscle stretch reflexes, autonomic dysfunction (tachycardia and vasomotor symptoms), oropharyngeal weakness, and ocular involvement.[25]

T e differential diagnosis of GBS is quite large and includes the spectrum of illnesses causing acute or subacute paralysis. T ese include spinal cord compression (myelopathy), UMN disorders, poliomyelitis, transverse myelitis, polyneuropathy, SLE, polyarteritis nodosa, myasthenia gravis, and sarcoidosis.[25]

All patients with suspected GBS should be hospitalized for vigilant monitoring because of the high risk of respiratory failure, which occurs in approximately one-third of patients.[25]

Syringomyelia

Syringomyelia is a disease that produces fluid-containing cysts (syrinx) within the spinal cord, often associated with stenosis of the foramen magnum. T e syrinx can occur within the spinal cord (syringomyelia) or brain stem (syringobulbia). Syringomyelia has been found in association with various disorders, including spinal column or brain stem abnormalities (scoliosis, Klippel–Feil syndrome, Chiari I malformation), intramedullary tumors, and traumatic degeneration of the spinal cord. Chiari I malformation is the most common condition in patients with syringomyelia.

Painful dysesthesias, which have been described variously as burning pain, pins-and-needles sensations, and stretching or pressure of the skin, occur in up to 40% of patients with syringomyelia.[26] T e pain tends to arise in a dermatomal pattern and is accompanied, in most cases, by hyperesthesia.

Radiologic features that suggest syringomyelia include an increase in the width and depth of the cervical canal, bony abnormalities at the craniovertebral junction, diastematomyelia, and occipitalization of the atlas.

INFLAMMATORY DISORDERS

Perhaps, the most common inflammatory disorders of the musculoskeletal system are the rheumatoid diseases.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) can be defined as a chronic, progressive, systemic, inflammatory disease of connective tissue, characterized by spontaneous remissions and exacerbations (flare-ups). It is the second most common rheumatic disease after osteoarthritis (OA), but it is the most destructive to synovial joints. Unlike OA, RA involves primary tissue inflammation rather than joint degeneration. Although most individuals who develop RA do so in their early-to-middle adulthood, some experience it either earlier (Juvenile RA—see Chapter 30) or later.

Although the exact etiology of RA is unclear, it is considered one of many autoimmune disorders. Abnormal immunoglobulin (Ig) G and IgM antibodies develop in response to IgG antigens, to form circulating immune complexes. T ese complexes lodge in connective tissue, especially synovium,

and create an inflammatory response. Inflammatory mediators, including cytokines (e.g., tumor necrosis factor), chemokines, and proteases, activate and attract neutrophils and other inflammatory cells. T e synovium thickens, fluid accumulates in the joint space, and a pannus forms, eroding joint cartilage and bone. Bony ankylosis, calcifications, and loss of bone density follow.

RA typically begins in the joints of the arm or hand. T e individual complains of joint stiffness lasting longer than 30 minutes on awakening, pain, swelling, and heat (synovitis). Unlike with OA, the distal interphalangeal joints of the fingers usually are not involved in RA.

T e signs and symptoms of RA vary among individuals, depending on the rate of progress of the disease. A complete musculoskeletal examination helps diagnose the disease. Clinical manifestations include both joint involvement and systemic problems; some are associated with the early stages of RA, whereas others are seen later in advanced disease.

Complaints of fatigue, anorexia, low-grade fever, and mild weight loss are commonly associated with RA. As the disease worsens, joints become deformed, and secondary osteoporosis (see "Metabolic Disease") can result in fractures, especially in older adults. Hand and finger deformities are typical in the advanced stages of the disease. Palpable subcutaneous nodules, often appearing on the ulnar surface of the arm, are associated with a severe, destructive disease pattern. As the disease progresses over years, systemic manifestations increase and potentially life-threatening organ involvement begins. Cardiac problems, such as pericarditis and myocarditis, and respiratory complications, such as pleurisy, pulmonary fibrosis, and pneumonitis, are common. RA can affect body image, self-esteem, and sexuality in older adults. T e person with RA loses control over body changes, is chronically fatigued, and eventually may lose independence in activities of daily living (ADLs). As a reaction to these losses, individuals may display the phases of the grieving process, such as anger or denial. Some people become depressed, feeling helpless and hopeless because no cure presently exists for the condition. Chronic pain and suffering interfere with quality of life.

T e physical therapy examination of the patient with RA involves:

- measurement of independence with functional activities;
- measurement of joint inflammation;
- measurement of joint range of motion; and
- determination of limiting factors including pain, weakness, and fatigue.

Because RA affects multiple body systems, lessens the quality of life, and affects functional ability, the approach to managing the patient with this condition must be interdisciplinary. Management typically includes drug therapy, physical and/or occupational therapy, and recreational therapy. Some clients also need psychologic counseling to help cope with the disease.

Rest and energy conservation are crucial for managing RA (Table 5-6). Pacing activities, obtaining assistance, and allowing rest periods help conserve energy. Positioning joints in their optimal functional position help to prevent deformities. Ambulatory and adaptive devices can help individuals maintain independence in ADLs. For example, a long-handled shoehorn may help in putting on shoes. Velcro attachments on shoes often are a better option than laces. Styrofoam or paper cups may collapse or bend, whereas a hard plastic or china cup may be easier to handle. T e clinician should also review principles of joint protection with the patient and family and provide adaptive equipment as needed to perform ADLs independently.

Strengthening exercises and other pain-relief measures, such as the use of ice and heat, can be prescribed. Ice application is used for hot, inflamed joints. Heat is used for painful joints that are not acutely inflamed. Showers, hot packs (not too heavy), and paraffin dips are ideal for heat application.

Some RA patients have associated syndromes. Two such syndromes are Sjogren and Felty syndromes. Sjogren syndrome is characterized by dryness of the eyes (keratoconjunctivitis), mouth (xerostomia), and other mucous membranes. Felty syndrome is characterized by leukopenia and hepatosplenomegaly, often leading to recurrent infections. It encompasses a diverse group of pathogenic mechanisms in RA, all of which result in decreased levels of circulating neutrophils.

No single test or group of laboratory tests can confirm a diagnosis of RA, but they can support the findings from the patient's history and the physical findings. A number of immunologic tests, such as the rheumatoid factor and antinuclear antibody titer, are available to aid diagnosis. Normal values differ, depending on the precise laboratory technique used.

Gout

Gout is the most common form of inflammatory arthritis in men older than 40 years and appears to be on the increase.[27] In the United States, the self-reported prevalence of gout almost trebled in men aged 45–64 years between 1969 and 1981.[28] T e rising prevalence of gout is thought to stem from dietary changes (high-purine diet and habitual alcohol ingestion), obesity, environmental factors, increasing longevity, subclinical renal impairment, and the increased use of drugs causing hyperuricemia, particularly diuretics.[29] High blood levels of uric acid lead to inflammation, joint swelling, and severe pain. Symptoms are caused by deposits of sodium urate or calcium pyrophosphate crystals in joints and periarticular tissues.

Onset is usually sudden, often during the night or early morning. T e classic finding of gouty arthritis (gout) is warmth, swelling, cutaneous erythema, and severe pain of the first metatarsophalangeal (MTP) joint (podagra). However, other joints may also be involved. T ese include the shoulder, knee, wrist, ankle, elbow, or fingers. Fever, chills, and malaise accompany an episode of gout. As the condition becomes chronic, the patient may report morning stiffness and joint deformity, progressive loss of function, or disability. Chronic gouty nephropathy may occur.

Differential diagnosis includes cellulitis, septic arthritis, RA, bursitis related to a bunion, sarcoidosis, multiple myeloma, and hyperparathyroidism.

Treatment is geared toward pharmacologic control of serum uric acid levels.

TABLE 5-6 Intervention Strategies for Rheumatoid Arthritis

Objective	Intervention	Example
Pain control	Therapeutic heat to decrease rigidity of joints, increase the flexibility of fibrous tissue, and decrease pain and muscle spasm Massage, usually applied with heat treatment and before stretching, can be used to relieve pain and prevent adhesions Therapeutic cold can be used for analgesic and vasoconstriction purposes in inflamed joints during the acute period. Care must be taken to avoid adverse effects	Heat applications: Aquatic therapy Instructions on the wearing of warm pajamas, sleeping bag, and electric blanket Paraffin for hands Ultrasound Heating pads—moist heat better than dry heat
Minimizing the effects of inflammation	Joint protection strategies Splinting Rest from abuse Body mechanics education	As needed—balance rest with activity by using splinting (articular resting) Resting splints are used to rest the joint in the appropriate position in the acute period Dynamic splints are used to exert adequate force that the tissue can tolerate and provide sufficient joint volume Functional splints are used to protect the joint in the course of activity Stabilizer splints are used in cases of permanent contractures. Gradual casting can be used to apply a stretch to the contracture
Preventing limitation and restoring ROM in affected joints	Range-of-motion and stretching exercises	Acute stage: passive and active assisted to avoid joint compression Subacute/chronic stage: active exercises, passive stretching or contract–relax techniques
Maintaining and improving strength	Resistive exercises Endurance exercises Electrical stimulation	Acute and subacute stages: isometric exercises progressing cautiously to resistive Subacute/chronic stages: strengthening exercises that avoid substitutions and minimize instability, atrophy, deformity, pain, and injury Chronic stage: judicious use of concentric exercise Provision of encouragement to exercise—fun and recreational activities of moderate intensity and 30 min duration per day Swimming Tai Chi Short-term electrical stimulation is useful in cases of excessive muscle atrophy and in those who cannot exercise
Ensuring normal growth and development	Posture and positioning Mobility and assistive devices	To maintain joint range of motion, patients should spend 20 min/d in prone to stretch the hip flexors and quadriceps; assess leg length discrepancy in standing and avoid scoliosis Extended comb handles, thicker spoons, shoehorns Clothes with easy openings and/or Velcro

Ankylosing Spondylitis

Ankylosing spondylitis (AS, also known as Bekhterev or Marie–Strümpell disease) is a chronic rheumatoid disorder that affects 1–3 per 1,000 people. The patient is usually between 15 and 40 years. There is a 10–20% risk that offspring of patients with the disease will later develop it.[30] Although males are affected more frequently than females, mild courses of AS are more common in the latter.[31]

A human leukocyte antigen (HLA) haplotype association (HLA-B27) has been found with AS and remains one of the strongest known associations of disease with HLA-B27, but other diseases are also associated with the antigen. C-reactive

protein has only 53% sensitivity and 70% specificity in spondyloarthropathies (X20).[32] T oracic involvement in AS occurs almost universally. T e disease includes involvement of the anterior longitudinal ligament and ossification of the intervertebral disk, thoracic zygapophyseal joints, costovertebral joints, and manubriosternal joint. T is multijoint involvement of the thoracic spine makes the checking of chest expansion measurements a required test in this region.

In time, AS progresses to involve the whole spine and results in spinal deformities, including flattening of the lumbar lordosis, kyphosis of the thoracic spine, and hyperextension of the cervical spine. T ese changes, in turn, result in flexion contractures of the hips and knees, with significant morbidity and disability.[31]

T e most characteristic feature of the back pain associated with AS is pain at night.[33] Patients often awaken in the early morning (between 2 and 5 am) with back pain and stiffness and usually either take a shower or exercise before returning to sleep.[31] Back ache during the day is typically intermittent, irrespective of exertion or rest.[31]

Calin et al.[34] describe five screening questions for AS:

1. Is there morning stiffness?
2. Is there an improvement in discomfort with exercise?
3. Was the onset of back pain before age 40 years?
4. Did the problem begin slowly?
5. Has the pain persisted for at least 3 months?

Using at least four positive answers to define a "positive" result, the sensitivity of these questions was 0.95, and specificity was 0.85.[34]

Peripheral arthritis is uncommon in AS, but when it occurs, it is usually late in the course of the condition.[35] Peripheral arthritis developing early in the course of the disease is a predictor of disease progression.[36] T e arthritis usually occurs in the lower extremities in an asymmetric distribution, with the involvement of the "axial" joints, including shoulders and hips, more common than involvement of more distal joints.[31,37]

T e inspection usually reveals a flat lumbar spine and gross limitation of extension, and side bending in both directions (capsular pattern). In addition, the glides of the costotransverse joints and distraction of the sternoclavicular joints are decreased. Mobility loss tends to be bilateral and symmetric. T ere is loss of spinal elongation on flexion in the McRae's modification of the Schober test,[38,39] although this can occur in patients with chronic low back pain (LBP), or spinal tumors, and is thus not specific for inflammatory spondylopathies.[40] T e McRae's modified Schober test is performed with the patient standing upright. T e clinician marks the spinous process of L5 with a pen, and then creates a mark 10 cm above the L5 and 5 cm below L5 in the midline. T e patient is then asked to bend forward maximally, and the distance between the upper and lower marks is measured. Patients with normal mobility of the spine have an increase of at least 5 cm in the measured distance from upright (15 cm) to maximal flexion (should be >20 cm).[38,39] T e patient may relate a history of costochondritis, and, upon examination, rib springing may give a hard end-feel. Basal rib expansion often is decreased with the chest expansion test. T e chest expansion test is performed with the patient's hands elevated and folded behind the head. T e clinician takes a circumferential measurement of the patient's chest at the level of the fourth intercostal space, or just below the breast in females. Chest circumference is measured after a maximal forced expiration and again after a maximal inspiration. T e expansion should be >5 cm. Expansion of <2.5 cm is abnormal.[38,39]

As the disease progresses, the pain and stiffness can spread up the entire spine, pulling it into forward flexion, so that the patient adopts the typical stooped-over position. T e patient gazes downward, the entire back is rounded, the hips and knees are semiflexed, and the arms cannot be raised beyond a limited amount at the shoulders.[41]

Longitudinal studies in patients with AS have revealed that deformities and disability occur within the first 10 years of disease.[36] Most of the loss of function occurs during the first 10 years and correlates significantly with the occurrence of peripheral arthritis, radiographic changes of AS in the spine, and the development of the so-called bamboo spine.

An exercise program is particularly important for these patients to maintain functional spinal outcomes.[42] T e goal of exercise therapy is to maintain the mobility of the spine and involved joints for as long as possible and to prevent the spine from stiffening in an unacceptable kyphotic position. A strict regimen of daily exercises, which include positioning, spinal extension exercises, breathing exercises, and exercises for the peripheral joints, must be followed. Several times a day, patients should lie prone for 5 minutes, and they should be encouraged to sleep prone or supine on a hard mattress and avoid the side-lying position. Swimming is the best routine sport.

Psoriatic Arthritis

Psoriatic arthritis, which is an inflammatory form of arthritis associated with a chronic skin condition called psoriasis, affects men and women with equal frequency, with its peak onset in the fourth decade of life, although it may occur in children and in older adults.[37] Psoriatic arthritis can manifest in one of a number of patterns, including distal joint disease (affecting the distal interphalangeal joints of the hands and feet), asymmetric oligoarthritis, polyarthritis (which tends to be asymmetric in half the cases), and arthritis mutilans (a severe destructive form of arthritis and a spondyloarthropathy that occurs in 40% of patients, but most commonly in the presence of one of the peripheral patterns).[37] Patients with psoriatic arthritis have less tenderness over both affected joints and tender points than patients with the classic RA.[43]

T e spondyloarthropathy of psoriatic arthritis may be distinguished from AS by the pattern of the sacroiliitis.[44] Whereas sacroiliitis in AS tends to be symmetric, affecting both sacroiliac joints to the same degree, it tends to be asymmetric in psoriatic arthritis,[37] and patients with psoriatic arthritis do not have as severe a spondyloarthropathy as patients with AS.[30]

Another articular feature of psoriatic arthritis is the presence of dactylitis, tenosynovitis (often digital, in flexor and extensor tendons and in the Achilles tendon), and enthesitis.[44] T e presence of erosive disease in the distal interphalangeal joints is typical.[44]

Nail lesions occur in more than 80% of the patients with psoriatic arthritis and have been found to be the only clinical feature distinguishing patients with psoriatic arthritis from

patients with uncomplicated psoriasis.[45] Other extra-articular features include iritis, urethritis, and cardiac impairments similar to those seen in AS, although less frequently.[44]

Treatment for psoriatic arthritis is directed at reducing and controlling inflammation, with milder cases of psoriatic arthritis often being treated with NSAIDs alone. More severe cases are treated using disease-modifying antirheumatic drugs or biological response modifiers to help prevent irreversible joint destruction and disability.

NEOPLASTIC DISEASE

Benign Tumors: Osteoblastoma and Osteoid Osteoma

Osteoblastoma and osteoid osteoma are benign bone-forming tumors with similar clinical findings.

- Osteoblastoma is a solitary bone neoplasm. It is most common in the vertebrae of children and young adults. Short and flat bones are more commonly affected than the long bones (76.5% vs. 23.5%).[46] In the vertebrae, the body is only rarely affected primarily; usually, it is involved only secondarily by tumors extending from other segments of the same or the nearest vertebra.[46]
- Osteoid osteoma is a benign osteoblastic tumor of unknown etiology. It occurs most often in the long bones, although the spine is the location of 10% of all osteoid osteomas.[47]
- Painful scoliosis is a well-recognized presentation of spinal osteoid osteoma and osteoblastoma and is thought to be caused by pain-provoked muscle spasm on the side of the lesion.[46]

Malignant Tumors

Metastatic disease of the spine is the most frequent neoplastic disorder of the axial skeleton. Malignant tumors can be primary or secondary.

1. Primary. Primary tumors include the following:
   a. Multiple myeloma. Myeloma is a plasma cell tumor. It is the most common malignant primary bone tumor. Early in its course, it can easily be overlooked as the cause of back pain. Common presentations of myeloma include bone pain, recurrent or persistent infection, anemia, renal impairment, or a combination of these. Some patients are asymptomatic. Presenting features, which require urgent specialist referral, include:
      (1) persistent, unexplained backache associated with loss of height and osteoporosis;
      (2) symptoms suggestive of spinal cord or nerve root compression.
   b. Chordoma. Chordomas are rare tumors of notochordal origin, representing approximately 5% of all malignant tumors of bone.[48] T ey typically are slow-growing, locally aggressive tumors. Chordomas usually are diagnosed in patients with pain or symptoms caused by compression of the surrounding structures. T e clinical presentation initially may be mild in nature, leading to considerable delay in seeking medical attention. Vertebral chordomas involve the spinal cord and nerve roots progressively, resulting in pain, numbness, motor weakness, and, eventually, paralysis.
   c. Osteosarcoma. Osteosarcoma is a relatively uncommon malignancy. T e peak incidence of osteosarcoma occurs in the second decade, with an additional smaller peak after the age of 50 years.[49] T ese tumors typically arise in the metaphyseal regions of long bones, with the rib, distal femur, proximal tibia, and proximal humerus representing the four most common sites. T e metaphysis of the vertebra is also predilected.[46] Osteosarcomas frequently penetrate and destroy the cortex of the bone and extend into the surrounding soft tissues.

      T e initial clinical symptom of a malignant tumor is frequently pain in the affected area, which may also be associated with localized soft-tissue swelling or limitation of motion in the adjacent joint.[50]
2. Secondary. Metastases to the spine most commonly arise from breast and lung cancer and from lymphoma.[51,52] Lesions associated with the metastasis of primary tumors from the breast, prostate, kidney, and thyroid and lesions associated with lymphoma and myeloma account for 75% of all spinal metastases.[51,52] When lung cancer is included, the percentage is greater than 90%.[53] T e clinical findings for a secondary spinal tumor are similar to those of a primary tumor.

METABOLIC DISEASE

Osteoporosis

More than 10 million adults in the United States have osteoporosis, 80% of which are women, but almost 3 million males are affected as well.[54] Osteoporosis or osteopenia can result from an insufficient bone formation (low bone mass), excessive bone resorption, or a combination of these two phenomena (see Chapter 1). T e result is decreased bone mineral density (BMD) and a progressive loss of trabecular connectivity that is irreversible and diminishes the bone quality in terms of its mechanical resistance to deformity underloading.[55] In addition to the loss of bone mass, there is also narrowing of the bone shaft and widening of the medullary canal. Osteoporosis causes pathological (fragility) fractures of the vertebrae and fractures of other bones such as the ribs, proximal humerus, distal forearm, proximal femur (hip), and pelvis. However, with appropriate care, osteoporosis, fractures, and resultant disability can be prevented.

Osteoporosis has been classified into two broad general types: type 1 (postmenopausal) and type 2 (involutional).[56] Type 2 osteoporosis generally is seen in the older age population and has been referred to as senile osteoporosis.[56]

CLINICAL PEARL

Women are more prone to develop osteoporosis because of the contribution of the loss of estrogen to accelerated bone loss in the postmenopausal female population.

It has been estimated that 15% of postmenopausal Caucasian women in the United States and 35% of women older than 65 years have osteoporosis.[56] Further, 50% of women older than 50 years have osteopenia of the femoral neck, and 20% have osteoporosis at this site.[57] The incidence of hip fracture rises dramatically with age to 3.4 per 100 in the 65–74-year-old age group and 9.4 per 100 in those older than 85 years.[55] The presence of a significant vertebral fracture (see "Vertebral Fracture") is associated with increased mortality.[58] Patients with these fragility fractures have a relative risk of death that is nine times greater than healthy counterparts.[59] Approximately 20% of women with vertebral fractures have another fracture of a different bone within a year.[58]

Numerous risk factors have been identified as contributing to the likelihood that an individual will develop bone loss. Genetics plays a major role, and female gender, positive family history, and racial characteristics associated with Caucasian, Asian, or Hispanic background increase the risk of osteoporosis.[60] Low body weight (less than 85% ideal body weight, or less than 127 lb) has also been correlated with the development of osteoporosis.[56]

Modifiable risk factors associated with osteoporosis include early or iatrogenic menopause, pregnancy at an early age, smoking, sedentary lifestyle, alcoholism, low body fat, low calcium intake, high caffeine intake, prolonged bed rest, and anorexia.[56,61,62] Medications such as corticosteroids, some diuretics, and thyroid hormone preparations can also increase bone loss and the risk of osteoporosis significantly.[63,64]

The populations most vulnerable to developing osteoporosis include the following:[65]

- Women aged 65 years and older.
- Postmenopausal women younger than 65 years with the risk factors for fracture, such as low body weight, prior fracture, or high-risk medication use.
- Women during the menopausal transition with clinical risk factors for fracture.
- Men aged 70 years and older.
- Men younger than 70 years with clinical risk factors for fracture.
- Adults with a fragility fracture.
- Adults with the disease or condition, or who are taking medications associated with low bone mass or bone loss.

In addition to risk factors for the disease, there are independent risk factors for fractures, including use of medications in elderly patients with adverse CNS side effects, balance problems, poor muscle strength, visual impairment, home environmental factors such as stairs, and medical comorbidities that increase the likelihood of falls.[55,61]

Diagnosis of osteoporosis defined in terms of BMD using dual x-ray absorptiometry (DXA) consists of the T-score ≤2.5 standard deviations below the young sex-matched mean as established by the World Health Organization (WHO). However, BMD alone has low sensitivity, so that the majority of osteoporotic fractures will occur in individuals with BMD values above the osteoporosis threshold, typically in the osteopenic range (T-score of less than –1 and greater than –2.5 SD). As a result, the initial diagnosis of osteoporosis often occurs following an osteoporotic, or fragility, fracture. Although, a physical therapist may not be able to order BMD testing, a DXA can be recommended to the primary care physician if the therapist suspects he or she is treating a patient with an undiagnosed low BMD. It is important to be able to identify this patient type so that safer choices can be made with regard to the types of intervention. At present, the only diagnostic tool available that is within the scope of practice of the physical therapist is the identification of those risk factors previously mentioned,[66] or through the use of tools developed for the medical community. One such tool is the FRAX, a fracture risk assessment tool, which is openly available at the University of Sheffield website (http://www.shef.ac.uk/FRAX).

The specific effects of physical activity on bone health have been investigated in several studies.[62,63,66–70] The conclusions drawn from these studies suggest that there is:

- strong evidence that physical activity early in life contributes to higher peak bone mass;[69]
- some evidence that resistance and high-impact exercise are likely the most beneficial for prevention;
- some evidence that high-intensity aerobic exercise (70–90% of maximal heart rate) may reverse or attenuate BMD loss; and
- some evidence that high-load low-repetition routines are more effective at increasing BMD than low-load high-repetition regimens.

Exercise during the middle years of life has numerous health benefits, but there are few studies on the effects of exercise on BMD.[69] Exercise during the later years, in the presence of adequate calcium and vitamin D intake, probably has a modest effect on slowing the decline in BMD, but it is clear that exercise late in life, even beyond age 90 years, can increase muscle mass and strength twofold or more in frail persons.[69]

Randomized clinical trials of exercise have been shown to reduce the risk of falls by approximately 25%,[71,72] but there is no experimental evidence that exercise affects fracture rates.[69] It also is possible that regular exercisers might fall differently, thereby reducing the risk of fracture caused by falls, but this hypothesis requires testing.[69]

The availability of new, effective drug therapies in the past decade has revolutionized the intervention for osteoporosis, and it is important that clinicians at least be aware of the intervention options. Many hormonal and hormone replacement therapies are also available. Experimental evidence indicates that slow-release sodium fluoride and low-dose parathyroid hormone are capable of increasing bone formation and thus preventing bone loss in women who are estrogen deficient.[73]

Diagnostic tools have focused on bone density. New minimally invasive procedures are finding a place among interventions for patients with osteoporotic fractures. For example, the use of injected hydroxyapatite that cements into distal radius fractures for percutaneous stabilization has shown efficacy as an intervention for patients with this type of fracture.[74]

CLINICAL PEARL

It should be the responsibility of the healthcare providers to educate their young female patients about the benefits of sufficient exercise and the recommended dietary calcium intake to build healthy bone.

What is known about prevention is that a key factor in the development of osteoporosis in later life is a deficient level of peak bone mass at physical maturity,[75] and that physical activity and calcium intake play substantial roles in the development of bone mass during these developmental years.[76]

Osteomalacia

Osteomalacia is the least common of the traditional forms of the metabolic bone diseases. It is characterized by impairment of bone mineralization, leading to an accumulation of unmineralized matrix or osteoid in the skeleton.[77] Among the causes of osteomalacia, the most important are disorders of vitamin D availability, synthesis, or action.[78]

Clinically, osteomalacia is manifested by progressive generalized bone pain, muscle weakness, hypocalcemia, and pseudofractures. In its late stages, osteomalacia is characterized by a waddling gait.[79] Osteomalacia is believed to be rare in the United States because of the routine fortification of milk and a few other foods with vitamin D. However, patients with various gastrointestinal diseases are known to be at risk.[79]

Paget Disease

Paget disease (osteitis deformans) of the bone is an osteometabolic disorder. T e disease is described as a focal disorder of accelerated skeletal remodeling that may affect one or more bones. T is remodeling produces a slowly progressive enlargement and deformity of multiple bones.

Despite intensive studies and widespread interest, the etiology of Paget disease remains obscure. T e pathologic process consists of three phases:

- Phase I. An osteolytic phase characterized by prominent bone resorption and hypervascularization.
- Phase II. A sclerotic phase, reflecting previously increased bone formation but currently decreased cellular activity and vascularity.
- Phase III. A mixed phase, with both active bone resorption and compensatory bone formation, resulting in a disorganized skeletal architecture. T e bones become sponge-like, weakened and deformed.

Complications include pathologic fractures, delayed union, progressive skeletal deformities, chronic bone pain, neurologic compromise of the peripheral and CNS with facial or ocular nerve compression and spinal stenosis, and pagetic arthritis.

Involvement of the lumbar spine may produce symptoms of clinical spinal stenosis. Involvement of the cervical and thoracic spine may predispose patients to myelopathy.

Although this disorder may be asymptomatic, when symptoms do occur, they occur insidiously. Paget disease is managed either medically or surgically.

GENERALIZED BODY PAIN

When discussing the issue of differential diagnosis with generalized body pain, it is well worth mentioning two conditions: fibromyalgia (FM) and myofascial pain syndrome (MPS). Although these conditions share several features, they are distinct entities whose physical findings and interventions differ significantly.[80]

Fibromyalgia

Primary FM is a common form of nonneuropathic chronic neuromuscular pain, which is poorly understood. FM is characterized by widespread and generalized body aches of at least 3 months duration, which can cause pain or paresthesias, or both, in a nonradicular pattern.[81–83] FM is not a disease, but rather a syndrome with a common set of characteristic symptoms, including constitutional symptoms of fatigue, nonrestorative sleep, and the presence of a defined number of tender points.[84]

T e relationship of tender points to FM has been the focus of much research,[85–88] and, according to the criteria of the American College of Rheumatology, a positive tender point is defined as a point that becomes painful (not merely tender) when approximately 4 kg of pressure is applied.[89] A positive tender point count of 11 or more of 18 standardized sites, when present in combination with the history of widespread pain, yields a sensitivity of 88.4% and a specificity of 81.1% in the diagnosis of FM.

T e pathology and pathophysiology of the tender point remain elusive. Normally, small C-fibers in the skin are activated by chemical, mechanical, or thermal stimuli (see Chapter 3). T e impulses are sent up the spinothalamic tract to the brain where they are processed. In FM, the constant bombardment of noxious inputs to C-fibers leads to central sensitization (allodynia).[90] As a consequence, large, myelinated A-delta fibers begin carrying some signals normally transmitted by the C-fibers. Central sensitization further expands to involve autonomically mediated B-fibers. It has also been hypothesized that the myalgias may result from neurohumoral changes rather than local metabolic or pathophysiologic features.[91] Prevalence of FM is about 10–20 times greater in women than in men, although the reason for this is unknown. Sleep studies show that stage 4 sleep is the most interrupted; however, sleep disturbances are common in the general population and thus not endemic to FM patients.[92]

T e medical intervention for FM includes the prescription of drugs that influence chemicals in the ascending and descending pain tracts, chemicals that influence cerebral function, nonsteroidals, and muscle relaxants.[90] A multifaceted physical therapy approach involving cardiovascular fitness training, spray and stretch, strength and endurance training, massage, and electrotherapeutic and physical modalities, including microstimulation, may help to reduce some of the disease's consequences.[93]

Myofascial Pain Syndromes

MPSs are closely associated with tender areas that have come to be known as myofascial trigger points (see Chapter 10).[83,94–97] Dysfunctional joints are also associated with trigger points and tender attachment points.[98] MPS often manifests with symptoms suggestive of neurologic disorders, including diffuse pain and tenderness, headache, vertigo, visual disturbances, paresthesias, incoordination, and referred pain that often can be

clarified by the musculoskeletal and neurologic examination.[99] MPS should always be considered as a diagnosis in the presence of persistent pain.[96,100–104]

DIFFERENTIAL DIAGNOSIS WITHIN SPECIFIC REGIONS

T e intent of the following sections is to provide the physical therapist with potential diagnoses based on the location of symptoms. It was Grieve who coined the term masqueraders to indicate those conditions that may not be musculoskeletal in origin and that may require skilled intervention elsewhere. To aid the clinician in the detection of these masqueraders, both neuromusculoskeletal disorders, and serious underlying medical conditions are included in the following sections, according to the various body regions. Although not inclusive, these diagnoses should provide the clinician with a list of possibilities to encourage divergent thinking during each examination.

CAUSES OF HEAD, FACE, EYE, AND TEMPOROMANDIBULAR JOINT SYMPTOMS

T e causes of head, face, and temporomandibular joint symptoms include, but are not limited to, those listed in Table 5-7.

Trauma

Head pain is common following trauma to the head and neck. T e traumatic episodes that do not produce profound neurologic damage are termed concussions (contusions) (see Chapter 3). A concussion is not always associated with some degree of loss of consciousness and typically involves a sudden acceleration (or deceleration) force, which causes the brain to move suddenly within the skull. For a loss of consciousness to occur, these forces must disconnect the alerting system in the brain stem, resulting in a temporary lack of activity in the reticular formation, probably secondary to hypoxia resulting from induced ischemia.[105] It is estimated that a velocity of only 20 mph can cause concussion from inertial loading (no head impact) in most healthy adults (see Chapter 3).[106]

TABLE 5-7 Potential Causes of Head and Facial Pain

Osteoarthritis
Rheumatoid arthritis and related rheumatoid arthritis variants (dermatomyositis and temporal arteritis)
Lyme disease
Fibromyalgia
Arteriovenous malformation
Intracranial infection (meningitis)
Cerebrovascular disease
Tumor
Encephalitis
Systemic infections
Multiple sclerosis
Miscellaneous

Headache

Headaches are a common complaint. Approximately 85–95% of the adult population in the United States experience a headache during a given 1-year period,[107] although only 1.7–2.5% of patients visit the emergency department with a complaint of a headache,[108] with most choosing to treat themselves with over-the-counter medications.[109,110]

Headaches, in general, can be grouped into two main divisions: primary or secondary, and benign or nonbenign.

- Primary headaches, as defined by the International Headache Society,[111] are the result of some underlying structural abnormality or disease process, and include migraine, cluster, tension type, and other primary causes such as cervical musculoskeletal dysfunction.
- Secondary headaches are the result of an underlying pathologic process including angina pectoris, and myocardial infarction.[112]

Benign headaches. T e origin of benign headaches can vary. Common causes include neurologic (trigeminal neuralgia [TN], cervical neuralgia, atypical facial pain, posttraumatic, and postlumbar puncture), musculoskeletal (tension headache, occipital headache, and cervicogenic headache), and vascular (migraine, cluster, and hypertension).[111] Other headaches, such as chronic daily and rebound, are thought to be related to a combination of neurologic and musculoskeletal causes (see later). OA, RA, and related RA variants (dermatomyositis and temporal arteritis, and systemic lupus erythematosus), Lyme disease, FM, and complex regional pain syndrome (CRPS) (formerly known as reflex sympathetic dystrophy [RSD]—see Chapter 18) have also been indicated as additional sources of head and neck pain.[113] Diseases of the sinus (maxillary sinusitis, frontal sinusitis, or malignancy), diseases of the eye (inflammation of the iris and glaucoma), and infection and inflammation of the ear apparatus may also cause headaches.[111] Sensitivity to tapping over the sinuses is fairly diagnostic for sinusitis, whereas diminished vision is characteristic of glaucoma.[111]

- Nonbenign. Medical experts have created the acronym SNOOP for diagnosis of red flags in those presenting with headaches who need immediate attention:[114]

  S—Systemic (e.g., fever, chills, night sweats);
  N—Neurological (e.g., abnormal neurological findings);
  O—Onset sudden (headache peaks with in one minute of onset)
  O—Onset after the age of 50 years
  P—Pattern change (increasing in frequency, associated with Valsalva maneuver, aggravated by postures that change cranial or high pressure).

Migraine Headache

Migraines are equally distributed among the sexes in childhood, but two out of every three adults with migraine headaches are

women.[113] According to the International Headache Society,[111] there are two types of migraine headaches: A migraine without aura (common migraine), and migraine with aura. T e migraine without aura type involves episodes lasting 4–72 hours, and symptoms that are typically unilateral and with a pulsating quality of moderate or severe intensity, which is thought to result from a change in the blood vessels of the brain. T is type of headache is aggravated by routine physical activity and is associated with nausea, photophobia, and phonophobia.

A migraine with aura type is characterized by reversible aura symptoms, which typically develop gradually over more than 4 minutes but last no longer than 60 minutes.[111]

It is thought that migraine headaches are a different expression of a common underlying problem.[113] As with cluster headaches (see below), it has long been recognized that migraine headaches are exacerbated by disturbances or irregularities in sleep patterns.[112]

Cluster Headache

Cluster headaches are severe, unilateral, retro-orbital headaches. T is type of headache is more common in men than in women. As their name suggests, cluster headaches occur in groups or clusters, and they tend to occur at predictable times of day. Cluster headaches may also develop because of specific sleep disorders, such as sleep apnea, bruxism, or sleep deprivation.[112]

Cluster headaches are often accompanied by nasal congestion, eyelid edema, rhinorrhea, miosis, lacrimation, and ptosis (drooping eyelid) on the symptomatic side.[112] T ese headaches can last from 15 to 180 minutes if untreated.[111]

Unlike migraine sufferers, who feel obliged to lie down during a severe headache, individuals with cluster headaches feel better during a headache by remaining in an erect posture and moving about.[113] Cluster headaches are thought to result from vasodilation in branches of the external carotid artery, because they often are triggered by vasodilating substances, such as nitroglycerine and alcohol.[115]

Tension-Type Headache

T e term tension-type headache is designated by the International Headache Society to describe what was previously called tension headache, muscle contraction headache, psychomyogenic headache, stress headache, ordinary headache, and psychogenic headache.[111] T e International Headache Society distinguishes between the episodic and the chronic varieties of tension-type headaches and divides them into two groups: those associated with a disorder of the pericranial muscles and those not associated with this type of disorder.[111]

Tension headaches, which constitute up to 70% of headaches and which occur more often in women than in men, are thought to result from emotional stress.[113,116] T ey are characterized by a bilateral, nonthrobbing ache in the frontal or temporal areas (Fig. 5-1) and by spasm or hypertonus of the neck muscles.[115] Unlike migraine headaches, the tension-type headache, is typically relieved by physical activity and usually responds well to soft tissue and specific traction techniques.

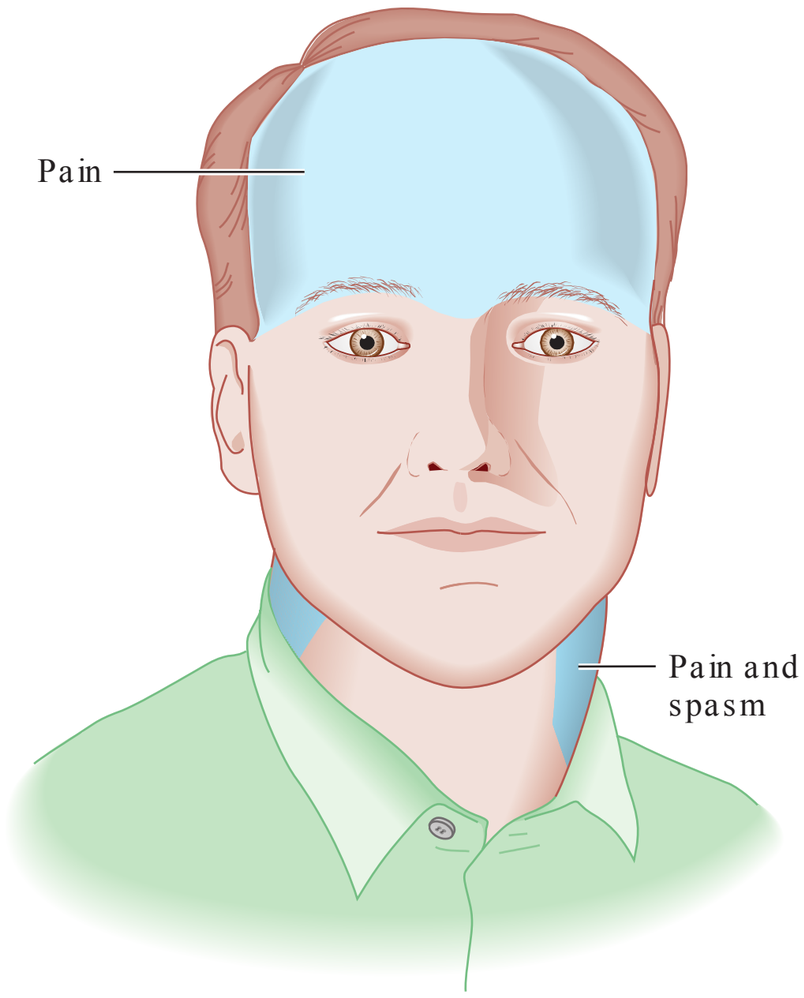

FIGURE 5-1 Distribution of symptoms and signs in a tension headache. (Reproduced, with permission, from Chapter 6. Headache & Facial Pain. In: Greenberg DA, Aminoff MJ, Simon RP. eds. Clinical Neurology, 8e. New York, NY: McGraw-Hill; 2012.)

Benign Exertional Headache

Benign exertional headache (BEH) has been recognized as a separate entity for more than 70 years.[117] Characteristic features of BEH include:[118]

- A headache that is specifically brought on by physical exercise, particularly with straining and Valsalva-type maneuvers, such as those seen in weightlifting;
- bilateral and throbbing at onset and may develop migrainous features in patients susceptible to a migraine;
- duration of 5 minutes to 24 hours;
- prevented by avoiding excessive exertion; and
- no association with any systemic or intracranial disorder.

Clearly, the major differential diagnosis to be considered in this situation would be a subarachnoid hemorrhage, which needs to be excluded by appropriate investigations.

Effort-Induced Headache

Effort headaches have been reported to be the most common type of headache in athletes.[119] T ese headaches differ from BEH in that they are not necessarily associated with power or straining types of exercise. T e clinical features of this effort headache syndrome include:[118]

- an onset of a mild-to-severe headache with aerobic-type exercise;
- more frequency in hot weather;
- vascular-type headache (i.e., throbbing);
- a short duration of a headache (4–6 hours);
- provoking exercise may be maximal or submaximal;
- the patient may have prodromal “migrainous” symptoms;

- the headache tends to recur in individuals with exercise;
- the patient may have a past history of a migraine;
- normal neurological examination and investigations.

Occipital Headache

An occipital headache is felt by many clinicians to be referred as pain from a cervical disorder, especially when cervical traction temporarily decreases the headache.

The underlying musculoskeletal mechanism for this type of headache is often structural, including cervical hypomobility or hypermobility, joint subluxation, and degenerative bony changes. Postures, movements, or activities that put a strain on the neck have been associated with headaches.[120] In one study,[121] 51% of patients associated their headaches with sustained neck flexion during reading, studying, typing, or driving a car.

There is considerable sensory input into the root of C1, but not from a cutaneous source (see "Occipital Neuralgia" later) (see Chapter 3).[122] Experiments have confirmed a close trigeminocervical relationship.[123,124] Because the head and neck comprise one functional unit, cervical musculoskeletal disorders can contribute to head, temporomandibular, or facial pain—with or without neck pain.[125] Cervical headaches are described in more detail in Chapter 23.

Hypertension Headache

Hypertension headaches usually occur in individuals with diastolic readings above 120 mm Hg, although the intensity of these headaches does not necessarily parallel the height of the blood pressure levels.[126] Typically, the headache begins in the early morning, reaching a peak upon awakening and then diminishes once the patient rises and begins his or her daily activity.[127] The headache is usually described as a nonlocalized, dull, and throbbing ache that is aggravated by activities that increase blood pressure, such as bending, coughing, or exertion.[128] The distribution of the headache can vary and may extend over the entire cranium.[127]

External Compression Headache

This entity, formerly known as swim-goggle headache, manifests with pain in the facial and temporal areas that results from wearing excessively tight face masks or swimming goggles and is thus commonly seen in swimmers and divers.[118,129] The etiology is believed to be related to continuous stimulation of cutaneous nerves by the application of pressure, although neuralgia of the supraorbital nerve has also been implicated.[118]

Idiopathic Carotidynia Headache

Idiopathic carotidynia is associated with a gradual onset of a unilateral headache, unilateral facial or orbital pain, but it may be an instantaneous, excruciating, "thunderclap" headache that mimics a subarachnoid hemorrhage.[130] The pain is most commonly located in the frontotemporal area, but occasionally involves the entire hemicranium or the occipital area.[130] The median interval between the onset of neck pain and the appearance of other symptoms is 2 weeks, whereas other symptoms occur only approximately 15 hours after the onset of a headache.[130]

Chronic Daily Headache

Chronic daily headaches, following trauma to the head or neck, are a common occurrence,[131] with the duration of these headaches unrelated to the severity or type of trauma.[132,133] These headaches typically consist of a group of disorders that can be subclassified into primary and secondary types.[134]

- The primary chronic daily headache disorders include a transformed migraine, chronic tension-type headache, new daily persistent headache, and hemicrania continua. This type of headache is defined as a constant tension headache with migrainous exacerbations.[135,136]
- The secondary chronic daily headaches include cervical spine disorders, headache associated with vascular disorders, and nonvascular intracranial disorders.

The chronic daily headache usually evolves over time from an episodic migraine, but the cause is still controversial. Individuals suffering from chronic daily headache often suffer from a rebound headache as well. A rebound headache involves the worsening of head pain in chronic headache sufferers. It is caused by the frequent and excessive use of nonnarcotic analgesics.[137] Several studies have demonstrated that as many as three-quarters of patients with chronic daily headache suffer from drug-induced rebound headache.[138,139]

The role of trauma in chronic daily headaches, however, may be understated. Tension headaches may well initiate a headache in patients predisposed by some previous and forgotten traumatic incident.

Posttraumatic Headache

In addition to the immediate pain following a head injury, posttraumatic headache, a more prolonged and enduring headache, may develop.[140] This condition, resembling either a migraine or tension-type headache, may last for weeks, months, or years. It may also be associated with posttraumatic syndrome, which includes a variety of symptoms, such as irritability, insomnia, anxiety, seizure, amnesia, depression, and reduced ability to concentrate.[140]

The more serious causes of a headache associated with trauma include subdural hematoma, epidural hematoma, intracerebral hematoma, aneurysm, subarachnoid hemorrhage, or cerebral contusion.

The clinician should attempt to establish the overall health of the patient through a review of the systems:[115]

- Nervous system. The physical examination of the nervous system can include sensory and motor testing of the cranial and spinal nerves, reflex testing, and an examination of gait, balance, and coordination. The need for such testing often can be determined by the presence of the signs and symptoms.
- Cardiovascular system. Fluctuations in blood pressure are often associated with headaches.
- Endocrine system. Headaches may be associated with hormonal changes and hormonal replacement therapy.[141]

- Musculoskeletal system. An examination must be made of the middle (see Chapter 25) and upper cervical segments (see Chapter 23), and the temporomandibular joint (see Chapter 26). In addition, a thorough postural examination should be performed to assess for muscle imbalances and overall alignment (see Chapter 6). Relative flexibility and strength are assessed during upper limb movements. Finally, the clinician should examine for myofascial trigger points, and the presence of adverse neural tension (see Chapter 11).

Occipital Neuralgia

Occipital neuralgia is a rare neuralgic disorder that involves the greater occipital nerve.[142] The greater occipital nerve originates from the second cervical root (C2). Occipital neuralgia is a headache syndrome that is characterized by an occipital and suboccipital headache that may radiate to the frontal, periorbital, retroorbital, maxillary, and mandibular regions.[143] It may also be associated with neck pain, dizziness, paresthesias or hyperesthesia of the posterior scalp, and loss of the normal cervical lordosis. Occipital neuralgia is more common in women than in men.[144] The pain usually awakens the patient from sleep in the morning but may occur at any time of day.[144] The causes of occipital neuralgia include:

- scalp trauma from a direct blow;
- compression neuropathy;
- sustained contraction (spasm) of the posterior neck muscles,[142] especially the semispinalis capitis, obliquus capitis inferior, and trapezius muscles[145];
- hyperextension injury and resultant compression of the ganglion and root of C2;
- fracture of the atlas or axis;
- gout;
- mastoiditis;
- OA of the craniovertebral joints.

Diagnosis is usually made using palpation over the greater occipital nerve as it passes the superior nuchal line. The intervention for patients with occipital neuralgia involves infiltrating the nerve with a mixture of local anesthetic and corticosteroid.[145]

Glossopharyngeal Neuralgia

The cause of a glossopharyngeal neuralgia is, at present, unknown, although most authors place the site of disturbance in the region of the posterior root[146,147] or in the nerve tract.[148] Glossopharyngeal neuralgia is characterized by intense unilateral attacks of pain in the retrolingual area, radiating to the depth of the ear.[128] The pain, typically, is aggravated by movement or contact with the pharynx, especially with swallowing.

Trigeminal Neuralgia

TN, or tic douloureux, is a severe chronic pain syndrome characterized by dramatic, brief stabbing, or electric shock-like pain paroxysms felt in one or more divisions of the trigeminal distribution, either spontaneously or on gentle tactile stimulation of a trigger point on the face or in the oral cavity.[149] It is unclear whether TN is a neuropathic pain state of the central or peripheral nervous system.

Bell Palsy

Bell palsy is a lower motor neuron (LMN) disease of the facial nerve characterized by a wide range of facial muscle movement dysfunction from mild paresis to total paralysis. Individual patients display a spectrum of symptoms: some maintain only reduced movement throughout the course of the disorder while others rapidly become totally paralyzed throughout the distribution of the facial nerve over a 24-hour period. Bell palsy is the most common form of facial paralysis, with an incidence of 20–30 per 100,000 persons.[150] The diagnosis is established by the exclusion of several localized lesions, such as temporal bone fracture, acoustic neuroma, suppuration or tumor of the middle ear, and disorders of the parotid gland.[151]

Fundamental to management issues of this disorder is the question of its etiology, once thought to be idiopathic. Two recent independent studies[152,153] strongly support the concept that the facial paralysis associated with Bell palsy is the result of a viral, inflammatory response that induces edema and ischemia of the facial nerve as it passes through its bony canal. The infectious agents associated with Bell palsy are herpes simplex virus type 1, varicella zoster virus, and the spirochete Borrelia burgdorferi, the causative organism of Lyme disease.[154]

The intervention for this condition is empiric, varying from observation alone to the use of corticosteroids, electric stimulation, surgical decompression, and antiviral agents. Transcranial magnetic stimulation of the facial nerve has also been reported to be useful.[155]

Healing is occasionally incomplete, resulting in residual nerve dysfunction, including partial palsy and motor synkinesis (involuntary movement accompanying a voluntary one) and autonomic synkinesis (involuntary lacrimation after a voluntary muscle movement). On the basis of the study of Peitersen,[156] all patients regain some function, and 85% of all patients will regain normal or very near-normal function within 6–8 weeks.

Surgical management of Bell palsy has been controversial since its inception because of the following points: issues of patient selection criteria based on electrodiagnostic studies, site of decompression, limited number of patients who require decompression at any single center, and the inability to transfer results from study to study because of the continued use of independent facial function grading systems.[157]

Ramsay Hunt Syndrome

Ramsay Hunt syndrome, a herpetic inflammation of the geniculate or facial nerve ganglia, or both, manifests as a peripheral facial nerve palsy accompanied by an erythematous vesicular rash on the ear (zoster oticus) or in the mouth.[158] It is the second most common cause of atraumatic peripheral facial paralysis. Other frequent symptoms and signs can include tinnitus, hearing loss, nausea, vomiting, vertigo, and nystagmus.

Compared with Bell palsy, patients with Ramsay Hunt syndrome often have more severe paralysis at onset and are less likely to recover completely. The intervention for Ramsay

Hunt syndrome can involve medication. Prednisone and acyclovir may improve the outcome although a prospective randomized treatment trial remains to be undertaken.[158]

Arteriovenous Malformation

This congenital malformation may manifest with an abrupt onset of head and facial pain.

Meningitis

The brain is protected from infection by the skull, pia, arachnoid, and dural meninges covering its surface and by the blood–brain barrier (see Chapter 3). When any of these defenses is broached by a pathogen, infection of the meninges and subarachnoid space can occur, resulting in meningitis.[159]

Since the fifth century bc, the seriousness of infectious meningitis has been recognized.[160] In the 20th century, the annual incidence of bacterial meningitis ranges from approximately 3 per 100,000 population in the United States[161] to 500 per 100,000 in the so-called meningitis belt of Africa.[162]

Predisposing factors for the development of community-acquired meningitis include pre-existing diabetes mellitus, otitis media, pneumonia, sinusitis, and alcohol abuse.[163]

The clinical features of meningitis reflect the underlying pathophysiologic processes.[164] Once the blood–brain barrier is breached, an inflammatory response within the cerebrospinal fluid (CSF) occurs. The resultant meningeal inflammation and irritation elicit a protective reflex to prevent stretching of the inflamed and hypersensitive nerve roots, which is detectable clinically as neck stiffness or rigidity (Kernig or Brudzinski signs).[165,166]

- Brudzinski sign: the patient is positioned in supine. The clinician passively flexes the patient's neck. A positive sign is the appearance of involuntary hip flexion, which lifts the patient's legs off the table.
- Kernig sign: the patient is positioned in supine. The clinician passively flexes the patient's hip to 90 degrees and then attempts to extend the knee. Pain with the knee extension is a positive sign.

CLINICAL PEARL

Rigidity of the neck can occur with neuralgia and other irritative lesions of the meninges, such as meningitis.[164]

The meningeal inflammation may also cause a fever and generalized headache and nausea.[167] If the inflammatory process progresses to cerebral vasculitis, or causes cerebral edema and elevated intracranial pressure, alterations in mental status, vomiting, seizures, and cranial nerve palsies may ensue.[159]

Despite classic descriptions of meningeal signs and sweeping statements about its clinical presentation, the signs and symptoms of meningitis have been inadequately studied.[164] Based on the limited studies, the following points should be remembered during the examination:[164]

- The absence of all three signs of the classic triad of fever, neck stiffness, and an altered mental status virtually eliminates a diagnosis of meningitis. Fever is the most sensitive of the classic triad of signs and occurs in a majority of patients, with neck stiffness being the next most sensitive sign. Alterations in mental status also have a relatively high sensitivity, indicating that normal mental status helps to exclude meningitis in low-risk patients. Changes in mental status are more common in bacterial than in viral meningitis.
- Among the signs of meningeal irritation, the Brudzinski and Kernig signs appear to have low sensitivity but high specificity.

Cerebrovascular Disease

The frequency of a headache with cerebrovascular disease is dependent on the size and location of the hemorrhage. Small hemorrhages may occur without an associated headache. Although a headache may be the presenting symptom of cerebrovascular disease, associated neurological changes are also likely and are more indicative of cerebrovascular disease. These could include, but are not limited to, loss of the ability to sit, stand, and walk; right- or left-sided weakness; visual disturbances; aphasia; apraxia; dysphasia; seizures; and mental status changes.

Intracranial Bleeding

Depending on the rate of arterial or venous bleeding, signs of intracranial bleeding may take minutes to days. A meningeal artery or branch laceration with an associated overlying skull fracture is a frequent source of delayed epidural bleeding.[168] However, venous bleeding is also associated with delayed and chronic hematomas by the nature of the low pressure and slow rate of bleeding.[168] Other causes of low-tension hemorrhages are small dural lesions or diffuse cerebral contusion sites.

A subarachnoid hemorrhage can be the cause of head, facial, orbital, or neck pain. The pain, which is usually severe, may occur in one region or over all of the areas. Neck stiffness and pain on movement are common findings and often are associated with nausea and vomiting. Other possible findings include:

- UMN signs and symptoms (Babinski, clonus, hyperreflexia, ataxia, and so on);
- photophobia;
- motor or sensory disturbances;
- syncope;
- somnolence and lethargy;
- seizures;
- visual disturbances;
- dysphasia.

Patients with intracranial bleeding usually prefer to remain still, with their eyes closed. They often become disoriented and demonstrate judgment and memory abnormalities.

Tumors

A complete discussion of each type of brain tumor is beyond the scope of this text. Tumors of the brain may be classified according to type as follows:

- Astrocytomas. Astrocytomas are benign brain tumors. Glioblastoma multiforme, a type of astrocytoma, is the most common adult brain neoplasm.
- Oligodendrogliomas. These are benign primary brain tumors that arise from oligodendrocytes.
- Meningiomas. These tumors are slow growing and benign and comprise about 20% of all intracranial tumors in adults.
- Metastatic tumors. These are tumors that originate from tissues outside of the brain. They can occur as single or multiple tumors.

The term benign is misleading when referring to brain tumors. Although benign may mean curable, this is not always true with brain tumors. Tumors, benign or otherwise, are space-occupying lesions that may increase to a size that compresses nearby structures or increases intracranial pressure. Patients with tumors of the brain may present acutely with the following symptoms:

- Abrupt onset of a severe headache
- Facial pain
- Episodes of loss of consciousness
- Changes in mental status
- Nausea and vomiting
- Focal neurologic signs and symptoms
- Neck stiffness or pain

Encephalitis

Encephalitis is an inflammation of the brain. The inflammation may be caused by an arthropod-borne virus, or it may occur as a sequela of influenza, measles, German measles, chickenpox, herpes simplex, or other infectious diseases. Clinical findings include:

- signs of meningeal irritation (Kernig or Brudzinski sign);
- changes in mental status;
- signs of increased intracranial pressure, including increased restlessness, vomiting, seizures, and pupil irregularities; and
- behavioral changes.

Systemic Infections

Systemic infections that are capable of provoking head or facial pain include Rocky Mountain spotted fever, Lyme disease, pneumonia, and pyelonephritis.

Rocky Mountain Spotted Fever

This condition begins abruptly with a high fever and bilateral frontal or a frontotemporal headache. The classic rash begins on the distal aspects of the extremities and spreads proximally. Serologic tests are required to confirm the diagnosis.

Lyme Disease

Lyme disease is a bacterial infection that is transmitted to humans by ticks that usually live on mice or deer. Most infections are acquired in three distinct sections of the United States: along the northeast coast, in areas of Wisconsin and Minnesota, and, to a lesser extent, in northern California and southern Oregon. People who hike, camp, or live in or near wooded areas in these locations during summer months are most at risk for Lyme disease. Following a bite from a deer tick, a red bump may occur at the site of the bite. If the tick is infected, a larger rash may form around the bite. The classic description of the rash is an enlarging area of redness with partial central clearing. However, it may take several days before the lesion expands enough to have the classic appearance.

The most common signs and symptoms associated with the rash are nonspecific flu-like symptoms, including myalgia, arthralgias, fever, joint pain and swelling, headache, fatigue, motor or sensory radiculoneuritis, mononeuritis multiplex, or neck stiffness.[169]

Cardiac symptoms can include fluctuating degrees of atrioventricular block, occasionally acute myopericarditis or mild left ventricular dysfunction, and, rarely, cardiomegaly or fatal pancarditis.[169]

The initial diagnosis usually is based on the recognition of the characteristic clinical findings. The culture of B. burgdorferi from specimens in Barbour–Stoenner–Kelly medium permits a definitive diagnosis.[169]

Pneumonia

Pneumonia is an inflammation of the lungs, usually caused by an infection of the lung tissue by one of many different microorganisms. The presenting symptoms depend on how much of the lung is affected and the type of infection. Related to this body region, patients with pneumonia may present with a fever and severe headache.

Pyelonephritis

Acute pyelonephritis is an inflammation of the kidney and renal pelvis. Clinical signs and symptoms of acute pyelonephritis include fever; shaking chills; thoracolumbar, interscapular, neck, and flank pain; nausea and vomiting; costovertebral angle tenderness; and, less commonly, symptoms of cystitis such as dysuria and increased frequency.[170] In addition, a bifrontal or a generalized headache may accompany the neck pain and stiffness.

Multiple Sclerosis

Multiple sclerosis (MS) is a chronic demyelinating disorder with a wide range of clinical manifestations that reflects multifocal areas of CNS myelin destruction. In adults, the clinical presentation of MS at onset is characterized by motor system (26.5%), sensory system (25%), or optic nerve (21%) involvement or a combination of all three.[171] Cerebellar and sphincteric involvement are less frequent (14.1% each).[171]

Patients with motor weakness may develop paralysis affecting one or more, or all, limbs. Sensory dysfunction may occur in one modality (e.g., to light touch, temperature, or deep sensation) and may manifest as hypoesthesia/anesthesia or hypersensitivity with numbness, burning sensation, paresthesia, and

dysesthesia in various parts of the body).[171] Other manifestations include fatigue, cognitive loss, and mood disturbance. Optic neuritis is associated with a decrease in visual acuity, sometimes resulting in blindness, accompanied by orbital pain when the involved eye moves.[172]

Most patients with MS (85%) have a relapsing–remitting course of the disease, with each relapse being associated with new neurologic symptoms or worsening of existing ones. With additional relapses, the possibility of complete recovery is reduced, and permanent disability may develop.[171] In the remaining 15% of patients, the disease course is primary progressive, with continuous neurologic deterioration.[171]

MS usually manifests between 20 and 40 years, with a peak onset at around 30 years and a female-to-male ratio of 2:1. At present, MS is regarded as being modifiable, but incurable.

Miscellaneous Causes

Temporal Arteritis

This condition, also known as giant cell arteritis, is an inflammatory condition affecting the medium-sized blood vessels that supply the head, eyes, and optic nerves. The disease usually affects those over 60 years and is characterized by a severe headache, which can begin abruptly or gradually, and is usually throbbing in nature. Associated symptoms may include flu-like symptoms, swollen and tender temporal arteries, jaw weakness, scalp tenderness, and visual loss. Women are approximately four times more likely to suffer from this disease than men.[173]

Acute Sinusitis

Sinusitis is an infection or inflammation of the sinuses. Sinuses are hollow air spaces located within the skull or bones of the head surrounding the nose. Each sinus has an opening into the nose for the free exchange of air and mucus, and each is joined with the nasal passages by a continuous mucous membrane lining. Anything that causes a swelling in the nose, such as an infection, an allergic reaction, or an immune reaction, may affect the sinuses. Sinusitis involves an infection or inflammation of one or more of the following:

- Frontal sinuses over the eyes in the brow area
- Maxillary sinuses inside each cheekbone
- Ethmoid sinuses just behind the bridge of the nose and between the eyes
- Sphenoid sinuses behind the ethmoids in the upper region of the nose and behind the eyes

Air trapped within a blocked sinus, along with pus or other secretions, may cause pressure on the sinus wall and subsequent pain. Similarly, when air is prevented from entering a sinus by a swollen membrane at the opening, a vacuum may be created, which also causes pain. The location of the sinus pain depends on which sinus is affected. Symptoms can include:

- a headache upon awakening in the morning and tenderness to palpation over the frontal sinuses;
- upper jaw, cheek, and tooth pain (maxillary sinuses);
- pain and swelling of tear ducts in the corner of the eyes and pain between the eyes and sides of the nose (ethmoid sinuses); and
- earaches, neck pain, and deep aching at the top of the head (sphenoid sinuses).

Other symptoms of sinusitis include:

- fever;
- weakness;
- tiredness;
- A cough that may be more severe at night; and
- A runny nose (rhinitis) or nasal congestion.

On rare occasions, acute sinusitis may result in brain infection and other serious complications.

Eclampsia

Eclampsia is the most commonly occurring hypertensive disease in pregnancy. Worldwide, preeclampsia and eclampsia contribute to the death of a pregnant woman every 3 minutes.[174] The classic clinical presentation consists of blurred vision, severe headaches, epileptic seizures, or coma manifesting during the third trimester or early puerperium in women who already have the triad of preeclamptic symptoms: edema, proteinuria, and hypertension.[175] The diagnosis of eclampsia requires the exclusion of other medical or neurologic disorders underlying the symptomatology. The differential diagnostic considerations include sinus or cerebral vein thrombosis, subarachnoid hemorrhage from an aneurysm, infectious or autoimmune-inflammatory disorders, and sickle-cell crisis.

CSF Hypotension

This condition commonly occurs following a lumbar puncture, which can produce leakage of CSF through a dural tear. A lumbar puncture is a routine procedure performed for a variety of functions: spinal anesthesia, intrathecal administration of cytotoxic and antibiotic drugs, myelography, obtaining CSF samples, and pressure measurement.[176] The leak of CSF results in CSF hypovolemia and downward shifting of the brain, causing pressure on the pain-sensitive dural sinuses that is amplified in the upright posture and relieved with recumbence.[177] The clinical manifestations of CSF hypotension are a headache and backache, which usually start within hours to a week following the lumbar puncture. More serious complications may include labyrinthine and ocular cranial nerve disturbances, meningitis, subdural hematomas, and fistulas.

Temporomandibular Joint Dysfunction

See Chapter 26.

Periodontal Disease

Periodontal disease may be associated with a small increased risk of coronary heart disease.[178] Clinically, periodontitis starts as an acute inflammation of the apical periodontal ligament and the neighboring spongiosa, accompanied by well-known imminent symptoms such as pain, tenderness to percussion, and swelling.

Thyroiditis

Acute bacterial thyroiditis (or pyogenic thyroiditis) is a rare, potentially life-threatening complication of bacterial infection elsewhere in the body, especially following an upper

respiratory tract infection.[179] The condition occurs in all age groups, although women with pre-existing thyroid disease constitute the group most likely to develop thyroid infection. In childhood, it is often linked to local anatomic defects. The ample blood supply and lymphatic drainage, high iodine content, and protective thyroid capsule contribute to the low incidence of infection.

Common pathogens include Streptococcus pyogenes, Streptococcus pneumoniae, and Staphylococcus. Less common organisms include Salmonella, Bacteroides, Haemophilus influenzae, Streptococcus viridans, and other streptococcal organisms.[179] Clinical signs and symptoms include fever (92%), anterior neck pain (100%), tenderness (94%), warmth (70%), erythema (82%), dysphagia (91%), dysphonia (82%), and pharyngitis (69%).[179]

Fracture of the Facial Bones or Skull

The examination of the face for a fracture requires knowledge not only of normal anatomy but also of common fracture patterns in the face. Computed tomography (CT) is currently the imaging procedure of choice for most facial fractures because it highlights the complex anatomy and fractures of the facial bones and their related soft-tissue complications extremely well. Approximately, 60–70% of all facial fractures involve the orbit.[180] The exception to this is a local nasal bone fracture or a zygomatic arch fracture. The most common mechanism producing facial fractures is auto accidents. Other mechanisms include fights or assaults, falls, sports, industrial accidents, and gunshot wounds. Less than 10% of all facial fractures occur in children, perhaps because of the increased resiliency of a child's facial skeleton.[180] The nose is the most frequently injured facial structure, and the most commonly missed facial fracture of the face is a fracture of the nasal bone. Patients with a temporal bone fracture may present with a conductive hearing loss caused by dislocations in the ossicular chain. Facial nerve paralysis may also occur secondary to either transection or edema of the facial nerve.

Trochleitis[181]

Trochleitis is a local inflammatory process of the superior oblique tendon trochlea characterized by periocular pain. Eye movement in supraduction typically aggravates the pain. Physical examination demonstrates exquisite point tenderness over the trochlea of the superior oblique muscle. The cause often is unknown, but trochleitis can occur in RA, SLE, psoriasis, or enteropathic arthropathy. Rare causes include sinusitis, trauma, and metastasis.

CAUSES OF CERVICAL PAIN

The causes of cervical pain are numerous, as outlined in Table 5-8 and Figure 5-2.

Thyroid Disease

The thyroid gland synthesizes, stores, and secretes thyroid hormones, mainly l-thyroxine (T4). l-triiodothyronine (T3) is produced from T4 by deiodination, mainly in the liver, kidney, and muscle. The thyroid gland controls the metabolic rate of many organs and tissues. The thyroid gland cannot function normally unless it is exposed to thyroid-stimulating hormone (TSH), which is produced by the thyrotrophs of the anterior pituitary.[182] Under-activity (hypothyroidism) and overactivity of thyroid function (hyperthyroidism), which represent the most common endocrine problems, have widespread manifestations, including cervical pain, and often require long-term treatment.

Rheumatoid arthritis
Ankylosing spondylitis
Gout
Osteoarthritis
Occipital neuralgia

Hypothyroidism

Most patients with hypothyroidism have a disease of the thyroid gland. Occasionally, hypothyroidism develops in patients with normal thyroid glands because of inadequate stimulation by TSH. Such individuals have disorders of the anterior pituitary or hypothalamus. Thyroid hormone deficiency affects practically all body functions. The complaints and physical findings vary widely from patient to patient, depending on the severity of the deficiency. Patients may present with weakness, fatigue, arthralgias and myalgias, muscle cramps, cold intolerance, constipation, lethargy, dryness of the skin, headache, neck pain, menorrhagia, hoarseness, edema, and weight gain.[182] Most patients have varying degrees of brittle nails and hair, pallor, delayed relaxation time of the muscle stretch reflexes, keratinic skin color, thickening of the tongue, mental status changes, and diastolic hypertension.[182] In some patients, severe hypothermia, edema, and even effusions into the pleura, and peritoneal and pericardial cavities may occur.[182]

Hyperthyroidism

Hyperthyroidism denotes clinical disorders associated with increased serum concentrations of the free T4 estimate or free T3 or both. The most common causes of hyperthyroidism are

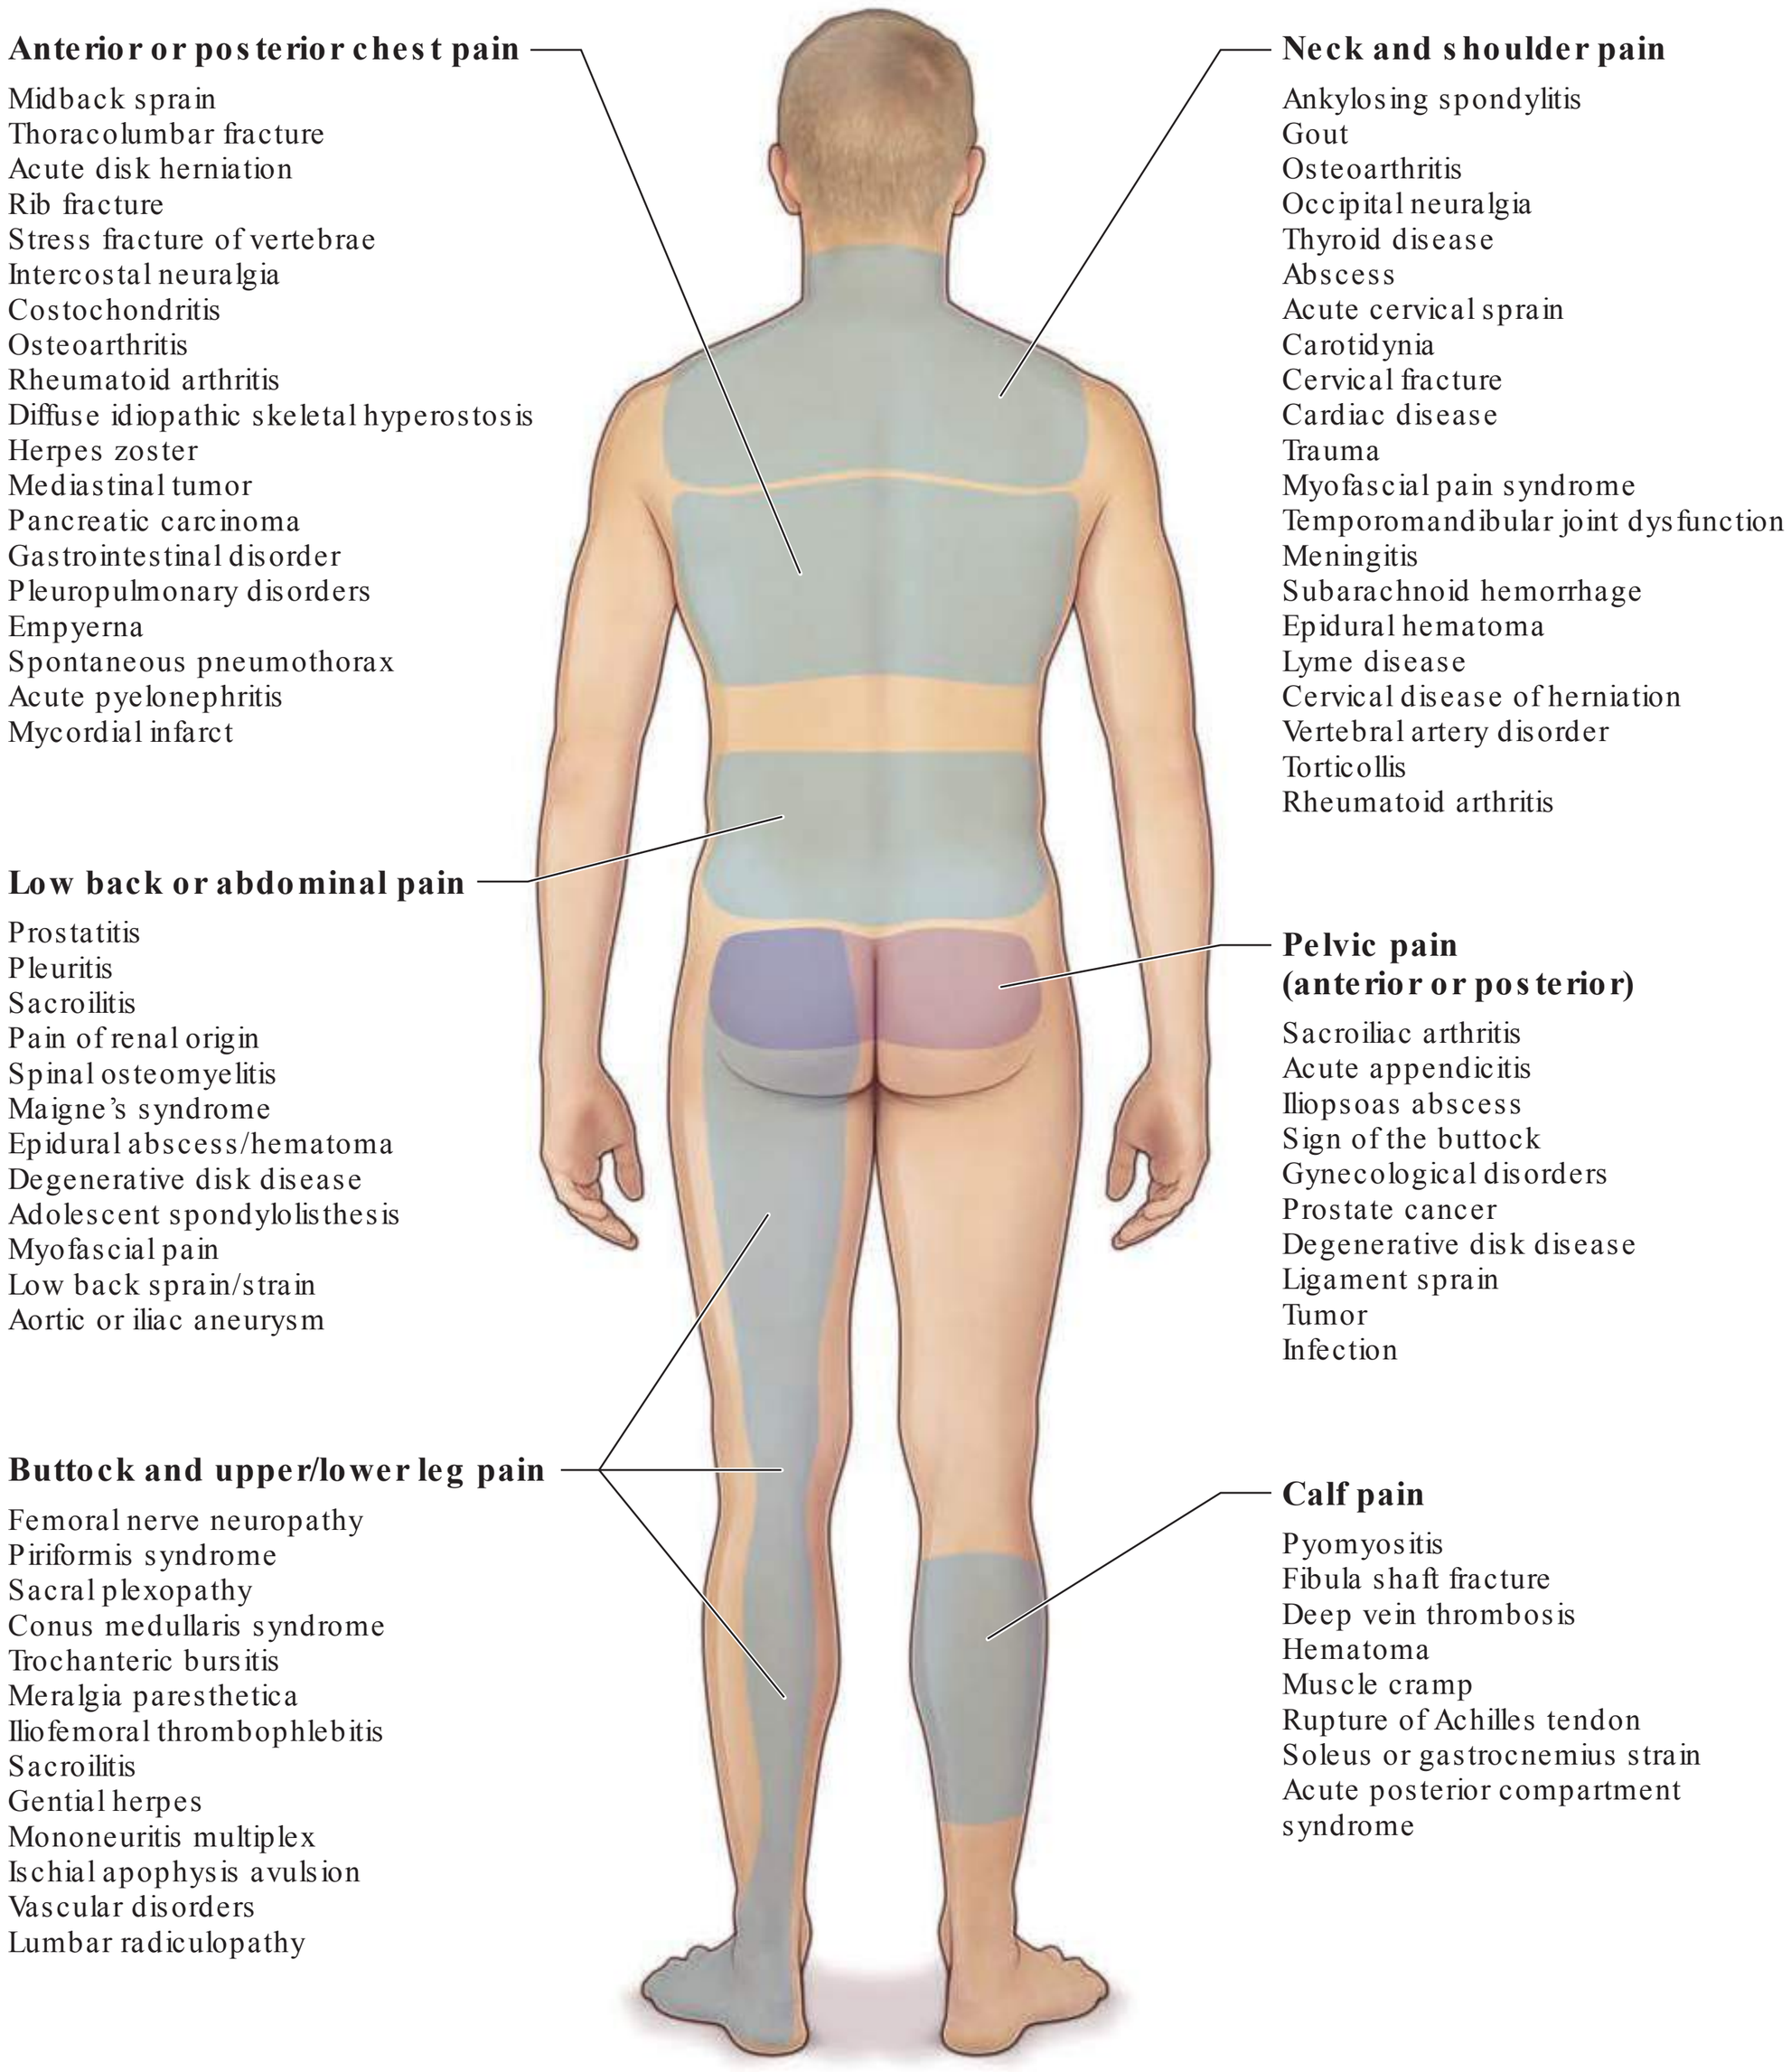

FIGURE 5-2 Potential causes of cervical, thoracic, lumbar, pelvic, and lower extremity pain.

Graves' disease, nodular goiter, and thyroiditis. Excessive thyroid hormone concentrations affect many body functions. Such symptoms include:[182]

- nervousness;
- restlessness;
- heat intolerance;
- increased and inappropriate perspiration;
- fatigue;
- muscle cramps;
- paratracheal neck pain;
- increased frequency of bowel movements;
- weight loss in association with unchanged or increased food ingestion; and
- palpitations.

The clinical signs of hyperthyroidism, which vary widely among patients, may include exophthalmus, tachycardia, fine resting tremors, moist warm skin, heat radiation from the skin, hyperreflexia, onycholysis, an enlarged thyroid gland with or without a bruit, and diplopia.[182] Patients who are found to have relatively specific symptoms and signs (such as goiter, nodule, eye findings of Graves' disease, or tremor)

should be referred to an endocrinologist for consideration of treatment.

Subarachnoid Hemorrhage

See the discussion of intracranial bleeding under "Causes of Head, Face, Eye, and Temporomandibular Joint Pain" earlier in the chapter.

Retropharyngeal Abscess

Retropharyngeal abscess (RPA) is a relatively uncommon infection of the space anterior to the prevertebral layer of the deep cervical fascia. T is infection is most common in children younger than 3 or 4 years, because of the rich concentration of lymph nodes in this space.[183] T e infection in children classically results from the extension of oropharyngeal infections, including pharyngitis, tonsillitis, and adenitis.[184] Trauma, often caused by a fall while holding a pencil or stick in the mouth, and dental infections are the usual underlying causes of RPA in older children and adults.[184] T e major causative organisms are S. pyogenes, Staphylococcus aureus, and oropharyngeal anaerobic bacteria.[185] T e infection progresses through three stages: cellulitis, phlegmon (diffuse inflammation of the soft or connective tissue), and abscess.

RPA can produce posterior neck and shoulder pain and stiffness. T ese symptoms are also associated with hyperextension of the neck, torticollis, fever, irritability, muf ed voice, stertor, and other signs of upper airway obstruction.[184] T e pain often is worsened with swallowing. Swelling of the lateral or posterior aspect of the neck can be present.

T e differential diagnosis includes acute epiglottitis, foreign-body aspiration, vertebral osteomyelitis, hematoma (particularly in boys with hemophilia), and lymphoma.[184]

Carotidynia

In addition to sinus and dental abnormalities and stress, several different neurologic conditions can cause facial pain. T ese include various neuralgias (trigeminal, vagoglossopharyngeal, and cranial), carotidynia (a painful carotid artery), and optic neuritis. Pain characteristics and results of specific neurologic tests establish the diagnosis. Carotidynia is associated with neck pain, tenderness, and a unilateral headache.

Cardiac Disease

See the discussion of myocardial infarction under "Causes of T oracic Pain" later.

Trauma or Whiplash

See Chapter 25.

Tumors

Tumors of the adult cervical spine may be primary, arising from the bone, or secondary (i.e., metastatic from a distant primary site.) Tumors of the cervical cord may cause neck pain. T ese tumors may be extramedullary, or intramedullary. A pain of insidious onset, with or without neurologic signs and symptoms (e.g., progressive leg weakness, bladder paralysis, and sensory loss), may occur.

Temporomandibular Joint Dysfunction

See Chapter 26.

Meningitis

See the discussion of "Causes of Head, Face, Eye, and Temporomandibular Joint Symptoms" earlier.

Epidural Hematoma

Most cervical epidural hematomas are spontaneous, with precipitating factors that include coagulopathy, vascular malformation, neoplasm, and pregnancy.[186] Cervical epidural hematoma can also be caused by trauma although this is uncommon. Traumatic causes of spontaneous epidural hematoma include vertebral trauma, epidural steroid injection, lumbar puncture, penetrating injuries, birth trauma, and spinal manipulation.[187] Excessive movement of the cervical spine, which may occur with a cervical manipulation, can injure the epidural veins, either by direct trauma or by a sudden increase in venous pressure, resulting in a cervical epidural hematoma.[186,188] T e clinician must therefore be particularly mindful of the risk factors for the complications of spinal manual therapy, such as misdiagnosis, unrecognized neurologic manifestations, improper technique, presence of coagulation disorder or disk herniation, and manipulation of the cervical spine.[189]

Presenting signs and symptoms vary. T e onset of neck pain is often the first symptom, but epidural hematoma has been diagnosed in its absence. Compression of the spinal cord can also produce sensory deficits, motor deficits, and bowel or bladder incontinence.

Lyme Disease

See the discussion of systemic infections under "Causes of Head, Face, Eye, and Temporomandibular Joint Symptoms" earlier.

Cervical Disk Disease or Herniation

See Chapter 25.

Vertebral Artery Disorders

See Chapter 24.

Torticollis

As many as 80 different causes of torticollis have been documented in the literature.[190] Torticollis is not a specific diagnosis but, rather, a sign of an underlying disorder resulting in the characteristic tilting of the head to one side. Differential diagnosis of torticollis ranges from innocuous abnormalities that require no specific therapy for potentially life-threatening tumors of the CNS. T e neuromuscular causes of torticollis may be classified as congenital or acquired. Congenital muscular tor-

ticollis is the most common type of torticollis.[191] Several causes are implicated, including fetal positioning, difficult labor and delivery, cervical muscle abnormalities, Sprengel deformity, and Klippel–Feil syndrome In addition to torticollis, patients with Klippel–Feil syndrome have the classic clinical triad described by Klippel and Feil in 1912: short, broad necks; restricted movement; and low hairlines.[192,193] T e restricted neck mobility is the result of the fusion of a variable number of cervical vertebrae, sometimes reducing their number, and cervical spina bifida.[194] Extraosseous changes, hemivertebra, vertebral body clefts, and thoracolumbar abnormalities sometimes are also seen.[195]

Acquired torticollis, which includes spasmodic torticollis, is clinically similar but has different etiologies.[196] Acquired torticollis in children may be related to trauma or infections, as in Grisel syndrome, which occurs after head, neck, and pharyngeal infections.[197] In this syndrome, the soft-tissue inflammation associated with pharyngitis, mastoiditis, or tonsillitis results in the accumulation of fluid in the nearby cervical joints.[198] T is edema may then lead to subluxation of the atlantoaxial joint.

Spasmodic torticollis is the involuntary hyperkinesis of neck musculature, causing turning of the head on the trunk, sometimes with additional forward flexion (anterocollis), backward extension (retrocollis), or lateral flexion (laterocollis) (see Chapter 25).[196] It is also marked by abnormal head postures.[198] T e sternocleidomastoid muscle is involved in 75% of cases and the trapezius in 50%.[198] Other muscles that might become involved include the rectus capitis, obliquus inferior, and splenius capitis.[199] In some cases, the spasm generalizes to the muscles of the shoulder, girdle, trunk, or limbs.[200]

Neck movements can vary from jerky to smooth[200,201] and are aggravated by standing, walking, or stressful situations but, usually, do not occur with sleep.[247]

Spontaneous remissions (partial or complete) have been reported in up to 60% of patients in some series;[201] others note full remission in 16%, with sustained remission for 12 months of 6–12%.[202,203]

Various treatments for torticollis have been described. Spencer et al.[204] described a single-subject study using behavioral therapies that consisted of progressive relaxation, positive practice, and visual feedback. T eir patient had significant improvements in all areas, which were maintained at a 2-year follow-up examination.

Agras and Marshall[205] used massed negative practice (i.e., repeating the spasmodic positioning), 200–400 repetitions of the movement daily, which achieved full resolution of symptoms in one of two patients. Results persisted for 22 months.

Another single-case study used positive practice (exercising against the spasmodic muscle groups) in a bed-ridden woman who had symptoms of spasmodic torticollis for 8 years. After 3 months of positive practice, she was able to ambulate unassisted; her therapeutic gains were maintained at a 1-year follow-up examination.[204]

Biofeedback has also been used successfully as an intervention for torticollis.[206]

Rheumatoid Arthritis

Involvement of the cervical spine is common in RA, AS, and juvenile polyarthritis.[105] Fifty percent or more of patients with RA have evidence of neck involvement, especially at the atlantoaxial joint.[105] T ese patients are prone to a cervical derangement, of which an anterior subluxation of C1 on C2, during head flexion, is the most common.[207] Although most patients with anterior subluxation have no neurologic complications, the more advanced and unstable lesions may result in myelopathy.[105]

Patients can also experience severe bony erosions of one or both of the lateral zygapophyseal joints. T is erosion can result in occipital pain with cervical rotation and a rotational head-tilt deformity if the lesion is unilateral.[207]

T e symptoms of these spondyloarthropathies typically fall into two categories:

1. Pain resulting *f*rom the in*fl*ammatory process. RA of the cervical spine may cause generalized aching of the posterior neck and shoulder, and occipital pain. T is pain is often worse with neck flexion.
2. Derangement or de*f*ormity. T is finding results from joint damage, typically with a concomitant risk to the nearby neural structures. Radicular symptoms may be present in one or both upper extremities. With myelopathy, spastic weakness, hyperreflexia, and other UMN signs are present. Depending on the level of involvement of the cervical spine, signs and symptoms of vertebral artery compromise may also be present (see Chapter 24).

Ankylosing Spondylitis

AS commonly affects the C1–2 segments, although this is usually a late manifestation of the disease process. Following ankylosing of the sacroiliac, lumbar, and thoracic segments, the atlantoaxial joint becomes painful initially, only to be less symptomatic as the joint begins to lose motion.[105]

Neurologic injury associated with AS is usually the result of cervical fracture of the syndesmophytes and resulting pseudoarticulation.[105,208] AS is described further under "Causes of T oracic Pain."

Gout

Although the occurrence of gout in the neck is distinctly uncommon, the medications used to treat it can have serious side effects in this region. T ese complications include ligament laxity with resultant instability and neck pain.[209]

Osteoarthritis

Degenerative OA of the subaxial cervical spine is common in elderly patients[210] and is typically characterized by posterior neck, shoulder, and arm pain in a specific dermatomal pattern rather than occipitocervical pain.[211] Diffuse or focal trigger point tenderness may be present in the posterior neck on the involved side.

OA of the atlantoaxial joints may be overlooked when the patient has occipitocervical pain associated with degenerative changes in the subaxial spine.

Occipital Neuralgia

See the discussion of "Causes of Head, Face, Eye, and Temporomandibular Joint Symptoms" earlier.

CAUSES OF THORACIC PAIN

T oracic pain has a wide differential diagnosis (Fig. 5-2). Pain may originate from structures within the thorax, such as the heart, lungs, or esophagus. However, musculoskeletal causes of chest pain must be considered. Musculoskeletal problems of the chest wall can occur in the ribs, sternum, articulations, or myofascial structures (see Chapter 27). T e cause is usually evident in the case of direct trauma.

Systemic origins of musculoskeletal pain in the thoracic spine (Table 5-9) are usually accompanied by constitutional symptoms affecting the whole body and by other associated symptoms that the patient may not relate to the pain and, therefore, may fail to mention to the clinician. T ese additional symptoms should be discovered during the subjective examination by the careful interviewer. When the patient (or the examination) indicates the presence of associated fever (or night sweats), a referral to a physician is indicated.

T e close proximity of the thoracic spine to the chest and respiratory organs may result in a correlation between respiratory movements and increased thoracic symptoms. When screening the patient through the subjective history, the clinician should remember that symptoms of pleural, intercostal muscular, costal, and dural origin all increase on coughing or deep inspiration; thus, only pain of a cardiac origin is ruled out when symptoms increase in association with respiratory movements.

T e causes of thoracic pain include those listed in Table 5-10.

Gastrointestinal Conditions

T e subjective history often provides several clues to a gastrointestinal cause of chest pain.

TABLE 5-9 Systemic Causes of Thoracic Pain

Systemic Origin	Location
Gallbladder disease	Mid-back between scapula
Acute cholecystitis	Right subscapular area
Peptic ulcer: stomach	5–10th thoracic vertebrae or duodenal ulcers
Pleuropulmonary disorders	
Basilar pneumonia	Right upper back
Empyema	Scapula
Pleurisy	Scapula
Spontaneous pneumothorax	Ipsilateral scapula
Pancreatic carcinoma	Middle thoracic or lumbar spine
Acute pyelonephritis	Costovertebral angle (posteriorly)
Esophagitis	Mid-back between scapula
Myocardial infarction	Mid-thoracic spine
Biliary colic	Right upper back, mid-back between scapula, right interscapular, or subscapular areas

Data from Goodman CC, Snyder TE. Dif erential Diagnosis in Physical Therapy. Philadelphia, PA: WB Saunders; 1990.

Intercostal neuralgia
Costochondritis
Osteoarthritis
Rheumatoid arthritis
Diffuse idiopathic skeletal hyperostosis
Manubriosternal dislocations

Colorectal Cancer

Colorectal cancer is the third most common cancer in both men and women in the United States. Risk factors include age, a diet rich in fat and cholesterol, inflammatory bowel disease (especially ulcerative colitis), and genetic predisposition.[212] T e most common metastatic presentation of colon cancer is in the thoracic spine and rib cage.[3] T e overall 5-year survival rate from colon cancer is approximately 60%, and nearly 60,000 people die of the disease each year in the United States.[212] T e 5-year survival rate is different for each stage; the staging classification for colon cancer can predict prognosis well. T e Dukes classification was traditionally used to predict prognosis but has since been replaced by the TNM staging (Table 5-11):

- Tumor (primary)
- Node (regional lymph)
- Metastasis (remote)

An excellent correlation exists between the stage and the 5-year survival rate in patients with colon cancer[212]:

- For stage I or Dukes stage A, the 5-year survival rate following surgical resection exceeds 90%.
- For stage II or Dukes stage B, the 5-year survival rate is 70–85% following resection, with or without adjuvant therapy.
- For stage III or Dukes stage C, the 5-year survival rate is 30–60% following resection and adjuvant chemotherapy.
- For stage IV or Dukes stage D, the 5-year survival rate is poor (approximately 5%).

It is important for the physical therapist to assist other healthcare professionals in stressing the importance of routine screening examinations for colorectal cancer (sigmoidoscopy and colonoscopy) for individuals with a family history of colon cancer.[3], and for those patients over 50 years of age. T e information collected by a physical therapist during a

TABLE 5-11 TNM Staging of Cancer			
Stage	**Primary Tumor (T)**	**Regional Lymph Node (N)**	**Remote Metastasis (M)**
Stage 0	Carcinoma in situ	N0	M0
Stage I	Tumor may invade submucosa (T1) or muscle (T2)	N0	M0
Stage II	Tumor invades muscle (T3) or perirectal tissues (T4)	N0	M0
Stage IIIA	T1–4	N1	M0
Stage IIIB	T1–4	N2–3	M0
Stage IV	T1–4	N1–3	M1

history or physical examination that could serve as red flags for colon cancer are:

1. age greater than 50 years;
2. history of colon cancer in an immediate family member;
3. bowel disturbances (e.g., rectal bleeding or black stools);
4. unexplained weight loss; and
5. back or pelvic pain that is unchanged by positions or movement.[213]

Peptic Ulcer Disease

Peptic ulceration of the stomach or duodenum is often accompanied by abnormalities of the gastric mucosa, and the key to determining the cause of ulcer disease often lies in the histologic diagnosis of the associated gastritis or gastropathy.

T e terms ulcer disease and peptic ulcer are used synonymously to refer to erosions or ulcers of the stomach and duodenum.

Ulcer disease was long assumed to be idiopathic, caused by acid hypersecretion or psychologic stress, or a combination. Helicobacter pylori are now well recognized as a major risk factor for the development of peptic ulcer disease.[214]

T e patient usually describes a typical history of ulcers characterized by periodic symptoms, relief with antacids, and the relationship of pain to certain foods and the timing of meals. For example, the patient may have relief from pain after eating initially, but the pain then returns and increases 1–2 hours after eating when the stomach is emptied. In the pediatric age group, abdominal pain is a very common reason for seeking medical advice. It is also the most common presenting symptom of peptic ulcer disease. However, peptic and other erosive or ulcerative gastritides and gastropathies of the stomach and duodenum are relatively uncommon in this age group.[215]

T e pain of a peptic ulcer occasionally occurs only in the back between the 8th and 10th thoracic vertebrae. Duodenal ulcers may refer pain from the fifth thoracic vertebra, either at the midline or just at either side of the spine. T is localization may accompany penetration through the viscera (organs). When questioned further, the patient may indicate that blood is present in the feces.

T e differential diagnosis of ulcer disease includes esophagitis, gastritis, gastropathy, nonulcer dyspepsia, gallbladder or liver disease, pneumonia, and pancreatitis among others.[215]

CLINICAL PEARL

Sparkes et al.[216] developed two specific clusters of questions to be used in identifying patients with abdominal pain that is musculoskeletal in origin:

Cluster 1

1. Does coughing, sneezing, or taking a deep breath make your pain feel worse? (Yes)
2. Do activities such as bending, sitting, lifting, twisting, or turning over in bed make your pain feel worse? (Yes)
3. Has there been any change in your bowel habit since the start of your symptoms? (No)

Cluster 2

1. Does eating certain foods make your pain feel worse? (No)
2. Has your weight changed since your symptoms started? (No)

A patient answering yes to either of the first two and no to the third question of Cluster 1 suggests a high probability that abdominal pain is musculoskeletal in origin.

If the patient answers no to both questions in Cluster 2, in addition to corresponding responses to the questions in Cluster 1, there is an even greater probability that abdominal pain is musculoskeletal in origin.[216]

Acute Cholecystitis

Acute cholecystitis is the result of cystic duct obstruction by gallstones or biliary sludge. In this condition, ductal obstruction is soon followed by chemical inflammation and a superimposed infection of the gallbladder. Acute cholecystitis may refer intense, sudden, paroxysmal pain to the right scapula, mid-back, or right shoulder. Pain intensity often increases with movement or respirations. Rebound tenderness and abdominal muscle guarding are often present. A low-grade fever also may be present. T ere may be reports of nausea and vomiting. Finally, mild jaundice, which is more apparent in fair-skinned patients, may be observed in those experiencing acute cholecystitis.[217] T is finding is attributable to edema of the common bile duct, which causes bilirubin to diffuse across the inflamed gallbladder mucosa.[217]

Biliary Colic

Biliary colic is a common initial presentation of gallstone disease. T e pain of biliary colic is referred to the right posterior

upper quadrant, with pain in the right shoulder. There may be pain in the interscapular area, with referred pain to the right side. Occasionally, the pain beneath the right costal margin may be confused with the shoulder girdle pain secondary to intracostal nerve compression. The pain is initially intermittent. Pain usually recurs, but the interval to the next attack of pain is quite variable.

Severe Esophagitis

Gastroesophageal reflux disease is defined as symptoms or mucosal damage (esophagitis) resulting from the exposure of the distal esophagus to refluxed gastric contents. Esophageal pain has many patterns. It is often described as burning, sometimes as gripping, and it can also be pressing, boring, or stabbing. It may be associated with a foul taste, morning pain, worsening pain after a meal, and epigastric tenderness. Severe esophagitis may refer pain to the anterior chest. It tends to be felt mainly in the throat or epigastrium. On occasion, it can radiate to the neck, back, or upper arms—all of which may equally apply to cardiac pain.

Pancreatic Carcinoma

Pain is the most frequent symptom of a pancreatic carcinoma. It first may be noted as a paroxysmal (sudden, recurrent, or intensifying) or steady, dull pain, radiating from the epigastrium to the back. The pain is usually slowly progressive, is worse at night, and is unrelated to digestive activities. Other signs and symptoms may include jaundice, anorexia, severe weight loss, and gastrointestinal difficulties unrelated to meals. The disease is predominantly found in men (3:1) and occurs in the sixth and seventh decades.

Mediastinal Tumors

Most spinal tumors occur in the first half of life. Although primary tumors of the thoracic spine are rare, the thoracic spine is the most common site for metastases. Tumors occur in the thoracic spine because of its length and proximity to the mediastinum. The vascularization of the vertebrae in the mid-to-lower thoracic spine is generally through a watershed effect rather than by direct segmental arteries, which leaves the region susceptible to a secondary metastatic invasion from lymph nodes involved with lymphoma, breast, or lung cancer.[218,219]

Tumors of T12–L2 (typically, multiple myeloma) may compress the conus medullaris containing the S3–5 nerve roots. This may lead to an impairment of the urinary or anal sphincter, which is sometimes associated with saddle anesthesia.

Myocardial Infarction

Pain of myocardial origin, resulting from a sudden and complete occlusion of the coronary artery, frequently radiates over the left pectoral region, left shoulder, medial left arm, right upper extremity, epigastrium, and jaw and can, therefore, mimic musculoskeletal pain. The pain typically has a crushing or gripping quality over the substernal region. Angina pectoris pain, which is a symptom that represents an imbalance between myocardial perfusion and demand, may be exertional or variant, making it difficult for the clinician to recognize. The distribution of symptoms for angina pectoris includes substernal and chest pressure, shoulder pain, and neck or jaw pain, which worsens with exertion and improves with rest. This condition constitutes a medical emergency.

Pleuropulmonary Conditions

Pneumothorax

Pneumothorax is defined as the entry of air into the pleural space with secondary lung collapse.[220] The pleura is a thin serous layer that covers the lungs (visceral pleura). The pleural space extends from 3 cm above the midpoint of the clavicle down to the 12th rib overlying the kidney. Three types of pneumothorax may cause thoracic pain: spontaneous, iatrogenic, and traumatic.

Spontaneous pneumothorax, in contrast to iatrogenic and traumatic pneumothorax, occurs without any precipitating event. Primary spontaneous pneumothorax, seen in otherwise healthy individuals, is rarely life threatening. Secondary spontaneous pneumothorax, seen in patients with underlying lung disease, is a more serious condition and is associated with substantial mortality.

Several findings in the examination of the respiratory and cardiovascular systems may help establish the diagnosis of pneumothorax. Patients with pneumothorax present with pleuritic pain or breathlessness. The pain is localized to the side of the pneumothorax. This pain may be referred to the ipsilateral scapula or shoulder, across the chest, or over the abdomen. Pneumothorax may also be associated with hemoptysis (blood in sputum), tachycardia (increased heart rate), tachypnea (rapid respirations), and cyanosis (blue lips and skin resulting from lack of oxygen).[12] The patient may be most comfortable sitting in an upright position.

A chest radiograph is usually sufficient to confirm the diagnosis. Intervention can range from simple aspiration, tube drainage, and chemical sclerosis of the pleura to thoracoscopy and thoracotomy.

Pleural Effusion

Pleural effusion describes fluid (transudative or exudative) within the pleural space. Pleural effusion usually results from an underlying disease, such as heart failure, or from medical disorders leading to hypoalbuminemia.[221] It may also be caused by infection (bacterial or mycobacterial), malignancy, collagen vascular disease, pancreatitis, or pulmonary embolism.[222]

Pleural effusions may be asymptomatic but, if large, produce breathlessness or pain, or both.[221] Breath sounds are reduced on the affected side, and the percussion note is stony dull.[221]

Intervention usually involves drainage of the fluid.

Acute Disk Herniation

Disk lesions account for a high percentage of the causes of anterior and posterior thoracic pain syndromes (see Chapter 27).[223] Thoracic disk herniations do not have a characteristic clinical presentation, and the symptomatology may be confused with other diagnoses. In a review of the

literature, covering 280 cases of thoracic disk herniation,[224] only 23% had sensory symptoms, most commonly numbness, paresthesias, or dysesthesias. A thoracic disk herniation can produce posterior, anterior, or radicular (bilateral or unilateral) pain, which can be so severe as to mimic a myocardial infarction. All movements are severely limited and extremely painful and may reproduce radicular pain.

Vertebral Fracture

A high percentage of spinal fractures involve the thoracolumbar spine. Fractures of the thoracolumbar spine can be classified into four groups according to mechanism:

- Flexion compression (a wedge or compression *f*racture). Compression fractures are relatively benign because they involve only the anterior column, with varying degrees of middle and posterior column insult. T ey are thought to occur because of the relative stiffness of the thoracic spine compared with the greater mobility of the neighboring lumbar spine.[225] T ese fractures, which most commonly occur in the mid-low thoracic and mid-lumbar spine, are typically stable, unless severe. Diagnosis is confirmed with a lateral radiograph, which demonstrates anterior wedging. Burst fractures involve both the anterior and the middle columns and also may involve ligamentous or bony injury of the posterior column. Although the mechanism for this type of fracture is the same as for compression fractures, the axial loading is of a greater magnitude and typically is combined with flexion. Consequently, the anterior body undergoes a bursting effect, with retropulsion of part of the posterior vertebral body wall (middle column) into the canal, decreasing the canal size.[226]
- Axial compression. T is type usually results in a burst fracture involving the failure of both the anterior and the middle columns. Both columns are compressed, and the result is a loss of height of the vertebral body.
- Flexion distraction. T is type results in an injury called a Chance (or seatbelt) fracture, involving the failure of the posterior column with an injury to the ligamentous components, bony components, or both.
- Rotational fracture dislocation. T is type results from a combination of side flexion and rotation with or without the involvement of a posterior-anteriorly directed force. Osteoporosis causes fractures of the vertebrae.

Osteoporotic fractures are most common in the mid to low thoracic spine and result from the inability of the vertebral body to sustain the compression forces involved with everyday activities.[68] T e prevalence rate for these fractures increases steadily with age, ranging from 20% for 50-year-old women to 65% for older women.[227] Most vertebral fractures do not have a history of an identifiable trauma (sensitivity, 0.30).[40] Many patients remain undiagnosed and present with symptoms such as back pain and increased kyphosis. Fractures that occur at the levels of T1–10 can have associated damage to the spinal cord, whereas fractures at T11–12 can manifest as mixed spinal cord, conus medullaris, or spinal nerve root injuries.[228]

Rib Fracture

Rib fractures are very common in the blunt trauma population, with one review demonstrating that 10% of patients admitted to a level 2 trauma center had evidence of rib fractures.[229] However, the true incidence of rib fractures is not known, because up to 50% of rib fractures may be missed on a standard chest x-ray film.[230] T e primary symptom of a rib fracture is a pain on inspiration, resulting in hypoventilation (see Chapter 27).[228] On physical examination, there is local tenderness, crepitation, and, on occasion, a palpable defect.

Stress Fracture of the Rib

T ere are more reports of stress fractures of the first rib than any other single rib.[231] A contraction of the anterior scalene muscle produces bending forces at the subclavian sulcus, which is the usual site of the fracture.[232] T is mechanism usually occurs in overhead activities, such as pitching, basketball, tennis, or weightlifting.[233,234]

Pain occurs in the region of the shoulder, anterior cervical triangle, or clavicular region.[234] T e pain may radiate to the sternum or pectoral region. T e onset is usually insidious, although it may start with acute pain. Pain may occur with deep breathing.[235]

Tenderness to palpation may be present medial to the superior angle of the scapula, at the base of the neck, supraclavicular triangle, or deep in the axilla.[231] Shoulder movements may be painful or restricted.

T e recommended treatment of a first rib stress fracture involves immobilization of the shoulder girdle on the affected side with a sling.[231] Pain resolves within 2–8 weeks of immobilization.[234]

Stress fractures of the other ribs may also occur. T e most common cause is a change in technique or training load. T e examination may reveal local tenderness to palpation. Rib springing is usually positive for pain.

Intercostal Neuralgia

Neurogenic pain of the thorax can be the result of infection, such as varicella zoster (shingles), mechanical compression of the nerve by a disk protrusion, an osteophyte, a neuroma, a fracture, or a condition called postherpetic neuralgia. Neuralgic pain, which typically has a burning quality, is unchanged by analgesics or rest.

Epidemic Myalgia

Epidemic myalgia, also known as epidemic pleurodynia or Bornholm disease, is characterized by the abrupt onset of either chest or abdominal pain, usually accompanied by fever, and was first described in the late 1800s.[236] T is acute viral illness is caused mainly by Coxsackie B virus, but other enteroviruses may be implicated.[231] T e mode of transmission is via a shared water source,[237] and there is a 3–5-day incubation period. Peak incidence is in the soccer and American football seasons, and outbreaks involving athletic teams have been reported.[237]

The presentation usually follows a nonspecific prodromal illness (early set of symptoms), with sudden onset of a sharp lateral chest or abdominal pain.[231] The intercostal and upper abdominal wall muscles are most commonly involved, with the pleura being involved rarely.[238] The pain is intermittent and exacerbated by movement, coughing, and deep inspiration, and is typically accompanied by fever and malaise.[231]

Diagnosis is made by isolation of the virus from the feces, or on throat swab, in the early stages of the disease. The condition is self-limiting and rarely requires any specific treatment.[231] Symptoms usually resolve after a few days but may recur.

Costochondritis

Costochondritis is a common but poorly understood condition that manifests as chest wall pain. It is usually characterized by pain and tenderness in the costochondral or chondrosternal joints in the absence of swelling. The second to fifth costal cartilages are the most commonly affected.[238]

Diagnosis is based on a history of chest pain with associated anterior chest wall tenderness that is localized to the costochondral junction of one or more ribs. Swelling, heat, and erythema usually are absent. The pain may be provoked by certain movements, such as adduction of the arm on the affected side, with accompanying rotation of the head to the same side.[231]

Costochondritis is a mostly benign, self-limiting condition. Symptoms usually resolve within 1 year.[239]

Osteoarthritis

OA of the thoracic spine affects three sites: the intervertebral disk, the zygapophyseal joints, and the articulations of the rib with the vertebral body and transverse process.[223]

Osteoarthritic changes in the zygapophyseal and costovertebral joints occur most commonly at T11 and L1, which coincides with those joints whose orientation is more sagittal, and the area that sustains the peak incidence of traumatic fractures in the thoracic spine.[225,240] OA of the costovertebral and costotransverse joints is a frequent source of chronic pain but is not typically associated with neurologic changes.[223] This is consistent with local pain and tenderness at the site of degeneration. Rib joint pain typically is exacerbated by exaggerated respiratory movements.[241]

Spondylosis, disk degeneration, and Schmorl nodes (see Chapter 27) are most frequently encountered within the T10–12 vertebrae,[240] probably as a result of reduced resistance to torsion in this area.[190]

The relationship between zygapophyseal joint orientation and OA suggests that repeated torsional trauma might well have a significant role in the development of OA in zygapophyseal joints that are sagittally oriented.[240]

Rheumatoid Arthritis

Thoracic pain related to RA is associated with pain and stiffness that is greatest in the morning and usually improves with movement.[223,242] Inspection usually shows a flat thoracolumbar spine, and a gross limitation of side flexion in both directions is demonstrated.

Ankylosing Spondylitis

See section "Ankylosing Spondylitis" earlier in the chapter.

Diffuse Idiopathic Skeletal Hyperostosis

Diffuse idiopathic skeletal hyperostosis, or Forestier disease, is a metabolic disease that typically affects men older than 40 years and does not usually result in severe disability.[243] The disease is characterized by an ossification of the anterior longitudinal ligaments and all related, anatomically similar ligaments,[223] without marked disk disease, which results in overall stiffness of the spine, particularly in the morning, and palpable tenderness.

Manubriosternal Dislocations

Traumatic disruption of the manubriosternal joint most often occurs via one of two mechanisms.[244,245] The first and most common mechanism results from a direct compression injury to the anterior chest. The direction of applied force displaces the fragment posteriorly and downward. The second type of mechanism follows hyperflexion with compression injury to the upper thorax. The force is transmitted to the sternum through the clavicles, chin, or upper two ribs.

CAUSES OF LUMBAR PAIN

Lumbar pain is most commonly caused by mechanical dysfunction, which can be defined as symptoms that are related to the musculoskeletal system and vary with movement. However, serious nonmechanical spinal disorders (e.g., neoplasm, infection, inflammatory arthritis, fracture) or visceral disease (e.g., gastrointestinal, genitourinary, vascular) may be the cause of LBP in a small percentage of patients (Fig. 5-2 and Table 5-12).[246]

Renal Origin

The pain of renal origin is associated with pelvic, flank, or LBP.

Acute Pyelonephritis

See the discussion of pyelonephritis under "Causes of Head, Face, Eye, and Temporomandibular Joint Symptoms" earlier.

TABLE 5-12 Potential Causes of Lumbar Pain

Renal dysfunction
Colorectal cancer
Epidural abscess and epidural hematoma
Sacroiliitis
Metastasis
Maigne syndrome

Prostatitis
Pleural dysfunction
Ankylosing spondylitis
Stiff-person syndrome

Renal Cortical Abscess

Renal abscess has been described as an elusive diagnosis in patients with variable symptoms of insidious onset. T is condition can cause flank pain, chills, and fever and may be associated with a history of recent infection.

Urologic management of renal abscesses includes surgical exploration, percutaneous drainage, intravenous antibiotic therapy, or nephrectomy.[247,248]

Acute Glomerulonephritis

T is condition occasionally can manifest with bilateral flank pain, costovertebral angle tenderness, and fever. Malaise, fatigue, anorexia, and nausea frequently accompany this condition.

Ureteral Colic

Ureteral colic causes constant severe pain in the right lower abdomen. T e pain is caused by the passage of a calculus (kidney stone), blood clot, or tissue fragment in the lower half of the ureter. T e pain, which may be intermittent, radiates down the course of the ureter into the urethra or groin area. Accompanying signs and symptoms include nausea, vomiting, sweating, and tachycardia.

Kidney stones are associated with conditions of hypercalcemia (excess calcium in the blood) such as hyperparathyroidism, metastatic carcinoma, multiple myeloma, senile osteoporosis, specific renal tubular disease, hyperthyroidism, and Cushing disease.[12] Other conditions associated with calculus formation are infection, urinary stasis, dehydration, and excessive ingestion or absorption of calcium.[12]

Urinary Tract Infection

A urinary tract infection (UTI) affecting the lower urinary tract is related directly to an irritation of the bladder and the urethra. T e intensity of symptoms depends on the severity of the infection, and, although LBP may be the patient's chief complaint, further questioning usually elicits additional urologic symptoms, such as urinary frequency, urinary urgency, or hematuria. T e diagnosis of UTI is based on symptoms and the presence of pathogens and white blood cells in the urine.

Epidural Abscess

Most spinal epidural abscesses or infections are thought to result from the spread of bacteria, usually from a cutaneous or mucosal source. Infection in the spinal epidural space is an uncommon but potentially fatal condition that often constitutes a surgical emergency. T e infectious agent may enter the epidural space by several routes:[249]

- Insertion of an epidural needle and catheter
- Migration along the outside of a catheter
- Local spread through soft tissue and bone
- Hematogenous spread
- Injection or infusion of contaminated fluid

Early diagnosis is essential for successful treatment.[250] T e diagnosis of a spinal abscess can be difficult because of its rarity and the insidious presentation. T e signs and symptoms may develop slowly over days to several weeks. Fever is not always present.[251] Localized back pain or radicular pain is frequently the first sign of epidural infection.[251,252] T is initial finding is followed by progressive radicular and cord compression signs.[251,252] Pain is the most consistent symptom and occurs in virtually all patients at some time during their illness.[250]

Intervention depends on the cause and ranges from antibiotic therapy to surgery.

Prostatitis

Prostatitis is an inflammation of the prostate gland. T e cause of the inflammation is usually infection, which can be bacterial or nonbacterial. In acute bacterial prostatitis, patients complain of a sudden onset of fever, chills, and low back or perineal pain. Typically, dysuria, frequency, or hesitancy is present. Patients with chronic bacterial prostatitis may have no systemic symptoms; that is, they may not have fever or chills, although complaints of perineal or LBP usually are present. Patients with nonbacterial prostatitis have a variable presentation and lack systemic symptoms. T ese patients have mild pain and may have voiding symptoms.

Differential diagnosis includes prostatodynia, cystitis, urethritis, and benign prostatic hypertrophy.

Pleural Dysfunction

Although usually associated with thoracic pain, pleuritic pain can produce right lower abdomen pain. T e cause is usually pneumonia or pulmonary embolism. T e symptoms accompanying pneumonia include fever, coughing, rales, wheezes, chills, and purulent sputum. Pulmonary embolism is usually associated with dyspnea, fever, cough, rales, and wheezes. High-risk patients for pulmonary embolism include those with recent:

- trauma;
- surgery;
- pregnancy;
- heart failure;
- malignancy;
- previous embolism;
- prolonged travel in automobile or airplane; and
- prolonged immobilization.

Abdominal Aortic Aneurysm

T e anatomy of the aorta is segmentally described in three sections: ascending aorta, aortic arch, and descending aorta. T e portion of the aorta above the diaphragm is designated as thoracic, and the abdominal aorta is that portion below the diaphragm. T e abdominal aorta gives rise to lumbar and musculophrenic arteries, renal and middle suprarenal arteries, and visceral arteries.

T e aorta consists of three layers: adventitia (the outermost), media, and intima. An acute aortic dissection is caused by a transverse disruption in the intima and media.[253] T is disruption results in the formation of a hematoma within the media. Aortic aneurysms can be described as either fusiform (circumferential dilatation) or saccular (balloon-like).[254]

T e underlying causes of aortic disease are not fully understood and are therefore associated with many factors, including

atherosclerosis, hypertension, medial degeneration and aging, aortitis, congenital abnormalities, trauma, smoking, cellular enzyme dysfunction, and hyperlipidemia.[253] Major risk factors include hypertension, and age greater than 60 years, male sex, past history of smoking, atherosclerosis, coronary artery disease, family history of AAA, and use of statins.[246] Factors that are negatively associated with AAA include female sex, black race, and diabetes.[246]

Acute aortic dissection is characterized by the onset of intense pain, described as sharp, tearing, or stabbing. T e pain occurs in the chest and spreads toward the back and into the abdomen and is unaffected by position. However, during the physical examination, overpressure into hip flexion may reproduce symptoms. [246] In addition, during abdominal palpation, a very strong, nontender abdominal pulsation may be detected.[246] Distal pulses frequently are decreased or absent. By convention, an infrarenal aorta that is 3 cm in diameter or larger is considered aneurysmal.[255] T e diameter of the infrarenal aorta is the strongest known predictor of risk for rupture.[246] T is is a potentially life-threatening condition, requiring immediate transport of the patient to an emergency department. T e patient is admitted to the intensive care unit for further evaluation and to temporarily manage the crisis with antihypertensive medications.[253]

Metastasis

Malignant neoplasm (primary or metastatic) is the most common systemic disease affecting the spine, although it accounts for less than 1% of episodes of LBP.[40] Metastatic lesions affecting the lumbar spine occur most commonly from the ovary, breast, kidney, thyroid, lung, or prostate gland. According to a study by Deyo and Diehl[256] that reviewed 1,975 consecutive patients seeking medical care for LBP, the four clinical findings with the highest positive likelihood ratios for detecting the presence of cancer resulting in LBP were a previous history of cancer, failure to improve with conservative medical treatment during the past month, an age of at least 50 years or older, and unexplained weight loss of more than 4.5 kg (10 lb) in 6 months.[256] T e absence of all four of these findings confidently rules out malignancy.[256,257]

Spondylolisthesis

T e term spondylolisthesis refers to an anterior slippage and inability to resist shear forces of a vertebral segment in relation to the vertebral segment immediately below it, which usually occurs in the lumbar spine due to a defect in the pars. T e most common site for spondylolysis and spondylolisthesis is L5–S1 (see Chapter 28).

Differential diagnosis includes coexisting OA of the hip, myelopathy, spinal tumors, and infections.

Ankylosing Spondylitis

See section "Ankylosing Spondylitis" earlier in the chapter.

Stiff-Person Syndrome

Stiff-person syndrome (SPS), also known as Moersch–Woltmann syndrome, or stiff-man syndrome is a rare, disabling neurological disorder characterized by rigidity and fluctuating muscle spasms, which is often underdiagnosed because of a lack of awareness of its clinical manifestations. T e condition primarily impacts the actual musculature and lower extremities, although variants of the syndrome may involve one limb only (stiff-leg syndrome) or a variety of additional neurological symptoms and signs such as eye movement disturbances, ataxia, or Babinski signs (progressive encephalomyelitis with rigidity and myoclonus) or be associated with malignant disease (paraneoplastic SPS).[258] T e etiology of SPS is unknown, but an autoimmune-mediated chronic encephalomyelitis (elevated levels of antibodies to glutamic acid decarboxylase [GAD]) is suggested due to its frequent association with other autoimmune disorders such as type 1 diabetes or thyroiditis. Patients with SPS have too little gamma-aminobutyric acid (GABA), which is an inhibitory neurotransmitter involved in skeletal muscle contraction together with its antagonist norepinephrine (see Chapter 9). T e lack of GABA results in disproportionately high levels of norepinephrine and increasing pulses to LMNs, which in turn result in continuous contraction of antagonist musculature.[259]

SPS, which affects both sexes equally, has an insidious onset, usually in the fourth or fifth decades, with a slow progression over months or years, followed by long-lasting stabilization. SPS is characterized by fluctuating symmetrical muscle rigidity and back pain with superimposed painful episodic spasms of the axial and proximal limb muscles.[260]

- T e muscle rigidity associated with SPS can lead to contractures, postural abnormalities, and simultaneous contraction of the thoracolumbar paraspinal and abdominal wall muscles causes lumbar hyperlordosis.
- T e episodic spasms, which are often provoked by noise, touch, emotional upset, or sudden movement, may manifest as an excessive startle reaction. T ese spasms can be violent enough to cause excruciating pain and, in rare cases, generate forces capable of fracturing long bones. Patients with SPS may exhibit excessive fear and avoidance of circumscribed situations that are assumed by patients to be difficult to master because of an increase in stiffness, and paroxysmal spasms.[261] Such situations include crossing a street, climbing downstairs without banisters, or walking unaided. T e gait is often wide-based, deliberate, and slow. T e rigidity and spasms gradually impair voluntary movements and postural reflexes, resulting in slow, restricted movements and an increased risk of falls. Patients may be incapacitated by the phobia to the same degree as the motor symptoms themselves. It has been suggested that the presence of this particular anxiety is one of the reasons for the frequent misdiagnosis of psychogenic movement disorder in these patients.[261]

Intellect is not affected, and motor and sensory nerve examination is also normal. However, almost all patients have an abnormal electromyographic (EMG) pattern, which shows continuous motor unit activity in affected muscles. Stiffness and spasms resembling SPS may occur as dominant symptoms in a variety of recognized neurological diseases such as MS, brain stem or spinal cord tumors, and paraneoplastic or circulatory diseases of the spinal cord.[258]

The mainstays of treatment for SPS are drugs that enhance GABA-mediated central inhibition (diazepam, baclofen, sodium valproate, and vigabatrin). Physical therapy can include gentle lumbar flexion exercises to help reduce lumbar hyperlordosis, stretching of the Achilles and hamstring tendons to prevent contractures, antispastic measures, and isometric abdominal exercises to help mobilize the trunk.[262–264] SPS should be considered in all patients with unexplained back pain, stiffness, and muscle spasms, as early recognition and therapeutic intervention can significantly decrease morbidity and improve the quality of life.

CAUSES OF BUTTOCK AND UPPER AND LOWER LEG PAIN

The causes for buttock and upper and lower leg pain include those listed in Figure 5-2 and Table 5-13.

Lumbar Disk Herniation

See Chapter 28.

Femoral Nerve Neuropathy

Femoral neuropathy has been described as a complication of compression resulting from:[265]

- hematoma;
- hemophilia;
- leukemia;
- hysterectomy and pelvic surgery;
- lithotomy position;
- blunt trauma;
- iliac artery aneurysm;
- inguinal herniorrhaphy;
- malignancy and radiation therapy;
- Epstein–Barr virus infection; and
- diabetes mellitus.

Typical signs of femoral neuropathy are a weakness of ipsilateral hip flexion, knee extension, and paresthesias of the anteromedial thigh. Symptoms may vary with both degree and location of the injury. The more distal injuries may have either sensory or motor symptoms whereas the proximal injuries tend to have both. A decreased or absent knee jerk is usually present. The differential diagnoses of upper lumbar nerve root symptoms include spondylolisthesis, disk prolapse, or an infective cause such as diskitis or an epidural abscess.

TABLE 5-13 Potential Causes of Buttock and Upper and Lower Leg Pain

Femoral nerve neuropathy

Sacroiliitis
Mononeuritis multiplex
Ischial apophysis and avulsion
Gluteal compartment syndrome
Genital herpes
Vascular disorders

Piriformis Syndrome

The "piriformis syndrome," a fairly common but often undiagnosed cause of buttock and leg pain, has been described as an anatomic abnormality of the piriformis muscle and the sciatic nerve, which can result in irritation of the sciatic nerve by the piriformis muscle causing buttock and hamstring pain. Piriformis syndrome may also be described as a sensation in which the hamstring muscles feel "tight" or are "about to tear."[266]

Multiple etiologies have been proposed to explain the compression or irritation of the sciatic nerve that occurs with the piriformis syndrome:[267]

- Hypertrophy of the piriformis muscle.[268,269] It has been reported that the sciatic nerve courses directly through this muscle in 14% of the population.[270,271]
- Overuse of the piriformis muscle. Although there is disagreement, overuse seems to be the most common cause of piriformis syndrome.[272] This is suggests that patients must be effectively cautioned about returning too quickly to the type of activity that bought about the piriformis syndrome once recovered.
- Trauma.[273–275] Trauma, direct or indirect, to the sacroiliac or gluteal region can lead to piriformis syndrome and is a result of hematoma formation and subsequent scarring between the sciatic nerve and the short external rotators.
- Hip flexion contracture. A flexion contracture at the hip has been associated with piriformis syndrome. This is flexion contracture increases the lumbar lordosis, which increases the tension in the pelvic–femoral muscles, as these muscles try to stabilize the pelvis and spine in the new position. This is increased tension causes the involved muscles to hypertrophy with no corresponding increase in the size of the bony foramina, resulting in neurological signs of sciatic compression.[276]
- Gender. Females are more commonly affected by piriformis syndrome, with as much as a 6:1 female-to-male incidence.[275,277–280]
- Ischial bursitis.
- Pseudoaneurysm of the inferior gluteal artery.[273]
- Excessive exercise to the hamstring muscles.[281]
- Inflammation and spasm of the piriformis muscle.[282] This is often in association with trauma,[268,283] infection, and anatomical variations of the muscle.[276,284,285]
- Anatomical anomalies. In 1938, anomalies of the piriformis muscle, with a subsequent alteration in the

relationship between the piriformis muscle and the sciatic nerve, were implicated in sciatica.[284] Local anatomical anomalies may contribute to the likelihood that symptoms will develop. Patients with this condition report radicular pain that is much like the nerve–root pain associated with lumbar disk disease with the movement of the hip.[286] T ese patients typically present with a history of gluteal trauma, symptoms of pain in the buttock and intolerance to sitting, tenderness to palpation of the greater sciatic notch, and pain with flexion, adduction, and internal rotation of the hip.

As early as 1937, two findings on physical examination were attributed to sciatic pain, with the piriformis as the cause[287]:

1. Positive straight-leg raise (pain in the vicinity of the greater sciatic notch on the extension of the knee, with the hip flexed to 90 degrees and tenderness to palpation of the greater sciatic notch).
2. Freiberg sign (pain with the passive internal rotation of the hip, which places tension on the piriformis muscle).

Robinson[283] has been credited with introducing the term pirif*o*rmis syndrome and outlining its six classic findings:

1. A history of trauma to the sacroiliac and gluteal regions.
2. Pain in the region of the sacroiliac joint, greater sciatic notch, and piriformis muscle that usually causes difficulty with walking.
3. Acute exacerbation of pain caused by stooping or lifting (and moderate relief of pain by traction on the affected extremity with the patient in the supine position).
4. A palpable sausage-shaped mass, tender to palpation, over the piriformis muscle on the affected side.
5. A positive straight-leg raise.
6. Gluteal atrophy, depending on the duration of the condition.

Other clinical signs have since been introduced. Pace and Nagle[275] described a diagnostic maneuver that is now referred to as the Pace sign: pain and weakness in association with resisted abduction and external rotation of the involved thigh.

Local muscle spasm usually is palpable in the obturator internus or, less commonly, in the piriformis muscle. T e neurologic examination is usually normal, although there may be neurologic symptoms in the posterior lower limb if the fibularis (peroneal) component of the sciatic nerve is involved.[266] An examination of the hip and lower leg usually demonstrates restricted hip adduction and internal rotation of the hip, and lumbosacral muscle tightness.[266] T e FABER (flexion, abduction, external rotation) test may be positive (see Chapter 29). Typically, piriformis syndrome is a diagnosis of exclusion.

Conservative intervention for this condition includes gentle, pain-free static stretching of the piriformis muscle, strain–counterstrain techniques, soft-tissue therapies (longitudinal gliding combined with passive internal hip rotation, as well as transverse gliding and sustained longitudinal release, with the patient lying on one side), ice massage to the gluteal region, and spray and stretch techniques.[288,289] Local corticosteroids or botox injections may be useful in more acute cases.[290] Botulinum neurotoxins, injected into the myoneural junctions of intrafusal muscle fibers, have been successfully used in clinical practice to reduce the strength of idiopathic muscular spasm and muscle tightness caused by overuse, trauma, or occupation in the piriformis muscle.[291–293] One study showed that this form of injection followed by physical therapy significantly shortens recovery time, thereby reducing both the patient's pain and treatment time.[293]

Sacral Plexopathy

T e sciatic nerve is the most frequently injured lower extremity nerve. Sciatic nerve compression has been reported secondary to piriformis entrapment, heterotopic ossification around the hip,[294] a ruptured aneurysm, retroperitoneal bleeding, pelvic fracture, dislocation or fracture of the hip, tumor, misplaced intramuscular injections, myofascial bands in the distal thigh,[295] and myositis ossificans of the biceps femoris muscle.[296] Additional causes include posttraumatic or anticoagulant-induced extraneural hematomas[297] and compartment syndrome of the posterior thigh.[298] Entrapment sciatic neuropathy complicating total hip arthroplasty has been described secondary to escaped cement, subfascial hematoma, and nerve impingement during trochanteric wiring.[299]

In the usual situation, the patient complains of an immediate onset of painful paresthesia, radiating down the posterior and posterolateral thigh and calf, and into the foot. Differential diagnosis also includes an L5–S1 radiculopathy caused by a herniated disk or zygapophyseal joint disease with lateral recess or foramen stenosis.

Intermittent Claudication

T e blood supply of the lumbar and sacral plexuses usually derives from branches of the internal iliac artery (iliolumbar artery, superior and inferior gluteal artery, and lateral sacral artery) and the deep iliac circumflex artery.[300] Acute ischemic impairments of the lumbosacral plexus are caused by high-grade stenosis and occlusion of the iliac arteries or of the distal abdominal aorta.

T e most frequent cause of such acute ischemic impairments of the lumbosacral plexus is during surgery of the aortic bifurcation and the pelvic arteries, or radiation therapy.[301] Finally, intraarterial injections into the iliac arteries or gluteal arteries may result in persistent ischemic plexopathy.[302]

Reduced perfusion of the area of the internal iliac artery can result in a temporary ischemic impairment of the lumbosacral plexus. T is impairment occurs only during muscular activity of the legs. In this condition, the pain is mostly localized to the pelvis and is followed by paresthesia, a diminishing of the muscle stretch reflexes, with possible motor weakness. T is special type of intermittent claudication is usually associated with stenosis of the pelvic arteries, including the internal iliac arteries.[302]

T e diagnosis is confirmed by changes in the lumbar motor-evoked potentials after exertion. T ese changes exclude the diagnosis of ischemia of the lower spinal cord or conus medullaris.

Peripheral nerves have a high tolerance to ischemia because of collateral circulation.[303] However, during leg activity, the muscles supplied by branches of the external iliac arteries

experience a steal phenomenon that privileges the leg muscles over the pelvic organs.[302]

Although the neurologic examination of the inactive patient usually discloses no abnormality, the clinical diagnosis of this type of intermittent claudication caused by exercise-induced ischemia of the lumbosacral plexus is based mainly on two specific features:[302]

1. T e symptoms appear in correlation with the degree of muscle activity. In early stages of the disease, complaints only occur during walking uphill or riding a bicycle. T is allows a distinction from the intermittent claudication caused by spinal stenosis. In the latter, symptoms predominantly appear during walking downhill. In addition, patients with spinal stenosis can ride a bicycle for a long distance without complaints (see the bicycle test of van Gelderen in Chapter 11).
2. In addition to pain, progressive sensorimotor deficits in the area of the lumbosacral plexus occur during exertion. T is cannot be seen in patients with the peripheral arterial occlusive disease.

Conus Medullaris Syndrome

Conus medullaris syndrome results from an injury to the spinal cord. T e injury can be caused by trauma, such as bone or bullet fragments. It may also result from cyst formation, aortic surgery, and vascular disease.

T e symptoms include severe low back and buttock pain, lower limb weakness, and saddle hyperesthesia or anesthesia. Bowel and bladder changes are also frequently reported.

Meralgia Paresthetica

T e term meralgia paresthetica comes from the Greek words meros (thigh) and algos (pain). Meralgia paresthetica is a syndrome of pain and/or dysesthesia caused by entrapment or neurinoma formation of the lateral cutaneous (femoral) nerve (LCN) of the thigh (see Chapter 3).[304–306] It is also known as Bernhardt–Roth syndrome. Although more commonly involving the LCN, meralgia paresthetica can also occur to other nerves that traverse the hip, such as the ilioinguinal, genitofemoral, obturator, and anterior cutaneous nerves of the thigh.[289]

T e LCN is primarily a sensory nerve but also includes efferent sympathetic fibers carrying vasomotor, pilomotor, and sudomotor impulses.[307] It is quite variable and may be derived from several different combinations of lumbar nerves, including L2 and L3, L1 and L2, L2 alone, and L3 alone.[308] T e LCN may be associated with the femoral nerve as it passes through the inguinal ligament, or it may anastomose with the femoral nerve distal to the inguinal ligament.[306]

T e compression of the nerve, which is most common in middle-aged men, may be at the level of the roots, but it may also be compressed along the retroperitoneal course.

Numerous direct and indirect causes of the disease have been suggested in the literature, including:[309–313]

- obesity;
- ascites;
- direct trauma;
- abdominal distention, including pregnancy;
- abdominopelvic tumors or inflammations; it may occur as the first sign of a lumbar cord tumor;
- metastatic carcinoma in the iliac crest;
- anatomic variation at the site of passage;[311]
- retroperitoneal tumors;
- leg-length discrepancy;
- idiopathic causes;
- tight clothing around the waist;
- complications after thoracoabdominal surgery; and
- complications after iliac bone graft harvesting.

Toxic and metabolic disorders, such as diabetes mellitus, alcoholism, and lead poisoning, which have been reported to be causative in several cases, have all been described to increase susceptibility of individual peripheral nerves, including the LCN, to mechanical insults.[314,315]

Neuropathy of this nerve may cause pain, numbness, and dysesthesia in the anterolateral aspect of the thigh, which is most marked in walking, standing, and sleeping in the prone position.[316] Sitting may relieve the symptoms in some patients but exacerbate them in others depending on the cause. Eventually, no position provides relief. Patients may have secondary hip, knee, and calf pain. Entrapment of the lateral cutaneous nerve of the thigh can also be the cause of chronic groin pain.[317–319]

Differential diagnosis includes back, hip, and groin pathology. Meralgia paresthetica symptoms may be confused with more frequently seen symptoms produced by entrapment of the upper lumbar nerve roots.[320,321]

Intervention is dependent on the cause.

Iliofemoral Thrombophlebitis

T rombophlebitis of the superficial veins of the leg is usually regarded as a mild and uncomplicated disease. Although this is generally true in the case of acute thrombosis of the branches of the saphenous vein, the natural history of superficial venous thrombophlebitis involving the main trunk may not be as benign. T e relationship between superficial venous thrombophlebitis and deep venous thrombosis (DVT) with attendant pulmonary embolus has become the focus of more recent studies. An association with DVT has been reported with frequencies of 12–44%,[322] and there have been several reports of pulmonary embolism in thrombophlebitis.[323]

T e clinical signs and symptoms of iliofemoral thrombophlebitis include generalized leg pain, bluish discoloration, and swelling of the lower extremities. T is condition may also be associated with acute lower abdominal, groin and flank pain, fever, chills, and localized tenderness.

Mononeuritis Multiplex

Mononeuritis multiplex can occur in association with a number of other medical conditions, including RA, vasculitis, polyarteritis nodosa, diabetes mellitus, sarcoidosis, and amyloidosis. An ischemic mechanism is the most likely cause of mononeuritis multiplex. It is generally accepted that mononeuritis multiplex in RA results from ischemia caused by vasa nervorum vasculitis. Involvement of peripheral nerves

precedes involvement of the CNS. The classic symptoms for mononeuritis multiplex include a sudden onset of severe aching, burning or lancinating leg pain, paresthesias, sensory loss, and motor weakness.[324] The symptoms can involve one or more nerves in each leg, usually in an asymmetric pattern.[324]

Ischial Apophysitis and Avulsion

The ischial apophysis constitutes the insertion of the hamstrings and the adductor magnus muscles (see Chapter 19). Ischial tuberosity pain may be caused by several clinical entities, which include acute and old bony or periosteal avulsions and apophysitis. The clinical diagnostic criterion for ischial apophysitis consists of a gradual increase in functional and palpatory pain at the ischial tuberosity, without any major trauma at the beginning of the symptoms. Usually, there is asymmetry on plain radiographs of the ischial tuberosities in apophysitis. The radiograph demonstrates a sclerotic area and osteoporotic patches on the lower margin of the ischial tuberosity. Patients with an avulsion usually report an acute traumatic incident. An avulsion fragment may be visible on plain radiograph immediately after injury or later. The pain is usually local but may also radiate down the thigh. Active or resisted knee flexion increases the pain unless the avulsion is complete. Complete avulsions can be painless.

The healing process of an avulsion may lead to a heterotrophic bone formation.

Differential diagnosis includes intervertebral disk disease, piriformis syndrome, ischial bursitis, and pubic arch stress fracture.

Conservative intervention for apophysitis consists of a modification of activities. Avulsions require at least 1 month of rest from training, depending on the displacement. Urgent surgical intervention is recommended in cases of a complete or nearly complete soft-tissue avulsion of the hamstring muscle.[325]

Gluteal Compartment Syndrome

The characteristic finding of a gluteal compartment syndrome is a tense, swollen buttock following a mechanism of severe contusion, such as a fall from a height.[326] The swelling in the buttock can result in necrosis of the gluteal muscles or sciatic neuropathy, or both. The patient should be referred immediately to an orthopaedic surgeon. A fasciotomy is typically performed if the pressure within the gluteal compartment is 30 mm Hg or higher for a duration of 6–8 hours.[327]

Genital Herpes

Genital herpes is a chronic, viral, sexually transmitted disease for which there is no cure. It affects over 30 million people in the United States and continues to increase worldwide.[328] The majority of individuals are asymptomatic; however, some present with painful and recurrent genital lesions and systemic complications. As a chronic illness, the individual's response to the disease may produce serious psychosocial morbidity.[329] Women are more likely to have genital herpes than men.[330]

Vascular Disorders

Gradual obstruction of the aortic bifurcation produces:[12]

- bilateral buttock and leg pain;
- weakness and fatigue of the lower extremities;
- atrophy of the leg musculature;
- absent femoral pulses;
- color and temperature changes in the lower extremities;
- pain that is often aggravated with lumbar extension;
- a pulsing sensation in the abdomen. On occasion, an abdominal aortic aneurysm (AAA) can cause severe back pain. Prompt medical attention is imperative because rupture can result in death. The patients are usually men in their sixth or seventh decade, who present with a deep, boring pain in the mid-lumbar region. Other historical clues of coronary disease or intermittent claudication of the lower extremities may be present. An examination may reveal a pulsing abdominal mass; and
- peripheral pulses may be diminished or absent.[331]

Involvement of the femoral artery along its course, or at the femoral–popliteal junction, produces:[12]

- thigh and calf pain;
- absent pulses below the femoral pulse.

Obstruction of the popliteal artery or its branches produces pain in the calf, ankle, or foot.

CAUSES OF PELVIC PAIN

The causes of pelvic pain include those listed in Figure 5-2 and Table 5-14.

Sacroiliac Arthritis

Sacroiliac arthritis is characterized by pain in the posterior aspect of the sacrum, or by groin pain (uncommon), which can radiate into the posterior thigh. The pain is usually increased with walking, either at heel strike or at midstance. Frequently the pain wakes the patient when turning in bed.

Lumbar extension is the most painful motion, ipsilateral side bending and rotation less so, and flexion least of all. If the pain is increased with unilateral weight bearing or hopping but is reduced if a sacroiliac belt is worn, sacroiliac joint arthritis may be present.

TABLE 5-14 Potential Causes of Pelvic Pain

Sacroiliac arthritis
Acute appendicitis
Iliopsoas abscess
Iliopsoas hematoma
Sign of the buttock
Gynecologic disorders
Prostate cancer

T e sacroiliac joint stress tests described in Chapter 29 are used to help with the clinical diagnosis. Imaging studies are used to confirm the diagnosis.

Acute Appendicitis

T is condition frequently begins with dull and aching pain in the right lower abdomen. T e pain is intensified by walking, coughing, and trunk movements. T ere is usually an associated low-grade fever. Dysuria, diarrhea, constipation, or increased urinary frequency also may be reported. T e patient is often able to localize the pain to McBurney point, which is located by palpation at the midpoint between the anterior superior iliac spine and the umbilicus.

Less common signs include rectal or testicular tenderness and right lower abdominal skin hyperesthesia.

Iliopsoas Abscess

T e pain associated with an iliopsoas abscess occurs in the right lower abdomen. T e pain is usually mild to moderate and is increased with hip extension and palpation in the right iliac fossa. T e abscess is caused by an infection of the thoracolumbar spine, such as tuberculosis, or is secondary to an intestinal disorder, such as Crohn disease.[332]

Iliopsoas Hematoma

Hematomas are more frequently seen in the iliacus muscle than the psoas.[333] T e causes of these hematomas include:

- heparin anticoagulation or DVT prophylaxis therapy;
- hemophilia;
- trauma from either a direct blow to the abdomen or a hyperextension moment at the hip, such as occurs in a slip or fall.

Nontraumatic hematomas often manifest insidiously with no obvious lesion or ecchymosis. Patients initially may complain of flank pain but frequently will develop motor and sensory deficits along the femoral nerve distribution of the affected side. Flank pain refers to pain in the side of the trunk between the right or left upper abdomen and the back. A palpable lower abdominal mass may be present, depending on the size and location of the hematoma.

Iliopsoas hematomas have been successfully managed with conservative treatment. T is intervention involves bed rest for 24–48 hours, followed by a gentle hip range-of-motion exercise. Progressive strengthening exercises are then initiated according to patient tolerance.

T e surgical intervention involves the evacuation of the clot.

Sign of the Buttock

T e sign of the buttock is not technically a cause of pain but is, rather, a collection of signs indicating a serious pathology present posterior to the axis of flexion and extension in the hip.[334] Among the causes of the syndrome are osteomyelitis, infectious sacroiliitis, fracture of the sacrum or pelvis, septic bursitis, ischiorectal abscess, gluteal hematoma, gluteal tumor, and rheumatic bursitis.

T e sign of the buttock typically includes almost all of the following:

- Limited straight-leg raising
- Limited hip flexion
- Limited trunk flexion
- Noncapsular pattern of restriction at the hip
- Painful and weak hip extension
- Gluteal swelling
- Empty end-feel on hip flexion

Greenwood et al.[335] have suggested that a noncapsular pattern of the hip in the presence of a positive sign of the buttock indicates that the pathology is not amenable to a physical therapy intervention.

Gynecologic Disorders

Gynecologic disorders have the potential to cause midpelvic or low back discomfort.

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is the general term describing endometritis, salpingitis, tuboovarian abscess, or pelvic peritonitis. T e microbial etiology of PID is unclear but is assumed to occur by the ascending spread of microorganisms from the vagina or endocervix into the upper genital tract.[336] PID has been considered primarily a sexually transmitted disease, caused in large part by the sexually transmitted pathogens Neisseria gonorrhoeae and Chlamydia trachomatis.[336] However, endogenous microorganisms that are part of the lower genital tract flora can also be recovered from the endometrium, fallopian tubes, and peritoneal fluid of women with acute PID.[336]

T e characteristic presentation of PID is one of suprapubic pain. T e pain is usually constant or crampy and may be associated with fever, chills, and direct abdominal tenderness.[332] T e use of an intrauterine device doubles the risk of endometritis.[332]

T e onset of PID is usually within 7 days of the beginning of a menstrual cycle. T ere may be fever and vaginal discharge.

Tubal Pregnancy

In its early stages, this condition usually produces mild and colicky lower abdominal pain. T e pain is caused by an ectopic pregnancy, in which the embryo locates itself in the fallopian tube instead of the uterus. A tubal pregnancy is usually associated with abnormal menstruation and irregular spotting or staining.

Endometriosis

Endometriosis is a common gynecological disorder that affects up to one in seven women and as many as 30–50% of all infertile women.[337] Endometriosis can be found anywhere in the pelvis, including the broad ligaments, uterosacral ligaments, and ovaries. T e condition is linked to abdominal, midline, and pelvic pain. T e incidence and prevalence of endometriosis are highest in the same age range as that of people with nonspecific LBP.[338] Associated signs and symptoms include

pelvic pain, pain with defecation, diarrhea, dysmenorrhea, dyspareunia (difficult or painful coitus), and dysuria.[339] The severity of the pain is not dependent on the stage of the disorder.[340] The diagnosis of endometriosis can be elusive because its most common symptoms are also symptoms of multiple disorders.[337] Although endometriosis is not considered a malignant disorder, it has characteristics in common with malignant cells. For instance, endometriosis, like cancer, can be both locally and distantly metastatic; it attaches to other tissues, invades, and damages them.[341] Given the associated symptoms with this disorder, it is imperative to include endometriosis as a differential diagnosis in women of reproductive age with pelvic, lower back, and lower extremity pain.[338]

Interstitial Cystitis

Interstitial cystitis is a clinical syndrome of urinary frequency or pelvic pain, or both, in a patient in whom no other pathology can be established. Interstitial cystitis has no single, definable presentation. The pain that occurs with this syndrome is not limited to pain on voiding (dysuria); it can refer to locations throughout the pelvis, including the urethra, vagina, suprapubic area, lower abdomen, lower back, medial aspect of the thigh, and inguinal area, in any combination.[342]

Prostate Cancer

Prostate cancer is the most common nonskin cancer and the second leading cause of male cancer deaths among U.S. men. Risk factors for prostate cancer include age, familial history of cancer, and ethnicity. Whether chronic or recurrent prostatic inflammation contributes to prostate cancer development has not been ascertained.

Prostate cancer is often diagnosed when a man seeks medical assistance because of urinary obstruction or sciatica. The sciatic (low back, hip, and leg) pain is caused by metastasis of cancer to the bones of the pelvis, lumbar spine, or femur.

Prostate cancer screening or early detection has been accomplished using digital rectal examination, measurement of serum prostate-specific antigen (PSA) and its various forms, transrectal ultrasonography, and combinations of these tests.

- **Digital rectal examination.** The vast majority of prostatic carcinomas arise in the peripheral zone of the prostate, which comprises the posterior surface of the gland, including the apical, lateral, posterolateral, and anterolateral portions of the prostate. It is this part of the gland that is accessible by digital rectal examination.
- **PSA.** Measurement of PSA levels is regarded widely as the most clinically useful tool for the early diagnosis of prostate cancer, although there is an abundance of conflicting advice as to its use. This is largely due to the fact that PSA levels can fluctuate up and down. It was previously thought that a high PSA result indicated the need for a biopsy. However, it is now believed that the results need to be confirmed by a second test taken 4–6 weeks later. Even then, approximately 70% of men with an elevated PSA level will not subsequently be diagnosed with prostate cancer.[343]

CAUSES OF HIP, TROCHANTERIC, PUBIC, AND THIGH PAIN

Potential causes of trochanteric, pubic, and thigh pain include those listed in Figure 5-3 and Table 5-15. Pain felt in the hip and pelvis may originate from hip structures or may be referred from structures in the torso or viscera.

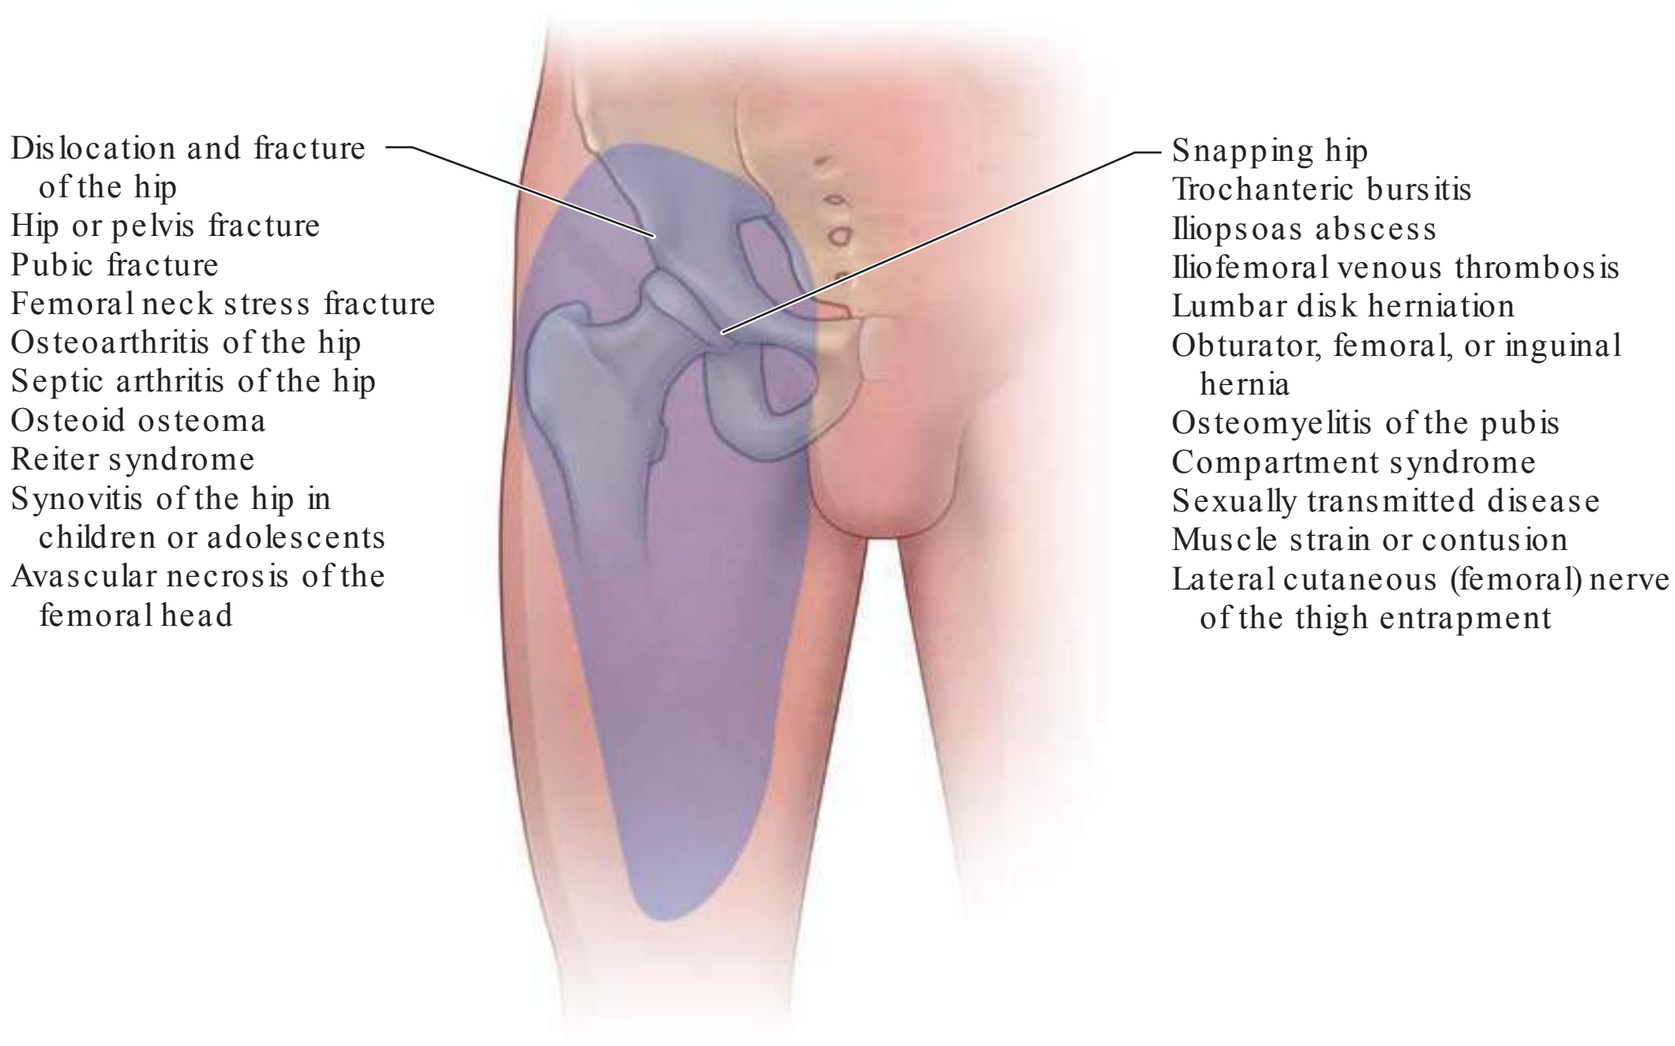

FIGURE 5-3 Potential causes of trochanteric, pubic, and thigh pain.

TABLE 5-15 Potential Causes of Trochanteric, Pubic, and Thigh Pain

Dislocation and fracture dislocation of the hip
Labral tear

Pubic stress fracture
Femoral neck stress fracture
Osteoarthritis of the hip
Septic arthritis of the hip
Reiter syndrome
Transient synovitis of hip in children or adolescents
Avascular necrosis of femoral head
Iliopsoas abscess
Iliofemoral venous thrombosis
Obturator, femoral, or inguinal hernia
Osteomyelitis pubis
Compartment syndrome
Genital herpes

Dislocation and Fracture-Dislocation of the Hip

A traumatic posterior dislocation of the hip usually occurs in a motor vehicle accident or fall. There is usually severe groin and lateral hip pain. The leg is shortened, and held flexed, adducted, and internally rotated. Posterior dislocations are more common than anterior dislocations.

An anterior dislocation usually occurs as the result of forced abduction. Anterior dislocations cause groin pain and tenderness. In a superior–anterior (pubic) dislocation, the leg is held extended and externally rotated. In an inferior–anterior (obturator) dislocation, the thigh is abducted, externally rotated, and held in flexion.

The intervention for a hip dislocation is early closed reduction under spinal or general anesthesia. Developmental dysplasia of the hip, previously referred to as congenital dysplasia of the hip, is described in Chapter 30.

Labral Tear

See Chapter 19.

Hip Fracture

A fracture of the proximal femur (femoral neck, intertrochanteric, or subtrochanteric) usually results from a fall but can occur spontaneously, especially in the elderly. The characteristic findings include a severe groin, anterior thigh, and, sometimes, trochanteric pain and tenderness. Fracture of the femoral neck typically occurs in an elderly osteoporotic patient, with a female-to-male ratio of 4:1.[344] Depending on the severity and location of the fracture, there may be a shortening of the involved leg.

Pubic Stress Fracture

Pubic rami fractures are the most commonly seen pubic fractures, with the superior ramus more commonly involved than the inferior ramus (see Chapter 30). Pubic rami and pubic bone fractures account for more than 70% of all pelvic fractures.[345] Pubic stress fractures are associated with a gradual onset of groin pain, which is intensified by weight bearing, walking, or abduction of the thigh.

Femoral Neck Stress Fracture

See Chapter 19.

Osteitis Pubis

See Chapter 29.

Adductor Muscle Strain

See Chapter 19.

Reiter Syndrome

Reiter syndrome refers to the clinical triad of nongonococcal urethritis, conjunctivitis, and arthritis first described by Reiter in 1916.[346] This form of arthritis usually follows an infection of the genitourinary or gastrointestinal tract. It usually manifests at least one other extra-articular feature, with asymmetric involvement of the large weight-bearing joints.[37] The joints of the mid-foot and the MTP and interphalangeal joints of the toes are most commonly affected. Onset is usually between the ages of 20 and 40, with males predominantly affected.[37]

The association of Reiter syndrome with HLA-B27, occurring in 70–90% of patients, has been recognized for nearly as long as the association of HLA-B27 with AS.[347]

Transient Synovitis of the Hip in Children or Adolescents

Transient synovitis of the hip is one of the most common causes of hip pain and limp in young children. It is defined as an acute, self-limiting inflammation of the synovial lining of the hip joint (see Chapter 30).

OA of the Hip

See Chapter 19.

Septic Arthritis of the Hip

The clinical presentation of septic arthritis of the hip is similar to that of synovitis of the hip. However, because delayed diagnosis of septic arthritis can be life threatening, correct and early differentiation of septic arthritis and transient synovitis is important.[348] Compared with patients who have transient synovitis, those with septic arthritis usually have more severe pain and spasm. The leg is rigid and is held in the standard flexed and externally rotated position to increase capsular capacity.[348]

Osteonecrosis of the Femoral Head

Osteonecrosis of the femoral head is also known as aseptic necrosis or avascular necrosis. According to Kenzora[349]

and Kenzora et al.,[350] the term avascular necrosis should be reserved exclusively for posttraumatic causes because they originate in ischemia as a result of blood flow interruption. When the etiology of the necroses has not been established clearly or is obscure, it is best to use the general term idiopathic osteonecrosis.

Avascular necrosis can occur secondary to trauma, such as a fracture or dislocation. Several etiologic factors have been implicated in the development of idiopathic osteonecrosis of the hip, but the precipitating event that is common to most, if not all, is a mechanical interruption of the circulation of the femoral head. If the affected area is sufficiently large, and the collateral circulation is inadequate, avascular necrosis will develop. T is may occur by direct external vascular occlusion without disruption of the vessels, as in marrow infiltrative diseases. Arterial thrombosis probably occurs in the vascular disorders, and emboli have been implicated in sickle-cell disease and caisson disease (dysbaric osteonecrosis). T e systemic administration of steroids and an excessive intake of alcohol are the two factors most often associated with idiopathic osteonecrosis.[351] Overall, etiologic factors can be clearly identified in most patients; perhaps only 10–20% of patients have truly idiopathic osteonecrosis.

T e symptoms of avascular necrosis and idiopathic osteonecrosis are nonspecific and usually insidious in onset. T e pain, which is typically felt in the groin, proximal thigh, or buttock area, is usually exacerbated by weight bearing, but it is often present at rest. T e clinical findings vary, and it is only when the femoral head becomes deformed that limitations of motion in a noncapsular pattern occur. T e loss of range of motion most commonly affects hip flexion, internal rotation, and abduction. Axial loading of the joint, as in the scour test, may reproduce the symptoms. A limp or an antalgic gait is typically a late finding, and the functional disability is proportionate to the level of pain.[351] Usually, the pain becomes more severe as fragmentation and collapse of the femoral head take place. Sometimes the pain will lessen if spontaneous improvement occurs, and small lesions may remain asymptomatic and resolve spontaneously.[351]

Radiographic evaluation is the gold standard for diagnosis of osteonecrosis.[352] MRI or arthrography can further evaluate the extent of articular cartilage. Clinically diagnosed avascular necrosis is progressive in 70–80% of patients who are managed nonoperatively, and this progression usually results in the collapse of the femoral head.[351] Although conservative intervention is aimed at limiting the stresses through the hip joint and utilizing a support, operative intervention generally is recommended.

A parallel condition that occurs in children (most common in boys aged 5–8 years) is Legg–Calvé–Perthes disease (see Chapter 30).

Iliopsoas Abscess

See the discussion of "Causes of Pelvic Pain" earlier.

Trochanteric Bursitis

See Chapter 19.

Obturator, Femoral, or Inguinal Hernia

T e clinical diagnosis of inguinal and femoral hernias is usually straightforward. A few hernias, however, present a diagnostic problem. T is diagnostic difficulty is usually encountered in obese patients or in patients with reducible hernias that are not protruding at the time of physical examination. False-positive findings include lipoma of the spermatic cord and preperitoneal lipoma. A cord lipoma appears as a smooth, finger-like projection of fat parallel to the cord vessels at rest. During straining, longitudinal sliding occurs. Unlike indirect inguinal hernias, the anteroposterior diameter of the inguinal canal does not increase during the Valsalva maneuver.

Osteomyelitis Pubis

Bony infection or inflammation of the pubic area is rare. Osteomyelitis pubis is an entity characterized by pelvic pain, a wide-based gait, and bony destruction of the margins of the pubic symphysis.[353] Delay in its diagnosis is common because the presentation is similar to that of osteitis pubis and urologic, gynecologic, and abdominal lesions. Osteomyelitis pubis should be considered when a patient presents with the following signs: pain or pubic tenderness, painful hip abduction, and fever.[353]

Antibiotic treatment is essential, with the specific drug therapy depending on the identification of the causative agent.

Compartment Syndrome

Compartment syndrome is a condition in which myoneural anoxia results from a prolonged increase in tissue pressure within a closed osseofascial space. T is compromises local blood flow of skeletal muscle, resulting in ischemia and necrosis.

Local blood flow may be impaired by:

- an increase in the pressure of the compartment resulting from the application of a tight bandage or plaster cast;
- a decrease in arterial flow, as in PVD;
- an increase in venous pressure that can reduce the gradient for local blood flow.

False aneurysms of the profunda femoris artery are a rare but recognized complication following orthopaedic procedures in the upper thigh. Such procedures include internal fixation of intertrochanteric, subtrochanteric, and intracapsular femoral neck fractures; subtrochanteric osteotomy; and intramedullary nailing of the femur.[354]

A compartment syndrome of the thigh usually manifests as a pulsating, expanding swelling of the upper thigh with an audible bruit. Potential complications include expansion and extensive soft-tissue destruction and pressure of neighboring structures.[354] T is can result in neuropathy or venous outflow obstruction and thrombosis. Rupture and severe hemorrhage, infection of an aneurysm, and sepsis of the nearby prosthesis, as well as fracture nonunion, also have been reported.[354]

Early recognition and repair of an aneurysm are of paramount importance to avoid life- and limb-threatening complications from delayed diagnosis.[354] Any unexplained thigh swelling encountered following a surgical procedure on the proximal femur and shaft should alert the clinician to a potential injury to the profunda femoris artery.[354]

Genital Herpes

CAUSES OF SHOULDER AND UPPER ARM PAIN

T e causes of shoulder and upper arm pain include those listed in Tables 5-16 and 5-17.

Local Conditions

Tendinous and Capsular Lesions

See Chapter 16.

Synovitis

T e shoulder joint is composed of two synovial cavities: the subacromial–subdeltoid bursa and the glenohumeral joint. In rotator cuff diseases, subacromial synovitis is responsible for the generation of shoulder pain, and its severity may correlate with the intensity of pain. During inflammation, the so-called hyperalgesia occurs, which is characterized by intensified pain with a reduced threshold to somatic stimulation.

Pigmented villonodular (PVN) synovitis is one of a group of benign, proliferative lesions arising from the synovium of joints, bursae, and tendon sheaths.[355] Traditionally, these lesions have been identified as a benign giant cell tumor of the tendon sheath, hemorrhagic villous synovitis, and proliferative synovitis.[356] PVN synovitis in the knee and hand has been described frequently, but its occurrence at the shoulder is rare.

T e cause of PVN synovitis is unclear, but it may be related to inflammation or trauma. T e lesions develop slowly, and patients usually present with a gradual onset of pain in the affected joint.[355] A palpable, tender, soft-tissue mass may be present. PVN synovitis is regarded as a locally aggressive but benign tumor. Early diagnosis and treatment are essential for preserving joint function and integrity. T e treatment of choice is complete synovectomy or bursectomy, or arthroscopic synovectomy.[355]

Subluxation

Shoulder subluxation can be caused by trauma, overuse, or hemiplegia. T e traumatic and overuse causes of shoulder subluxation, which can often be diagnosed on the basis of history and physical examination, are described in Chapter 16. T e most common complaints are of instability, restricted activities, and pain. Strength and range of motion are usually normal. T e most common significant finding on physical examination is apprehension.

One of the most commonly cited causes of shoulder pain in hemiplegia is shoulder subluxation. Shoulder subluxation occurs in hemiplegia because of the paralysis of active restraints, which play a critical role in maintaining glenohumeral joint integrity. In this population, glenohumeral joint subluxation may inhibit functional recovery by limiting the glenohumeral range of motion.

TABLE 5-17 Origin and Location of Shoulder Pain

Right Shoulder		Left Shoulder	
Systemic Origin	**Location**	**Systemic Origin**	**Location**
Peptic ulcer	Lateral border of right scapula	Ruptured spleen	Left shoulder
		Myocardial ischemia	Left pectoral/shoulder area
Myocardial ischemia	Right shoulder and down arm	Pancreas	Left shoulder
Hepatic/biliary			
Acute cholecystitis	Right shoulder, between scapulae, and right subscapular area		
Liver abscess	Right shoulder		
Gallbladder	Right upper trapezius		
Liver disease (hepatitis, cirrhosis, and metastatic tumors)	Right shoulder and right subscapular area		

Data from Goodman CC, Snyder TE. Dif erential Diagnosis in Physical Therapy. Philadelphia, PA: WB Saunders Company; 1990.

Unfortunately, the available options for preventing and treating shoulder subluxation in the hemiplegic population are limited. Armboards and laptrays have not been shown to be effective and may lead to an overcorrection of inferior subluxation.[357] T is overcorrection may predispose the involved shoulder to impingement syndromes. T e use of slings remains controversial. Slings may cause lateral subluxation, contribute to the deleterious effects of joint immobilization, or promote undesirable synergistic patterns of muscle activation.[357] Intramuscular neuromuscular electrical stimulation (NMES) delivered via percutaneously placed electrodes may address the limitations of transcutaneous systems in the treatment of shoulder subluxation and pain.[357]

Dislocation

In contrast to the hip, in which the ball-and-socket joint is deep and well stabilized, the articular surface of the shoulder rests in the shallow glenoid cavity. Ninety-five percent of shoulder dislocations occur in the anterior direction and result in stretching and detachment of the anterior capsule and labrum.[358] Dislocation of the shoulder is a common and often disabling injury, resulting in damage to nerves, blood vessels, and the rotator cuff muscles (see Chapter 16). Most shoulder dislocations are traumatic in origin. T e most common mechanisms are a fall on an outstretched hand, a blow against the anterior arm when the limb is extended and externally rotated, or, rarely, a blow to the back of the shoulder.

Traumatic shoulder dislocations are accompanied by extreme pain that worsens as the supporting musculature goes into spasm.[359] Generally, patients present with the arm somewhat abducted and externally rotated, often grasped tightly by the opposite hand to minimize movement.[359]

T e examination of a patient who has recently dislocated the shoulder is often difficult because of associated pain and muscle guarding (see Chapter 16). It is important to attempt to examine for axillary nerve function (deltoid power and overlying sensation), supraspinatus power, and glenohumeral range of motion.[360] Axillary nerve palsy and avulsion of the supraspinatus are common complications of a dislocated shoulder. Associated fractures may be present. Vascular compromise is uncommon in this injury, but when it occurs, rapid surgical referral is necessary to save the limb.[359]

Spondyloarthropathy

RA affects the joints in a characteristic and symmetric fashion. In addition to the smaller joints, RA can affect the larger joints, including the shoulders. It results in pain and stiffness, which are usually greatest in the morning.[361–363] T is condition should be considered when patients have symmetric involvement of the shoulder, morning stiffness, constitutional signs, and physical signs of joint inflammation.[364] Synovial inflammation of the subacromial–subdeltoid bursae can occur, resulting in pain with abduction to approximately 90 degrees in both shoulders.[364] Chronic inflammation or long-term corticosteroid use, or both, may also result in rotator cuff tearing, another viable cause of pain and function loss in the patient with RA. T is should be suspected when significant weakness is noted on abduction or external rotation of the shoulder.[364] T e clinician should also look for other signs of inflammatory arthritis, which include synovial thickening of the MCP joints and thickening at, and loss of range of motion of, the wrists. T e rheumatoid factor is often negative in older patients with RA.[364]

CLINICAL PEARL

Polymyalgia rheumatica is another cause of shoulder pain in older individuals. These patients have pain in the shoulder and hip girdle muscles, profound morning stiffness, and malaise.[364] This condition can be dif cult to distinguish from RA in older people.

Acute Arthritis

Septic arthritis of the shoulder is uncommon but can occur in patients who are debilitated from generalized disease,[365] in those taking immunosuppressive medications, or in combination with an underlying shoulder disease process, such as rotator cuff tearing[366] or RA.[367,368]

Diabetic patients are at higher risk of developing monoarticular steroid-sensitive arthritis.[369] A condition of unknown etiology, it can affect the rotator cuff and the glenohumeral joint capsule.[370] As the name suggests, the condition is provoked by the patient's reaction to hydrocortisone.

Diagnosis requires joint aspiration and bacteriological testing. Monoarticular arthritis, which usually resolves spontaneously in 2 years with medical intervention,[371] is an absolute contraindication to capsular stretching.[372]

Degenerative Conditions

Intrinsic glenohumeral arthritis is an infrequent cause of shoulder pain, but the loss of glenohumeral motion is often seen in patients with periarticular syndromes (see Chapter 16).[364] Although the rotator cuff often is intact, the subscapularis muscle often is shortened, limiting external rotation.[373] X-ray findings include[373]

- flattening posterior erosion of the glenoid and an enlarged or deformed humeral head[374,375];
- inferiorly located osteophytes; and
- acromioclavicular arthritic changes.[374]

Infections

Osteomyelitis

T e most commonly involved bones with acute hematogenous osteomyelitis in order of frequency are the femur, tibia, humerus, fibula, radius, phalanges, calcaneus, ulna, ischium, metatarsals, and vertebral bodies.[376] Patients with sickle-cell disease are at an increased risk of bacterial infections, and osteomyelitis is the second most common infection in these patients.[377]

Patients usually present with fever, malaise, irritability, pain, and localized tenderness at the site of infection. Muscle guarding may also be a feature, as well as decreased movement and pain of the affected limb and adjacent joints. T ese symptoms may be accompanied by edema and erythema over the involved area.

Cat-Scratch Disease

Cat-scratch disease is generally a benign, self-limited infectious disease in immunocompetent patients. It is caused by Bartonella henselae, a small, gram-negative, argyrophilic, nonacid-fast, pleomorphic bacillus.[378] Domestic cats, especially kittens, serve as a reservoir for B. henselae.[378] In general, patients present with a history of a scratch, bite, or close contact with a kitten or cat. Often a red-brown nontender papule develops at the region of the inoculation within 3–10 days and may persist for several weeks. Most patients develop tender regional lymphadenopathy, particularly in the axilla, and many develop a fever.

Tumors

T e differential diagnosis of all painful shoulders includes tumors of a wide variety. Evaluation of a shoulder tumor has several areas in common with other musculoskeletal neoplasms. A thorough evaluation of patients requires not only routine radiography but also radionuclide imaging, CT scanning, magnetic resonance imaging (MRI), and angiography. T e typical clinical features of a bone tumor include variable pain, which is often worse at night and markedly unresponsive to NSAIDs. Surgical treatment of shoulder tumors depends on the patient's age and the type, extent, and aggressiveness of the tumor.

Vascular Conditions

Nontraumatic osteonecrosis of the humeral head may be idiopathic or associated with the systemic use of corticosteroids, dysbaric conditions (blockage of the blood vessels by a bubble of nitrogen coming out of solution), transplantation, systemic illness, alcoholism, sickle-cell disease, hyperuricemia, pancreatitis, lymphoma, or Gaucher's disease.[368,379–382]

Diagnosis is through imaging, particularly MRI, which detects the pathology at its earliest stage.

Metabolic Conditions

Gout is a metabolic disease characterized by recurrent episodes of acute arthritis that can manifest in the shoulder joints.

Fractures

See Chapter 16.

Referred Pain

Referred pain from the cervical region may be experienced in the shoulder or interpreted as a distal sensation.[383]

Referral sources for this region include the heart,[384] pleura, lung tissue, diaphragmatic pain,[385] lymph nodes of the neck, shoulder, chest, and breast tissue.[385]

Pain in the shoulder area can be caused by direct or referred pain from an underlying malignancy, such as a Pancoast tumor (see "Tumor").[385] T e scapula and humerus are frequently sites of metastases in tumors of the kidney, breast, lung, and prostate.[364] T ese patients have persistent pain that is unaffected by movement but is associated with fatigue, weight loss, and other constitutional signs. A history of gradually progressive pain, starting as a mild ache but developing into persistent severe pain, should initiate a search for malignancy.[364] Severe shoulder pain in a patient with a normal physical examination of the shoulder and cervical spine should increase the suspicion of malignancy.

Intrinsic neck pathology can cause referred pain to the head, anterior and posterior chest wall, shoulder girdle, and upper limb.[383] In the case of radiculopathy, muscle function might be affected directly. Cervical spine symptoms are usually affected by head position, with neck extension causing an exacerbation and flexion producing some relief.[364]

Intracerebral and Intraspinal Conditions

Cerebrovascular Disease

See the discussion of "Causes of Head, Face, Eye, and Temporomandibular Joint Symptoms" earlier.

Subclavian Steal Syndrome

T is condition (see Chapter 24) results in signs and symptoms of cerebral ischemia and upper arm pain. Ischemia is the result of subclavian artery stenosis proximal to the origin of the vertebral artery and, subsequently, "steals" of blood from the cerebral circulation of the Circle of Willis and basilar vessel (see Chapter 24).

T e symptoms of subclavian steal syndrome are usually precipitated or aggravated by arm exercises.[386]

Multiple Sclerosis

Pain, either acute or chronic, occurs in more than 65% of patients with MS[387] during all stages of the disease. Chronic pain may be characterized by dysesthetic extremities, back and shoulder pain, and pain secondary to spasticity.[172] Complications of disuse, such as frozen shoulder and osteoporosis, are other painful syndromes that may develop.[172]

Extraspinal Conditions

T e extraspinal causes of shoulder pain include tumor, clay shoveler fracture, brachial plexopathy, and herpes zoster.

Tumor. Pancoast syndrome is a constellation of characteristic symptoms and signs that includes shoulder and arm pain along the distribution of the eighth cervical nerve trunk and first and second thoracic nerve trunks, Horner syndrome (see Chapter 3), and weakness and atrophy of the muscles of the hand, most commonly caused by local extension of an apical lung tumor at the superior thoracic inlet.[388,389] T ese tumors are called superior pulmonary sulcus tumors or Pancoast tumors.

T e most common initial symptom is shoulder pain due to the localization of the Pancoast tumors in the superior pulmonary sulcus. Pain can radiate up to the head and neck or down to the medial aspect of the scapula, axilla, anterior part of the chest, or ipsilateral arm, often along the distribution of the ulnar nerve.[390] T is radicular causalgic pain is often difficult to treat. Sensory loss and motor deficit in the upper extremity may also occur. Weakness and atrophy of the intrinsic muscles of the hand are not uncommon, along with pain and paresthesia of the medial aspect of the arm, forearm, and fourth and fifth digits along the distribution of the ulnar

nerve, caused by extension of the tumor to the C8 and T1 nerve roots.[390]

The differential diagnosis of Pancoast syndrome includes other primary thoracic neoplasms, metastatic and hematologic conditions, infectious diseases, thoracic outlet syndromes, and pulmonary amyloid nodules.[390]

Clay Shoveler Fracture. Clay shoveler fracture is a rare condition. The condition was first described by McKellar[391] and was based on a few cases reported, found in English men, who spent long hours digging heavy clay. It has since been described in power lifters.[392] The condition is characterized by a traction fracture of the lower cervical or upper thoracic spine due to an excessive pull of the trapezius, rhomboid muscles during heavy work. Typically, the patient reports a sudden onset of a sharp neck, shoulder, and arm pain and exhibits limited active bilateral arm elevation to around 150 degrees. Passive elevation remains unaffected. Other conditions that mimic these symptoms include a fracture of the first rib, mononeuritis of the long thoracic nerve, mononeuritis of the accessory nerve, a C5 root palsy, or a total rupture of the supraspinatus.[372]

Brachial Plexopathy.[393] Idiopathic brachial plexopathy (IBP) is a syndrome of shoulder pain and weakness. IBP has a number of pseudonyms, including neuralgic amyotrophy, Parsonage–Turner syndrome, and idiopathic brachial neuritis. The initial symptom typically seen with IBP is sudden, sharp, and throbbing pain in the shoulder girdle, followed by weakness in the scapular and proximal arm muscles. Sensory loss is usually not prominent. The pain usually subsides within 24 hours to 3 weeks, and the weakness and atrophy are recognized as the pain resolves. Weakness is maximal within 2–3 weeks of the onset of symptoms and often is accompanied by muscle wasting and scapular winging. Slow resolution of the weakness follows in nearly all patients, but recovery may be incomplete.

Herpes Zoster.[394] Herpes zoster is characterized by deep, boring, or stabbing thoracic and arm pain. Varicella zoster virus infection is unique because of its two clinical manifestations: varicella (chickenpox) and herpes zoster (shingles). After an individual has chickenpox, the virus lies dormant in the posterior (dorsal) root ganglia and sensory ganglia of cranial nerves. Herpes zoster occurs if the virus becomes reactivated, causing an acute, painful infection of a sensory nerve and its corresponding cutaneous area of innervation. Herpes zoster, therefore, occurs only in individuals previously infected with the chickenpox virus.

Postherpetic neuralgia is the most common complication of herpes zoster. It arises from inflammatory injury to sensory nerves, ganglia, and nerve roots and from maladaptive responses to pain signaling and the likely inability of pain receptors to return to normal after the inflammation subsides. The nerve dysfunction can result in hyperesthesia, hypoesthesia, dysesthesia, and allodynia (pain as the result of innocuous stimuli, such as clothing touching the affected skin).

The characteristic rash begins as erythematous macules and papules that progress to vesicles within 24 hours, then to pustules (3–4 days), and finally to crusts (7–10 days). The most common distribution of herpes zoster is unilateral involvement of the thoracic dermatome, followed by the cranial, cervical, and lumbar dermatomes. Involvement of the maxillary division of the trigeminal nerve causes vesicles of the uvula and tonsillar area. Involvement of the mandibular branch produces vesicles on the floor of the mouth, buccal membranes, and the anterior part of the tongue. Herpes zoster near or involving the eyes is considered an emergency because this potentially serious development can lead to blindness.

In general, the diagnosis of herpes zoster is based on the history and the clinical examination, which shows the characteristic painful, grouped vesicular rash in a dermatomal distribution. Acute herpes zoster infection is a self-limiting condition, and the primary treatment goals are to reduce and manage the acute pain and modify the duration of the rash and inflammation.

CAUSES OF ELBOW AND FOREARM PAIN

The causes of elbow and forearm pain include those listed in Table 5-18.

Fracture

See Chapter 17.

Dislocation

See Chapter 17.

Osteochondritis Dissecans Capitellum

See Chapter 17.

Ligament Sprain

See Chapter 17.

TABLE 5-18 Potential Causes of Elbow and Forearm Pain

Fracture
Dislocation
Osteochondritis
Ligament sprain
Arthrosis
Peripheral nerve entrapment
Soft-tissue injury or tendinosis (lateral epicondyle, medial epicondyle, triceps, biceps, brachialis and Little League elbow)
Infective arthritis
Polyarthritis
Gout
Bursitis
Vascular disorders
Referred pain

Arthrosis

Arthrosis of the elbow is often the result of a previous micro- or macrotraumatic injury to the elbow. Unless the case is severe, the patient does not complain of much pain, except perhaps with vigorous activity. However, complaints of early morning stiffness and pain at the end of the day are common. Motion testing reveals a capsular pattern, with a bony end-feel, in both flexion and extension, and crepitus is felt during both motions. T ere is no specific treatment for this condition. Surgery may be necessary to remove loose bodies or for debridement in severe cases.

Peripheral Nerve Entrapment

See Chapters 3 and 17.

Soft-Tissue Injury or Tendinopathy

See Chapter 17.

Infective Arthritis

T e source of infective arthritis is commonly tooth decay or a pelvic disease. A history of a puncture wound of the skin also should arouse suspicion. T e pain is described as a severe aching or throbbing. T e involved joint feels hot and appears swollen. T e involved elbow is usually held stif y in slight flexion. Associated findings include fever and joint tenderness.

Polyarthritis

T e polyarthritis that can affect the elbow includes acute rheumatic fever, Reiter syndrome, and Lyme disease arthritis.

Gout

Gout at the elbow is characterized by acute pain, swelling, redness, and tenderness of the elbow joint.

Bursitis

See Chapter 17.

Vascular Disorders

Volkmann Ischemia (Anterior Compartment Syndrome)

T is condition occurs as the result of increased tissue fluid pressure within a fascial muscle compartment that reduces capillary blood perfusion below a level necessary for tissue viability.[395] In the upper extremity, acute compartment syndrome that involves the forearm is the most common type of compartment syndrome. Nerve injury resulting from the compression produces a deformed limb known as Volkmann ischemic contracture.[396]

Acute compartment syndrome can be caused by constrictive casts or dressings, limb placement during surgery, blunt trauma, hematoma, burns, frostbite, snake bite, strenuous exercise, and fractures.[395] Clinical findings include[395]:

- a swollen and tense, tender compartment;
- severe pain exacerbated with a passive stretch of the forearm muscles;
- sensibility deficits;
- motor weakness or paralysis; and
- no absence of radial and ulnar pulses at the wrist.

T e clinical diagnosis is confirmed by measuring the intracompartmental tissue fluid pressure.

Conservative intervention involves the removal of the constricting splint, dressing, or cast. Surgical intervention, by performing a fasciotomy, is reserved for patients whose symptoms do not resolve quickly.[395]

Acute Axillary or Brachial Artery Occlusion

T e causes of arterial occlusion include emboli from the heart or from an atheromatous plaque or aneurysm of the innominate or subclavian-axillary arteries.[397] Trauma to the chest, shoulder, or upper arm may also cause arterial obstruction. T e five P's describe the signs and symptoms of this medical emergency:

- Pain
- Paralysis
- Paresthesias
- Pallor
- Pulses (absent)

T e pain is usually severe and constant, involving the forearm, hand, and fingers. Paralysis and paresthesia indicate severe ischemia of the arm. Gangrene can begin to develop 6 hours after the onset of symptoms in such scenarios. T e pallor occurs because of lack of blood flow and cutaneous vasoconstriction. T e absence of pulses confirms occlusion.

Referred Pain

Referred pain to the elbow can have a number of causes, including coronary heart disease, polyarthritis, or an acute C8 radiculopathy.

CAUSES OF WRIST, HAND, AND FINGER PAIN

Wrist, hand, and finger pain can be caused by, but are not limited to, those listed in Table 5-19 and shown in Figure 5-4.

Fracture

See Chapter 18.

Sprains and Dislocations

See Chapter 18.

Triangular Fibrocartilage Complex Lesions

See Chapter 18.

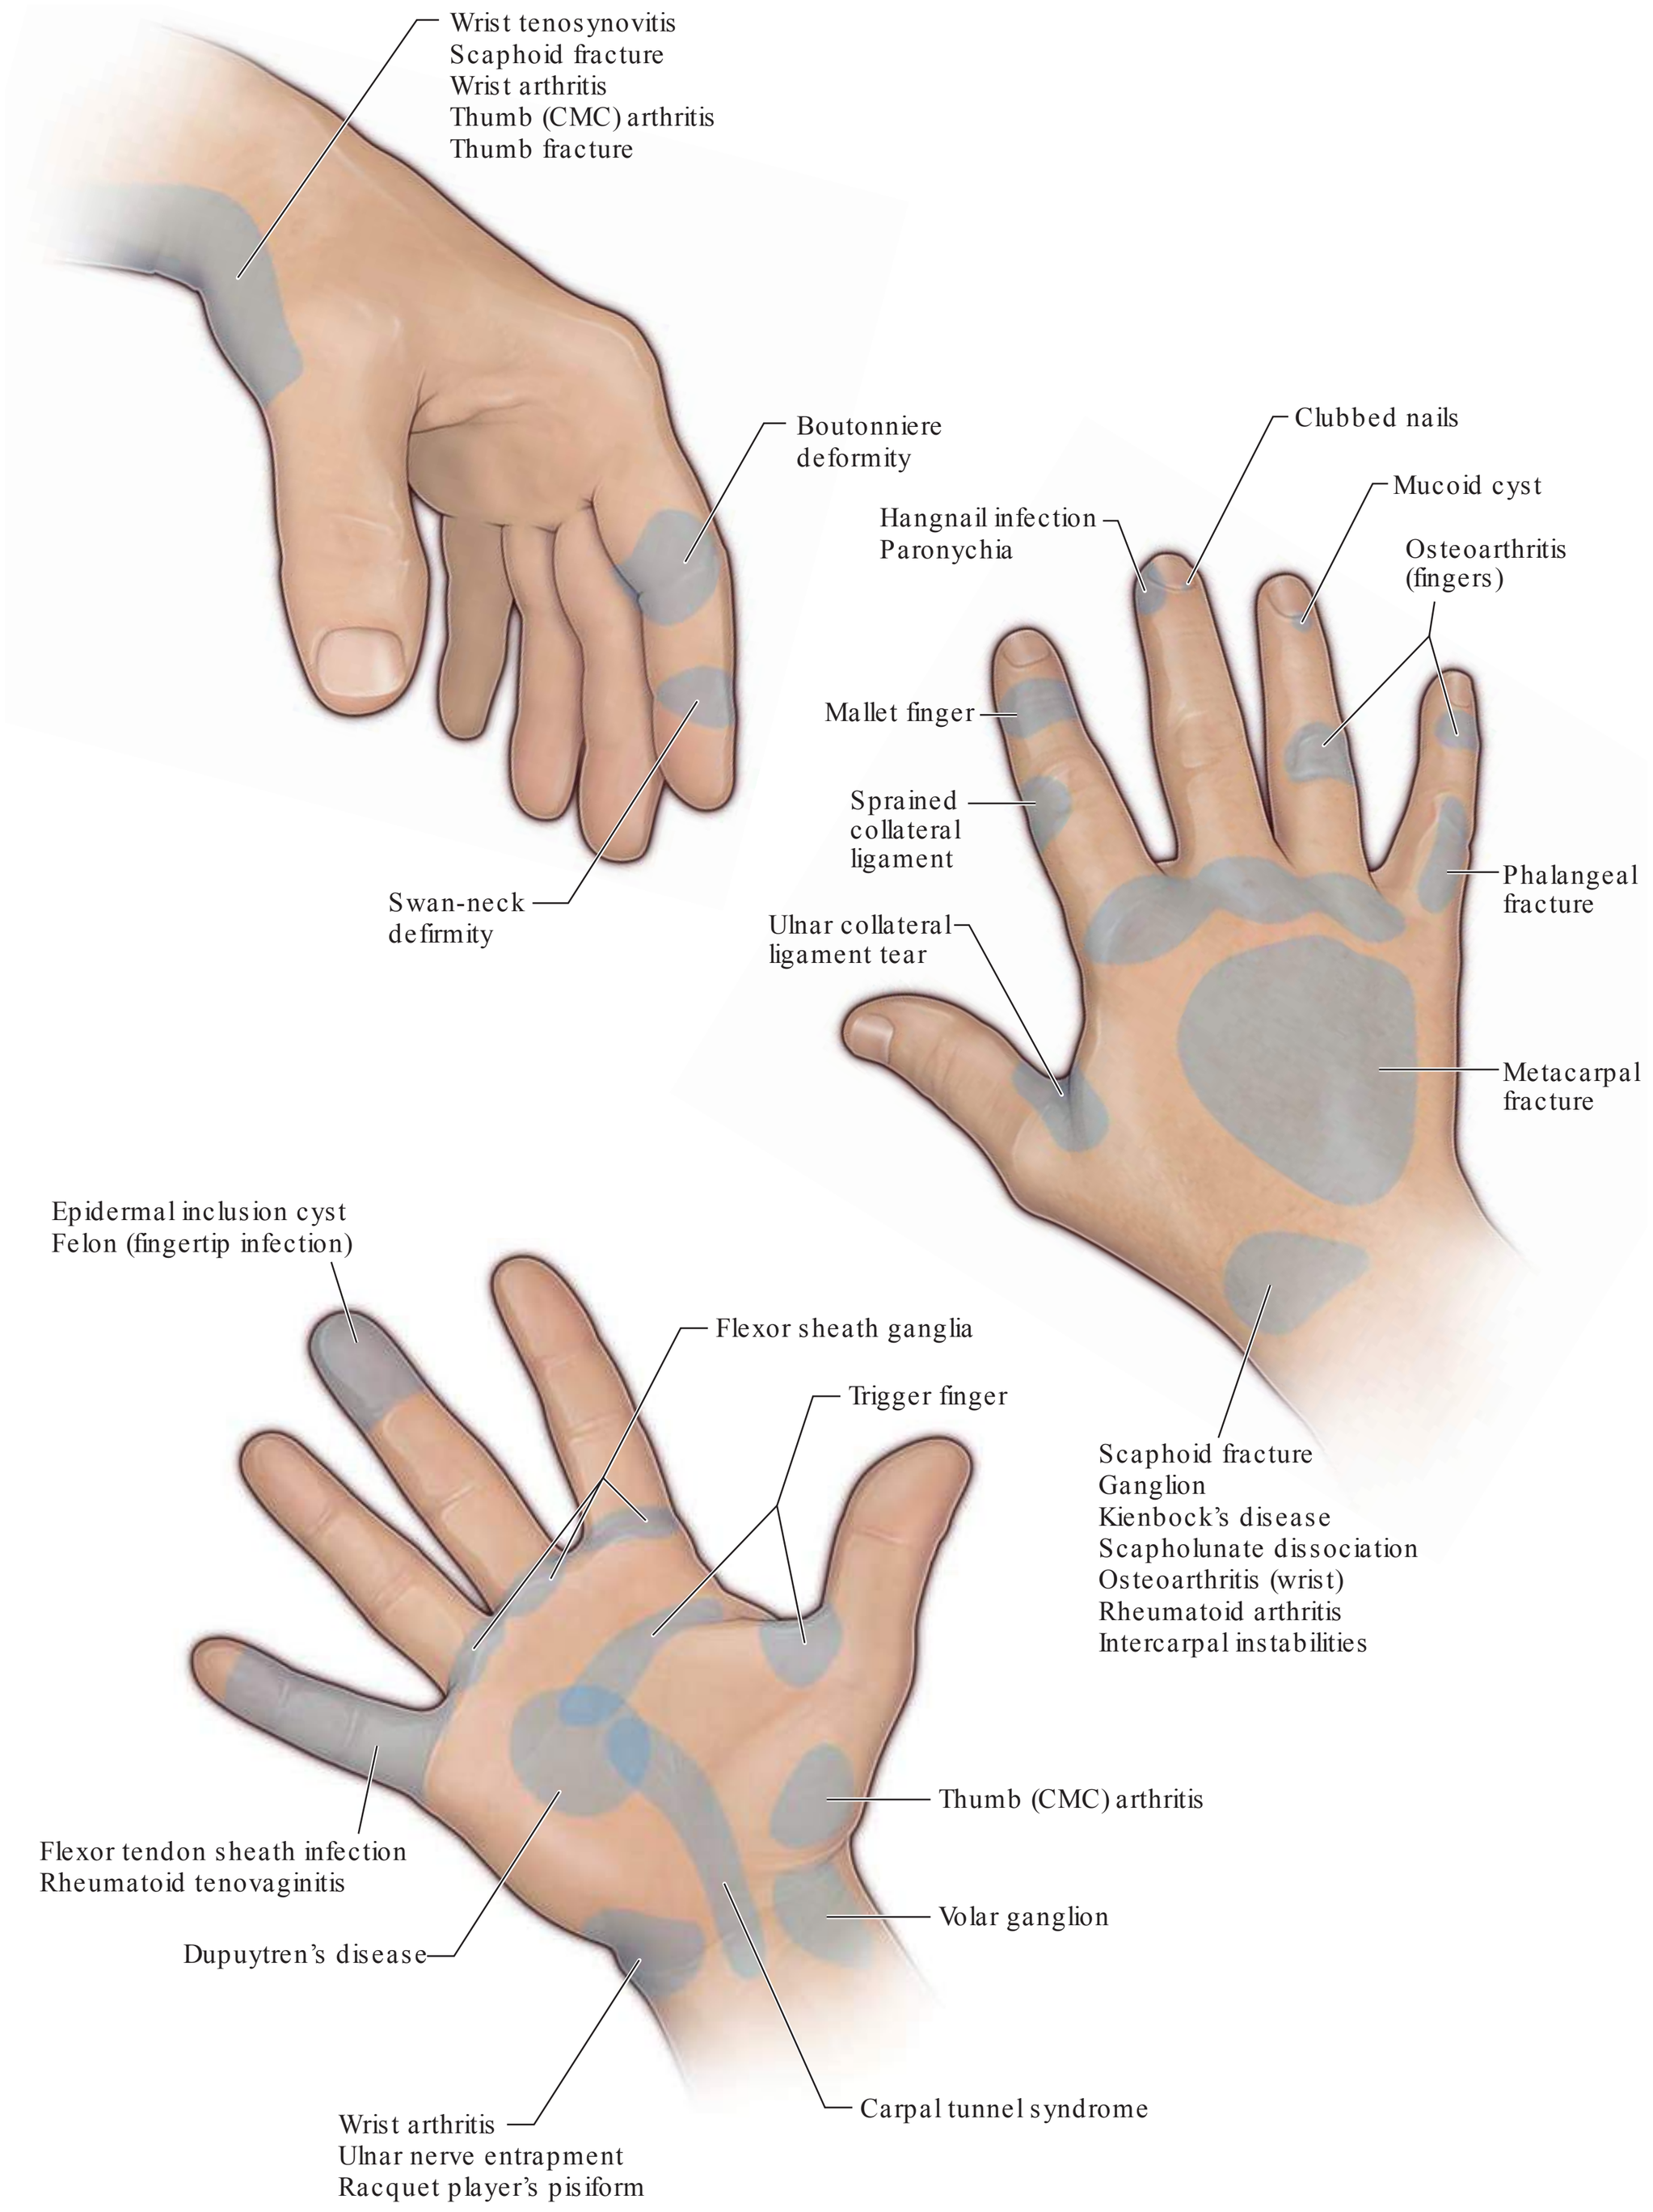

FIGURE 5-4 Potential causes of wrist and hand pain.

TABLE 5-19 Causes of Wrist, Hand, and Finger Pain

Tenosynovitis

See Chapter 18.

Tendinopathy

See Chapter 18.

Carpal Instability

See Chapter 18.

Gout and Pseudogout

Gouty arthritis and pseudogout are metabolic joint diseases caused by the deposition of sodium urate or calcium pyrophosphate crystals in the joint, leading to arthritis (see also, earlier discussions). The wrists are the second most commonly affected joint in pseudogout, after the knees. Radiographs demonstrate crystal deposits in articular fibrocartilage of the wrist.[398] Septic arthritis of the wrist can cause the destruction of joint cartilage and bony structures. Generally, the diagnosis of acute infection is not problematic, but differentiation between pure soft-tissue infection and infection involving the bony structures can be complicated.[399] Furthermore, identification of a chronic infection as the cause of chronic wrist pain may be difficult.[400,401] If there is a clinical suspicion, a (ultrasound-guided) needle aspiration or synovial biopsy should be taken.[399] The new generation of ultrasonography has proven to be a valuable technique, with a high success rate, for obtaining synovial fluid or membrane samples for pathologic and bacteriologic examinations.[402]

Rheumatoid Arthritis

In the hand, many common deformities can be seen, such as ulnar deviation of the MCP joints, boutonnière deformity, and swan neck deformities of the digits (see Chapter 18).

Psoriatic Arthritis

See section "Psoriatic Arthritis" earlier in the chapter.

Osteoarthritis

See Chapter 18.

Carpal Tunnel Syndrome

See Chapter 18.

Infection

Wrist

The most common infection of the wrist is infectious tenosynovitis of the flexor pollicis longus.

Hand

These infections include:

- bursal infections;
- space infections;
- infected bites;
- Cellulitis. Cellulitis is an infection of the skin and underlying structures. With treatment, it usually follows a relatively benign course. However, in some cases, the same pathogens can cause other diseases, such as necrotizing fasciitis or toxic shock syndrome, and even death. The most common pathogens in cellulitis are S. aureus and β-hemolytic streptococci. Symptoms include localized redness, swelling, and pain. Associated symptoms include fever, chills, and nausea and vomiting. Cellulitis typically is treated with systemic antibiotics via either the oral or the intravenous route.

Fingers

Paronychia and Eponychia. Paronychia is an acute inflammation of the lateral or proximal nail folds that are usually caused by infection, producing a red, tender, throbbing, and intensely painful swelling of the proximal or lateral nail folds.[403] It is the most common infection of the hand. If the infection involves the eponychium as well as the lateral fold, it is called eponychia.

Mild cases of paronychia typically are treated with warm soaks two to four times daily and splinting with or without systemic antibiotics. The more severe cases require incision and drainage.[404]

Differential diagnosis includes apical abscess, felon, and subungual infection.[405] A subungual infection may result from an extension of the paronychia under the nail.[405]

Felon

A felon is an abscess of the terminal phalanx pulp. The most common cause is a puncture wound. Initially, the condition

is characterized by mild swelling, erythema, and tenderness. Over a period of a few days, the pulp becomes tense, red, and exquisitely tender.[405]

Mild cases are treated with antibiotics and elevation. Most cases, however, require a combination of incision and drainage, and systemic antibiotics.

Web Space Infections

A web space abscess usually is caused by a puncture in the skin between the fingers. It is characterized by its collar-button or dumbbell shape, as the expanding abscess penetrates the palmar fascia.[405] Swelling and tenderness are noted on the palmar and posterior (dorsal) aspects of the web space. The adjacent fingers adopt an abducted position. The intervention involves incision and drainage.

Herpetic Whitlow

Herpetic whitlow is a viral infection of the fingers. It is caused by contact with the herpes simplex virus.[405] The condition usually manifests with intense throbbing and erythema of the involved finger. The condition is self-limiting and typically lasts for 2–3 weeks. The intervention is conservative and symptomatic.[405]

Kienböck Disease

Kienböck disease, or lunatomalacia, is a complication of injury to the lunate. It is defined as an aseptic or avascular necrosis of the lunate. The etiology of this disease remains elusive, although it is thought that trauma plays a large part in disrupting the blood supply to the bone.[406] The disease occurs predominantly in males, with a 2:1 prevalence,[407] and the majority of patients are 20–40 years of age.[408]

Subjective complaints include pain on the central-posterior (dorsal) aspect of the wrist, especially during and after activities. Hand stiffness is another common complaint.[409] With time, the pain becomes severe and constant, with accompanying weakness of grip strength and loss of wrist motion, especially wrist extension.[409] Imaging techniques are needed to make a definitive diagnosis.

The intervention for Kienböck disease depends on the stage of the disease. Conservative measures involve immobilization during the acute phase. Surgical options include joint leveling by radial shortening or ulnar lengthening, intercarpal fusion, arthroplasty and vascularized bone grafts.[410]

Ganglia

Ganglia are thin-walled cysts containing mucoid hyaluronic acid that develop spontaneously over a joint capsule or tendon sheath. Ganglia, seen primarily in 20–30-year olds may also occur in association with such systemic diseases as arthritis or with trauma.[411–414] The exact cause of the ganglia is controversial. However, there is consensus that a one-way connection to the synovial sheath allows fluid to enter the cyst but not to flow freely back into the sheath.[411]

Upon examination, a ganglion is smooth, round, or multilobulated and tender with applied pressure. The key to distinguishing a ganglion from other soft-tissue tumors is the history of size variation (Table 5-20). Suspicious soft-tissue masses require evaluation and further diagnostic testing or excisional biopsy.[411]

Tumors

Benign tumors account for the majority of tumors of the wrist and hand, although malignancies can occur.[415] The clinical presentation is variable and depends on the condition, location, size, and degree of soft-tissue involvement, although there are a number of scenarios that warrant suspicion of a possible occult lesion:[416]

- A young patient complaining of bone pain that is not related to any preceding trauma.

TABLE 5-20 Differential Diagnosis of Wrist Ganglia

Aneurysm/arteriovenous malformation	Benign tumor (chondroma, fibroma, giant cell tumor of tendon sheath, hemangioma, lipoma, and neuroma)
Anomalous muscle and other anomalous structure	Malignant tumor (epithelioid sarcoma, malignant fibrous histiocytoma, metastasis, and synovial sarcoma)
Bursa	Skeletal
Displaced tendon	Benign tumor (cyst, chondroma, giant cell tumor, collagen osteochondroma, and osteoid osteoma)
Foreign-body granulomas	Malignant tumor (chondrosarcoma, metastasis, and osteosarcoma)
Hypertrophic structure	Infectious
Nerve entrapment	Fungus, mycobacteria, pyogen, tuberculosis
Nerve ganglion	Disease/metabolic
Periarticular calcaneal	Rheumatoid arthritis and disease, rheumatoid nodule, synovial cyst, and tenosynovitis
Repetitive use fibrosis	Gout and pseudogout
Scar	Neuritis (PIN), vasculitis, and amyloidosis
Tendon entrapment	
Tuberous sclerosis	
Skeletal	
Arthritic residuum	
Pigmented villonodular synovitis	
Posttraumatic residuum: subluxed scaphoid	

Data from Kozin SH, Urban MA, Bishop AT, et al. Wrist ganglia: Diagnosis and treatment. J Musculo Med. 1993;10:75–76.

- The presence of swelling, or a mass, in the absence of trauma.
- Pain or swelling that persists despite intervention.

Peripheral Nerve Entrapment

The pain of a neurogenic origin can be referred to the wrist and hand. These can include C5–T1 nerve–root lesions, peripheral nerve lesions, thoracic outlet syndrome, and brachial plexus tension syndromes (see Chapter 3). In addition, neurogenic causes can be secondary to adhesion formation or trauma.

Proximal Nerve Entrapment

Proximal causes of pain, paresthesias, and numbness in the lateral hand, thumb, and index and middle fingers include:

- C6 or C7 radiculopathy (see Chapter 25);
- thoracic outlet syndrome (see Chapter 25);
- pronator teres syndrome (see Chapter 17).

Proximal causes of these symptoms in the medial hand and the fourth and fifth fingers include:

- C8 radiculopathy;
- brachial plexus compression at the thoracic outlet; and
- cubital tunnel syndrome (see Chapter 17).

Distal Nerve Entrapment (see Chapter 18)

Entrapment of the following nerves may occur:

- Median nerve (carpal tunnel syndrome)
- Ulnar nerve (Guyon canal entrapment)
- Radial nerve

Complex Regional Pain Syndrome (Reflex Sympathetic Dystrophy)

See Chapter 18.

Vascular Occlusion

An embolus or trauma may obstruct the brachial, ulnar, or radial artery. The amount of pain distal to the obstruction is dependent on the degree of collateral circulation. The prolonged restriction to the blood flow may result in gangrene.

Raynaud Phenomenon

Raynaud phenomenon is a vascular disorder that can affect one hand or both hands and the feet. Reversible vasospasm of the extremities occurs either as an isolated symptom without underlying disorder (primary Raynaud phenomenon) or in association with another disorder or condition (secondary Raynaud phenomenon). The clinical findings include digital pallor followed by cyanosis and then rubor.[417] Throbbing and tingling sensations usually accompany the rubor stage.

Raynaud phenomenon is usually managed with simple measures, such as using warm clothes, mittens (not gloves), hand warmers, and automatic car starters.[418] The most frequently used drugs are calcium-channel antagonists.

Scleroderma

Scleroderma means "hard skin." The term is used to describe two distinct diseases: localized scleroderma and systemic scleroderma. Localized scleroderma is primarily a cutaneous disease. Systemic sclerosis is a multisystem connective tissue disease. The etiology of both of these diseases is not known.

There are two main subsets of systemic sclerosis, limited scleroderma (formerly referred to as CREST syndrome) and diffuse scleroderma:

- Limited scleroderma. Patients generally have a long history of Raynaud phenomenon, in some cases 10–15 years, and mildly puffy or swollen fingers before they present to their physician with a digital ulcer, heartburn, or shortness of breath.
- Diffuse scleroderma. Patients have a much more acute onset of disease. They have arthralgias, carpal tunnel syndrome, swollen hands, swollen legs, and crepitus-like friction rubs over the tendon areas of hands, wrists, and ankles. These patients potentially have severe problems not only from skin thickening and contractures but also from other organ systems, including gastrointestinal, pulmonary, cardiovascular, and renal.

Raynaud phenomenon is present in almost all patients with scleroderma.

Mononeuritis Multiplex

This condition is associated with a sudden onset of severe aching or sharp forearm and hand pain, paresthesias, and dysesthesias in the distribution of the median, ulnar, or radial nerves.[417] Mononeuritis multiplex can occur in association with a number of other medical conditions, including RA, vasculitis, polyarteritis nodosa, diabetes mellitus, sarcoidosis, and amyloidosis. An ischemic mechanism is the most likely cause of mononeuritis multiplex. It is generally accepted that mononeuritis multiplex in RA results from ischemia caused by vasa nervorum vasculitis.

Referred Pain: Viscerogenic

The heart, apical lung, and bronchus are all capable of referring pain to the wrist and hand.

CAUSES OF KNEE PAIN

Generalized Knee Pain

Causes of generalized knee pain include:

- fracture (supracondylar, patellar, and proximal tibia);
- acute dislocation of the tibiofemoral joint;
- acute dislocation of the patella;
- intraarticular ligament injury (see Chapter 20);
- monoarthritis;
- polyarthritis;
- reactive arthritis;
- CRPS (RSD); and
- referred pain.

Anterior Knee Pain

Anterior knee pain is a common problem in active adolescents and young adults. The causes of anterior knee pain generally fall under three categories:[419]

- Focal musculoskeletal lesions. This group consists mainly of lesions that can be clinically and radiologically defined. Such lesions include Osgood–Schlatter disease, jumper's knee, bipartite patella, tumors, plical irritation, and ligamentous injuries (see Chapter 20). These lesions normally respond well to locally applied interventions.
- Traumatic lesions. This group includes all (see Chapter 20) the conditions with a specific mechanism of injury involving direct trauma. These conditions include osteochondritis dissecans and bone contusions.
- Miscellaneous lesions. This group includes the more obscure causes of anterior knee pain including dynamic problems, such as maltracking of the patella and the excessive lateral pressure syndrome (see Chapter 20), as well as idiopathic chondromalacia, referred pain, CRPS, and psychogenic pain.

Musculoskeletal Causes

Osgood–Schlatter Disease

See Chapter 30.

Bursitis

See Chapter 20.

Jumper's Knee

See Chapter 20.

Bipartite Patella

This condition is common in childhood. It is often bilateral and usually is regarded as a variation of normal ossification. Very rarely, in response to overuse or acute injury, the synchondrosis separating the two centers of ossification may become painful and the site of local tenderness. There are three sites at which bipartite patella is found, and each has an important soft-tissue attachment:[419]

- The distal pole of the patella with attachment of the patellar tendon. This type may represent the end stage of Sinding–Larsen–Johansson syndrome.
- Lateral margin of the patella with attachment of the lateral retinaculum.
- Superior-lateral corner of the patella, the insertion of vastus lateralis. This is the most common site for symptoms.

Trauma-Related Causes

Osteochondritis Dissecans

Osteochondritis dissecans (OCD) is a rare cause of anterior knee pain in young athletes. It involves the weight-bearing portions of the medial and lateral femoral condyles. Occasionally, pain may not be the most prominent symptom, but a catching sensation with knee flexion or an extensor weakness may be the primary complaint. Sometimes the lesion is associated with maltracking. If the lesion is small, a painful arc is produced as it passes over the articular surface of the femur during movement.

MRI, CT, and bone scans are often used to characterize these lesions.

Conservative intervention with rest is appropriate for intact lesions, which usually will show no sclerosis, and in patients younger than 13 or 14 years, in whom healing is the rule.[419]

Surgical techniques can be used to securely attach the loose osteochondral fragments to the underlying bone.

Bone Contusion

Bone contusions (bruises) are related to trauma and can occur at sites other than the knee. There is no unique mechanism of injury, but they seem to result from direct impact, axial overloading, and impingement. They pose a potential risk for chondrolysis and stress fracture, and mobilization and weight bearing should be increased gradually.

Miscellaneous Causes

Tumors

Neoplastic involvement of the knee is a less common cause of knee pain. Malignant primary tumors arising from the patella include hemangioendothelioma, hemangiosarcoma, lymphoma, fibrous histiocytoma, osteoblastoclastoma, and plasmacytoma.[420] Soft-tissue sarcomas are the most common malignant tumor of the knee, and these include osteosarcomas, Ewing sarcoma, rhabdomyosarcoma, and synovial sarcomas.[421,422] Metastasis to the patella is rare.[423]

Benign tumors are more prevalent at this site. In a published series of 42 patellar tumors,[424] 90% were benign, with the most common diagnosis being chondroblastoma. Other benign tumors of the knee may include osteochondromas, nonossifying fibromas, and osteoid osteomas. Very rarely, soft-tissue tumors may occur within the fat pad; in addition, synovial lesions, such as PVN synovitis, can cause anterior knee pain, clicking, and catching.[419]

A history of knee pain worsened by activity and relieved by rest suggests benign involvement. However, pain that is constant, unrelenting, severe, and that occurs at night suggests a malignant process.[425–427] In malignant tumors of the patella, the pathologic fracture is often the presenting complaint.

Plicae

See Chapter 20.

Hoffa Syndrome

See Chapter 20.

Osteomyelitis of the Patella

Osteomyelitis of the patella usually affects children between the ages of 5 and 15 years. It is exceedingly rare in adults and in children younger than 5 years.[428]

The patient may present with complaints of an insidious onset of pain and swelling in the knee and calf. Pain localized to the

patella may be mild or severe, causing a limp and restriction of motion. Motion is less severely affected than in patients with septic arthritis. Swelling may be minimal in the more indolent cases, or marked with distention of the pre-patellar bursa or the knee, which may divert attention from the patella. Cellulitis overlying the patella may also be present. Isolated pinpoint tenderness over the patella is probably the single most useful clinical sign.[428]

Differential diagnosis of the swollen knee in an individual with sepsis includes septic arthritis; osteomyelitis of the distal femur, proximal tibia, or patella; and septic bursitis.[429] With more benign symptoms and the presence of a lytic lesion of the patella, neoplasm, and Brodie abscess must be considered.[429]

Excessive Lateral Pressure Syndrome

See Chapter 20.

Maltracking of the Patella

See Chapter 20.

Iatrogenic Causes: Infrapatellar Contracture Syndrome

See Chapter 20.

Medial Knee Pain

The causes of medial knee pain include the following.

- Medial meniscus tear: see Chapter 20.
- Medial collateral ligament sprain: see Chapter 20.
- Medial collateral ligament bursitis: see Chapter 20.
- Hoffa's disease: see Chapter 20.
- Pes anserine bursitis: see Chapter 20.
- Semimembranosus tendinopathy: see Chapter 20.

Lateral Knee Pain

The causes of lateral knee pain include the following.

- Iliotibial band friction syndrome: see Chapter 20.
- Popliteus tenosynovitis
- Popliteus tendon rupture
- Lateral meniscal tear: see Chapter 20.
- Lateral collateral ligament sprain: see Chapter 20
- Tibiofibular disorder: see Chapter 20.
- Biceps femoris tendinopathy: see Chapter 20.
- Osteochondral fracture of the lateral femoral condyle

Posterior Knee Pain

The causes of posterior knee pain include the following.

- Gastrocnemius muscle strain or rupture
- Plantaris muscle strain or rupture
- Hamstring muscle and tendon disorder
- Muscle spasm or cramp
- Posterior cruciate ligament or posterior capsule tear: see Chapter 20
- Baker cyst: see Chapter 20

TABLE 5-21 Potential Causes of Anterolateral Leg Pain

Anterior compartment syndrome
Lateral compartment syndrome

Muscle strain of one or more of the fibularis (peroneal) muscles or of anterior tibialis

CAUSES OF LOWER LEG PAIN

Anterolateral Lower Leg Pain

The causes of anterolateral lower leg pain include those listed in Table 5-21.

Anterior Compartment Syndrome

A compartment, or chronic exertional compartment, syndrome is a condition of pain associated with increased tissue pressure in the involved muscular compartment with sustained exercise. During heavy exercise, fluid accumulates within the interstitial space of skeletal muscle, increasing mass up to 20% as the fluid increases.[430] The gradual buildup of interstitial fluid combined with a limited expansion of the fascial compartments, especially in the anterior and lateral leg compartments, may lead to elevated intramuscular pressures, causing capillary occlusion, and eventual cell hypoxia and death.[431] Thus, this condition is suggested by lower leg muscular pain with running or other activity and is relieved, very rapidly, by stopping the activity. The clinical signs of compartment syndrome can be remembered using the mnemonic of the five P's: pain, paralysis, paresthesia, pallor, and pulses. Pain, especially disproportionate pain, is often the earliest sign, but the loss of normal neurologic sensation is the most reliable sign.[432,433]

Palpation of the compartment in question may demonstrate swelling or a tense compartment.[434] A decrease or loss of two-point discrimination also can be an early finding of compartment syndrome.[432,433] Clinical findings may also include shiny, erythematous skin overlying the involved compartment (described as "woody") and excessive swelling. Intracompartmental tissue pressure is usually lower than arterial blood pressure, making peripheral pulses and capillary refill poor indicators of blood flow within the compartment.[434]

Compartment syndrome is confirmed by elevated compartment pressures. Normal tissue pressure ranges between 0 and 10 mm Hg.[434] Capillary blood flow within the compartment may be compromised at pressures greater than 20 mm Hg. Muscle and nerve fibers are at risk of ischemic necrosis at pressures greater than 30–40 mm Hg.

Differential diagnosis includes tibial stress fracture, anterior tibialis tendinopathy, and the catch-all group of "shin splints." Acute compartment syndrome requires emergent surgical fasciotomy.

Lateral Compartment Syndrome

Lateral compartment syndrome is very rare. It is often misdiagnosed as tenosynovitis of the tibialis anterior and flexor hallucis longus, fibular stress fracture, or a lateral gastrocnemius strain. Characteristic findings include tenderness along the

proximal half of the leg, with swelling and tightness over the lateral compartment. On occasion, there may be complaints of numbness over the posterior aspect of the foot caused by compression of the superficial fibular (peroneal) nerve.[433,434]

Intervention is based on the severity of the symptoms. In mild cases, treatment involves relative rest, education, and examination for underlying etiologies.[435] These include lower extremity malalignment, muscle imbalances, training errors, inadequate footwear, and poor technique.[435]

An acute compartment syndrome, or one that does not respond to conservative intervention, requires an open fasciotomy.

Popliteal Artery Entrapment Syndrome

Most cases of popliteal artery entrapment syndrome (PAES) are caused by anatomic variations in the normal course of the popliteal artery (see Chapter 20), including an abnormal attachment of the medial head of the gastrocnemius within the intercondylar notch, medial course of the popliteal artery, hypertrophy of surrounding musculature and/or aberrant fibrous bands.[436,437] Any one of these anomalies can result in a focal compression of the popliteal artery against the medial femoral condyle during forceful plantarflexion.[438] Since popliteal artery entrapment syndrome is very similar in its presentation to chronic exertional compartment syndrome; care must be taken with the diagnosis. PAES is commonly diagnosed using the ankle-brachial index (i.e., ratio of the blood pressure in the lower legs to the blood pressure in the arms).[439] Since this entrapment is typically functional, it is recommended that the ankle-brachial index be done with the ankle in the neutral, forced dorsiflexion, and forced plantar flexion positions.[439] An ankle brachial index of less than 0.9 is considered abnormal.[439]

Irritation of the Superficial Fibularis (Peroneal) Nerve

Compression of a peripheral nerve causes deformation of the nerve fibers, local ischemia, edema, and increased endoneurial pressure caused by accelerated vascular permeability, resulting in the loss of nerve fiber function (see Chapter 3).

Muscle Strain

See Chapter 20.

Calf Pain

The causes of calf pain include those listed in Table 5-22.

TABLE 5-22 Potential Causes of Calf Pain

Pyomyositis
Fibular shaft fracture
Deep vein thrombosis
Hematoma
Rupture of Achilles tendon
Soleus muscle strain
Acute posterior compartment syndrome
Muscle cramps

Pyomyositis

Pyomyositis is a term used to denote a spontaneous muscle abscess of skeletal muscle. It is predominantly a disease of tropical countries. The etiology of pyomyositis is poorly understood. Local mechanical trauma at the time of incidental bacteremia is frequently postulated as a mechanism. Underlying conditions, such as immunodeficiency, or chronic illness, such as diabetes mellitus, may predispose to pyomyositis.

The natural history of pyomyositis may be divided into three stages: invasive, purulent, and late.

1. Invasive stage. This stage occurs when the organism enters the muscle. It is characterized by an insidious onset of dull, cramping pain, with or without fever and anorexia.[440] There is localized edema, sometimes described as indurated or woody, but usually little or no tenderness. This stage lasts from 10 to 21 days.
2. Purulent stage. This stage occurs when a deep collection of pus has developed in the muscle. The muscle usually but not always is tender, and fever and chills are common. The overlying skin may be normal or show mild erythema.
3. Late stage. This stage is characterized by exquisite tenderness of the site, which is red and fluctuant. The patient has a high fever and occasionally may be in septic shock.

The iliopsoas is one of the most common sites of pyomyositis (see the discussion of iliopsoas abscess under "Causes of Pelvic Pain" earlier), but they can also occur in other leg muscles.

Fibular Shaft Fracture

Direct trauma is the most common cause of isolated fibular fractures.[441] Another cause is a forced muscle contraction of the soleus.[442] Fibular stress fractures are common in long-distance runners. Maximal loading of the fibula occurs during the initial period of stance and forces up to three times body weight are transmitted through the leg.[443] Thus, pain with this condition is typically reported with weight bearing during the initial period of stance. There also may be tenderness over the fracture site.

Deep Venous Thrombosis

Muscle veins drain into the deep veins of the lower extremity. Soleal muscle veins drain into the fibular and tibial posterior veins. The veins of the gastrocnemius drain into the popliteal vein. Thrombosis usually develops as a result of venous stasis or slow-flowing blood around venous valve sinuses (see Chapter 2). Extension of the primary thrombus occurs within or between the deep and superficial veins of the leg, and the propagating clot causes venous obstruction, damage to valves, and possible venous thromboembolism (VTE). Most episodes of VTE are clinically silent. The most common cause of leg swelling is edema, but expansion of all or part of a limb may result from an increase in any tissue component (muscle, fat, blood, etc.).[444]

The clinical features of a deep vein thrombosis (DVT) include:[444]

- calf pain or tenderness, or both;
- swelling with pitting edema;
- swelling below the knee (distal deep vein thrombosis) or up to the groin (proximal deep vein thrombosis);

- increased skin temperature;
- superficial venous dilation; and
- cyanosis, in patients with severe obstruction.

The intervention is aimed at reducing symptoms and preventing complications. The main complications of a DVT are a pulmonary embolism (see Chapter 2), postthrombotic syndrome, and recurrence of thrombosis.[444] Proximal thrombi are a major source of morbidity and mortality. Distal thrombi are generally smaller and more difficult to detect noninvasively, and their prognosis and clinical importance are less clear.[444]

Hematoma

A strain of the gastrocnemius muscle may follow a trivial trauma. Complete or partial tears of the musculotendinous unit may result in a hematoma. Clinical manifestations of gastrocnemius hematoma may include local swelling, pain, and tenderness aggravated by passive dorsiflexion of the ankle joint. This condition can mimic a DVT. The subjective history may help with the diagnosis. A definite diagnosis is established by CT scanning examination, which will reveal a local soft-tissue mass within the gastrocnemius consistent with a hematoma.

Rupture of the Achilles Tendon

See Chapter 21.

Soleus Muscle Strain

See Chapter 21.

Acute Posterior Compartment Syndrome

Acute calf pain can occur as a result of a posterior compartment syndrome. Causes include a DVT, rupture of a Baker cyst, and spontaneous rupture of the medial head of the gastrocnemius. The diagnosis of posterior compartment syndrome is made by measuring the pressure in the posterior compartment. The intervention usually involves a fasciotomy.

Anteromedial Lower Leg Pain

The causes of anteromedial lower leg pain include those listed in Table 5-23.

Medial Tibial Stress Syndrome

See Chapter 21.

TABLE 5-23 Potential Causes of Anteromedial Lower Leg Pain

Stress fracture of tibia
Medial tibial stress syndrome
Saphenous neuritis
Osteomyelitis of tibia
Soleus syndrome
Shin splints
Greater saphenous vein thrombosis

Saphenous Neuritis

Saphenous neuritis, also known as gonalgia paresthetica, is a painful condition caused by either irritation or compression at the adductor canal or elsewhere along the course of the saphenous nerve.[445] The condition may also be associated with surgical or nonsurgical trauma to the nerve, especially at the medial or anterior aspect of the knee.

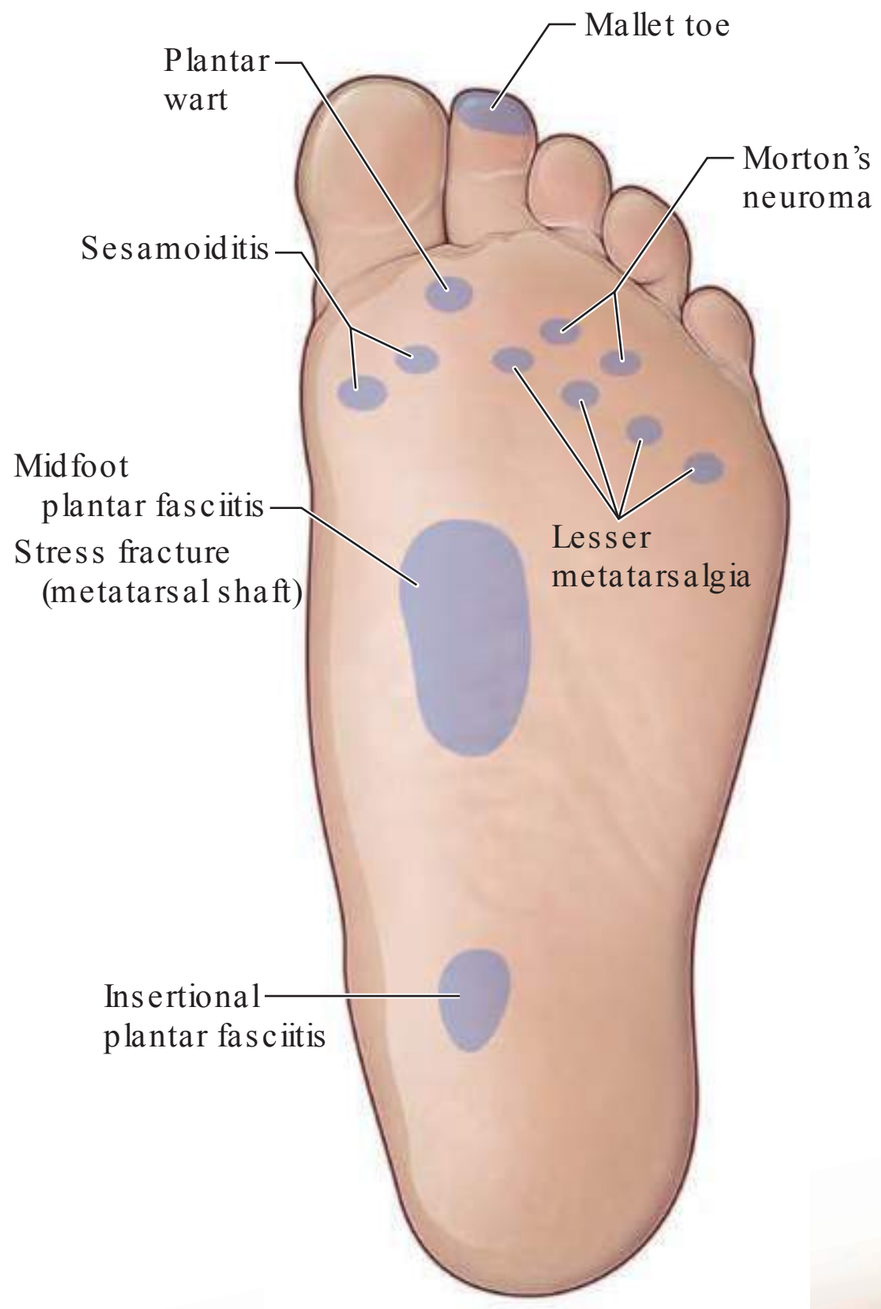
Saphenous neuritis can imitate other pathology around the knee or calf, particularly a medial meniscal tear, muscle injury, or OA. As an isolated entity, saphenous neuritis may appear in conjunction with other common problems, such as OA and patellofemoral pain syndrome. Its clinical appearance is characterized by a dull or achy pain along the course of the saphenous nerve on the medial side of the thigh, knee, or calf. Hyperesthesia of the nerve is common. There is usually tenderness to light palpation along the course of the nerve, especially at the exit of the nerve from the adductor canal, near the medial joint line, or along the nerve in the proximal third of the leg. The diagnosis is confirmed by relief of symptoms after injection of the affected area with local anesthetic.

Initial treatment can include nonsurgical symptomatic care, treatment of associated pathology, desensitization therapy, transcutaneous electrical nerve stimulation (TENS), and diagnostic or therapeutic injections of local anesthetic. In recalcitrant cases, surgical decompression and neurectomy are potential options. The key to treatment is prompt recognition; palpation of the saphenous nerve should be part of every routine examination of the knee.

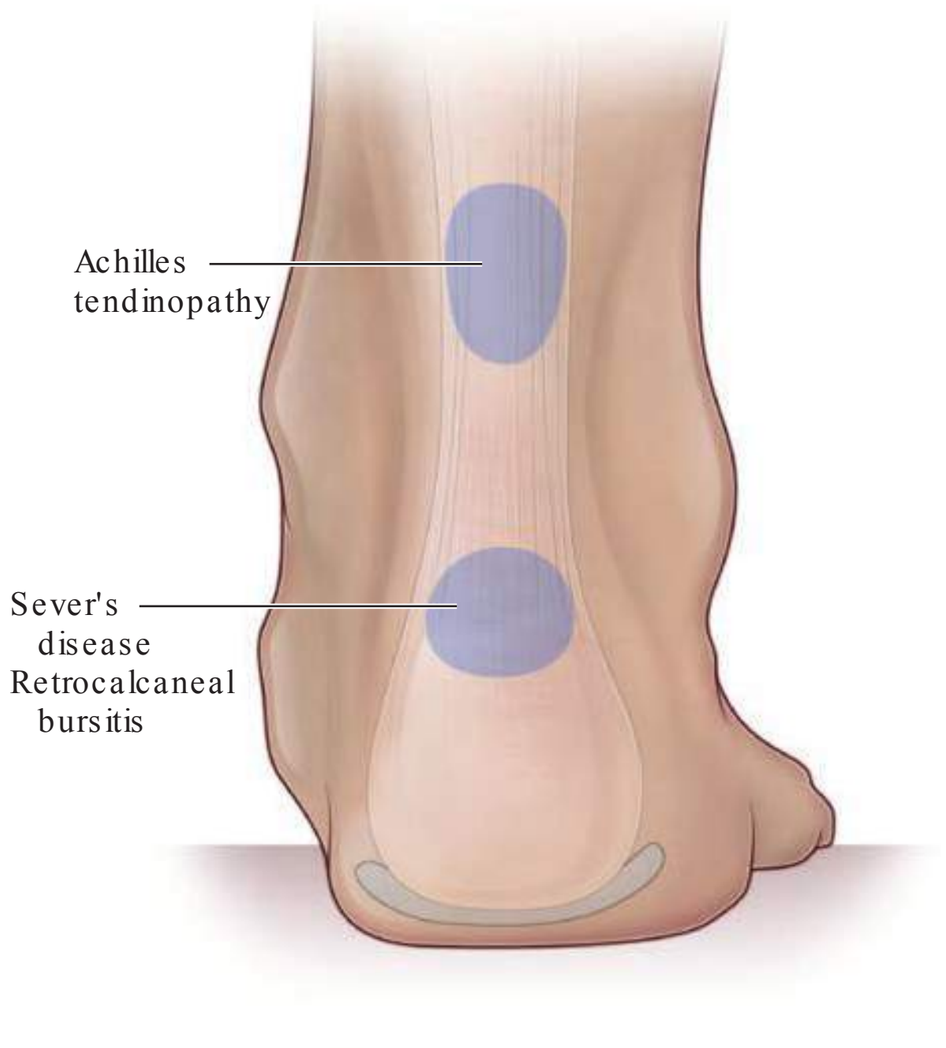
Osteomyelitis of the Tibia

Osteomyelitis is a severe infection that can arise after operative treatment of bone and from an acute, penetrating trauma to the bone. The tibia is the most common site of posttraumatic osteomyelitis.[446] Posttraumatic tibial osteomyelitis results from trauma or nosocomial infection from the treatment of trauma that allows organisms to enter the bone, proliferate in traumatized tissue, and cause subsequent bone infection.[446] The resulting infection is usually polymicrobial.

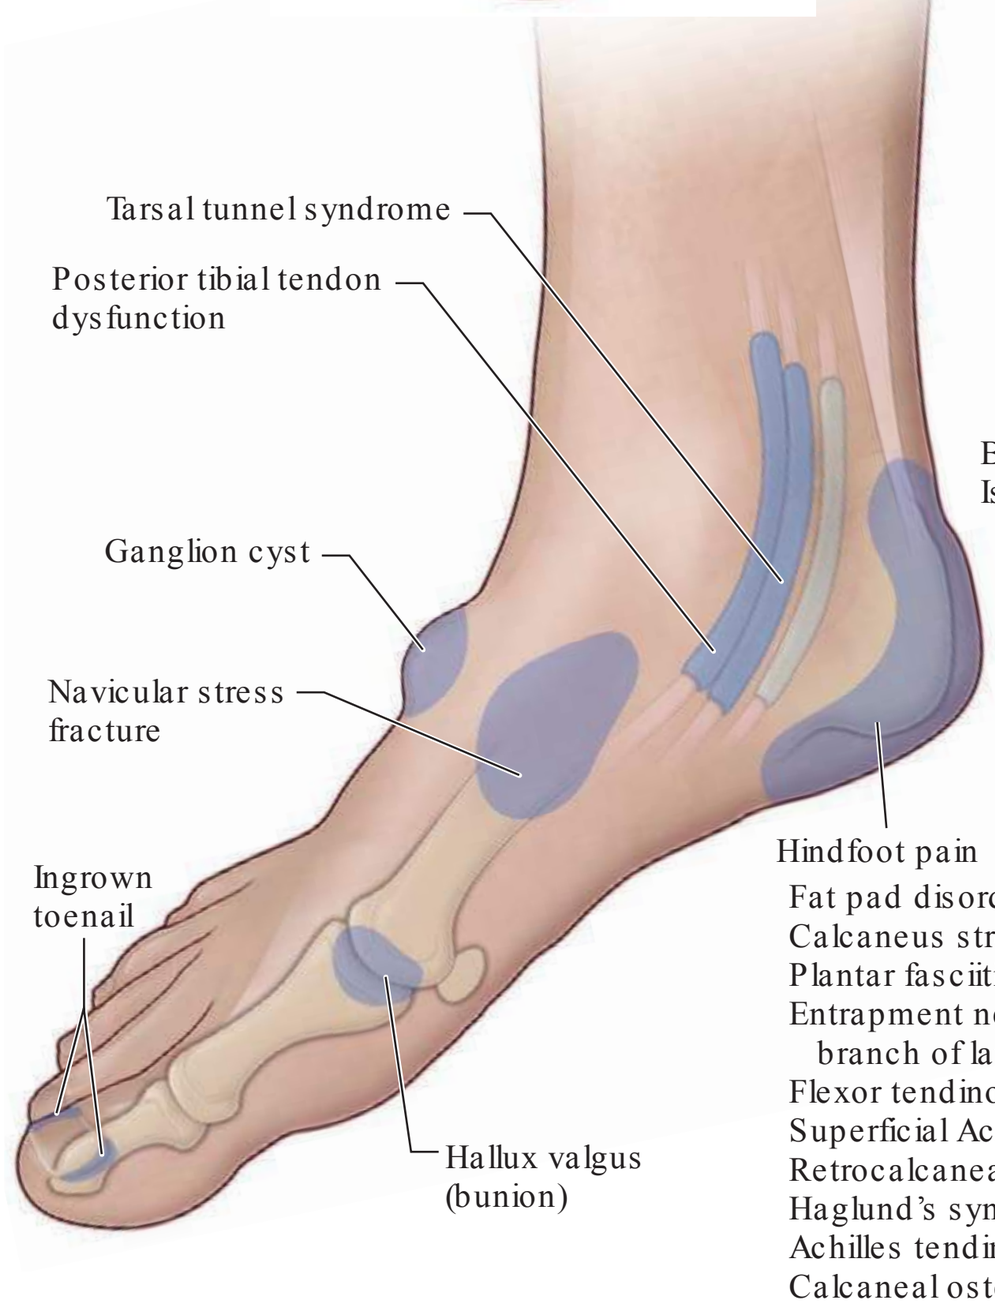
Patients with posttraumatic osteomyelitis of the tibia may present with localized bone and joint pain, erythema, swelling, and drainage around the area of trauma, surgery, or wound infection.[446] Signs of bacteremias, such as fever, chills, and night sweats, may be present in the acute phase of osteomyelitis, but not in the chronic phase.[446]



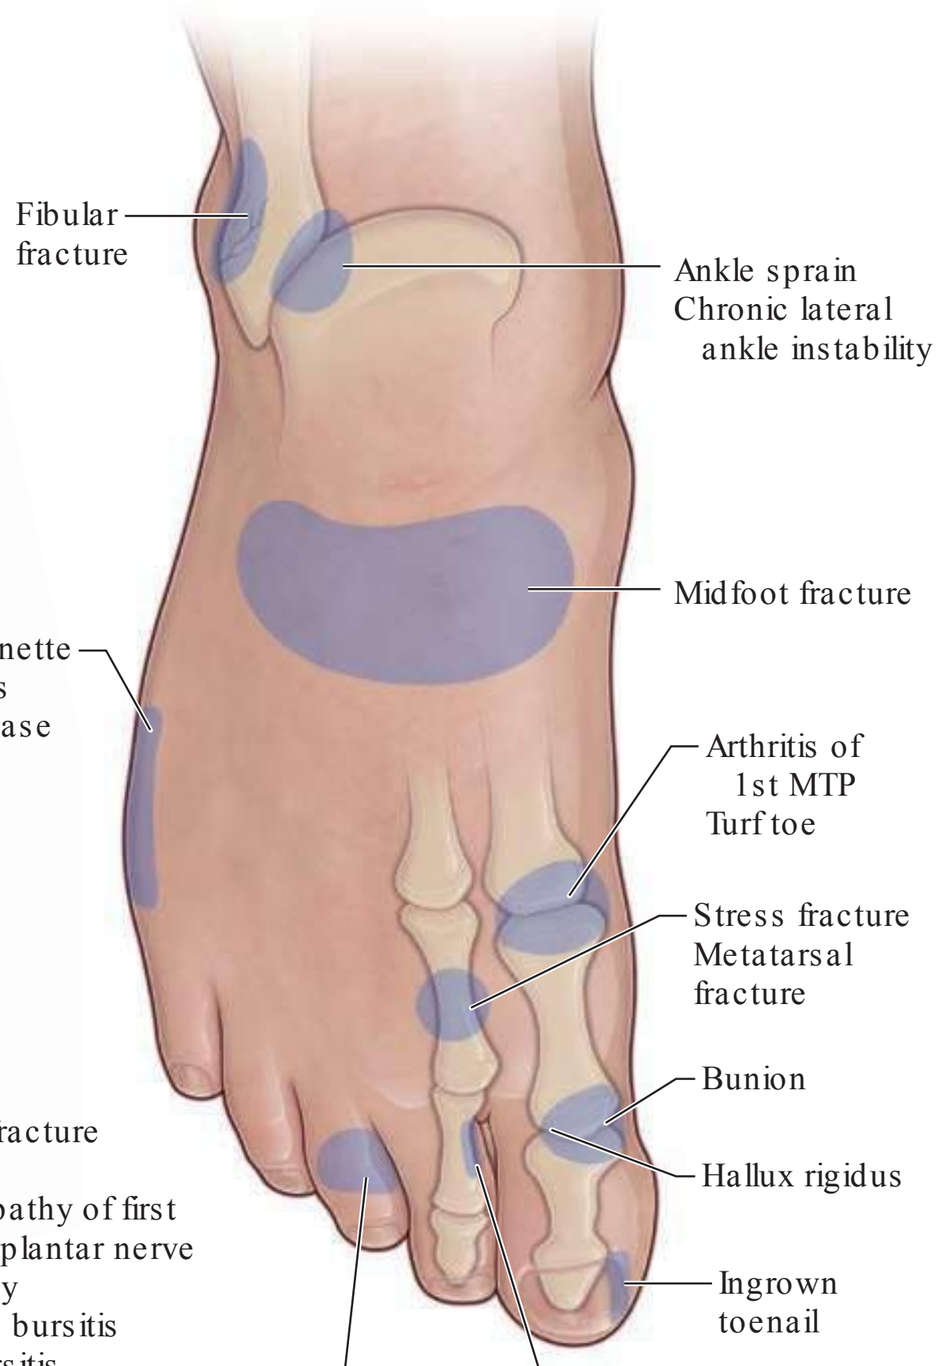
Radiographs are important for the diagnosis, staging, and evaluation of the progression of posttraumatic osteomyelitis.[446]



CAUSES OF ANKLE PAIN



The causes of generalized ankle pain include those shown in Figure 5-5 and listed in Table 5-24.



Crystal-Induced Arthropathies

Two types of arthritis, gout, and pseudogout are quite common in the ankle joint. Episodes of acute arthritis in this region, without apparent cause, should arouse the suspicion of a gout attack, especially in a middle-aged man.

Fat pad disorders
Calcaneus stress fracture
Plantar fasciitis
Entrapment neuropathy of first branch of lateral plantar nerve
Flexor tendinopathy
Superficial Achilles bursitis
Retrocalcaneal bursitis
Haglund's syndrome
Achilles tendinopathy
Calcaneal osteomyelitis
Flexor hallucis longus tendinopathy
Tarsal tunnel syndrome
Calcaneal fracture
Fibularis muscle strain or tendinopathy
Osteochondral fracture of talar dome

Bursitis

See Chapter 21.

Os Trigonum

The term os trigonum refers to a failure of the lateral tubercle of the posterior process to unite with the body of the talus during ossification, producing an impingement with extreme plantar flexion.[447] The posterior aspect of the talus often exhibits a separate ossification center, appearing at 8–10 years in girls and 11–13 years in boys. Fusion usually occurs 1 year after its appearance.[448,449] When fusion does not occur, an os trigonum is formed. An os trigonum has been reported to be present in approximately 10% of the general population and is often unilateral.[448,450–452] The origin of this ossicle may be congenital or acquired. Congenitally, it can be a persistent separation of the secondary center of the lateral tubercle from the remainder of the posterior talus secondary to repeated microtrauma during development.[448,452] The acquired form may be secondary to an actual fracture that has not united.[448,452,453] With either form, the os trigonum is usually asymptomatic in most cases.[447] However, it can become symptomatic in young athletes who actively plantar flex the ankle, such as ballet dancers, gymnasts, ice skaters, or, on occasion, soccer players.[448,450,452,454,455]

Symptoms associated with os trigonum include pain with maximum plantar flexion as the posterior talus impinges on the posterior tibia.[456] The pain, which is typically in the posterolateral ankle, results from the mechanical impingement of the posterior talus between the posterior tibia and the calcaneus.[447] Repetitive impingement of the soft tissues in this interval can also result in hypertrophic capsulitis.[448,451,457–459] Associated posteromedial pain. Associated posteromedial pain[448,454,458] may indicate a concurrent flexor hallucis longus tendinopathy. The diagnosis is confirmed by imaging studies.

Plain radiographs should include a lateral view of the ankle and a lateral view in plantarflexion. A bone scan may be used to determine the reactivity of the os trigonum,[448,460] but absence of uptake does not exclude impingement.[447]

Differential diagnosis includes posterior ankle impingement, Achilles tendinopathy, fibularis tendinopathy, and flexor hallucis longus tendinopathy.[448]

Conservative intervention may include rest, anti-inflammatory medications, avoidance of plantarflexion casting, and injection.[448,454] Once appropriate, restoration of normal strength, ROM, and biomechanics are introduced. If symptoms persist, surgical removal of the bone may be required but is delayed until skeletal maturity is achieved.[456]

Osteochondritis Dissecans

OCD of the talus may result from an inversion stress to the ankle. This is actually a "transchondral fracture" secondary to trauma.[461] More commonly, the onset of pain is insidious, and some prior macrotrauma is evident.[447] Young patients may present with pain over the anterolateral or posteromedial talus and often report recurrent ankle effusions or weakness. Plain radiographs of the ankle usually show the lesion, but sometimes a bone scan or MRI is necessary for diagnosis.[462] The Berndt–Harty[463] classification of talus OCD is as follows:

- Type I. Small area of compression of subchondral bone.
- Type II. Partially detached osteochondral fragment.
- Type III. Completely detached osteochondral fragment but remaining in its crater.
- Type IV. Displaced osteochondral fragment.

Berndt and Harty[463] reported that 43% of OCD lesions involved the middle third of the lateral talus, with 57% involving the posterior third of the medial talus.[461] One study[464] reported that lateral OCD lesions rarely heal on their own, whereas most medial lesions do.[461]

The intervention for type I and II lesions begins with casting and orthotics.[447] The intervention for type III medial lesions starts off conservatively, as well, but may require arthroscopic or open debridement. Type III lateral lesions and type IV lesions all require arthroscopic removal or pinning for the best chance of healing.[465]

CAUSES OF FOOT PAIN

Generalized Foot Pain

The causes of generalized foot pain include those shown in Figure 5-5 and listed in Table 5-25.

Infection

Infection of the foot includes such diagnoses as cellulitis, necrotizing fasciitis, and osteomyelitis.

TABLE 5-25 Potential Causes of Generalized Foot Pain

Trauma

Peripheral vascular disease
Peripheral polyneuropathy
Systemic disorders
Nerve and root compression syndromes
Foot cramps
Cold injury
Bites
Cutaneous disorders

Cellulitis. Cellulitis is common after foot and ankle surgery. It is important to distinguish a superficial infection from one that involves the deeper soft-tissue envelope and possibly the joint or bone.

- Superficial. With a superficial infection, the skin is warm, tender, and erythematous, but joint motion is painless. Occasionally, lymphangitis or lymphadenopathy is present. The area is tender to palpation. The most common causative organisms in uncompromised hosts are S. aureus and β-hemolytic streptococci.
- Deep. Deep infections with abscess formation are a serious complication. In patients with deep infections, the skin is warm, tender, swollen, and possibly fluctuant. White blood cell count and temperature may be increased. Plain radiographs, MRI, and needle aspiration are helpful in making the diagnosis.

Necrotizing Fasciitis. Necrotizing fasciitis is characterized by rapidly progressive necrosis and edema of the subcutaneous fat and fascia that can result in septic shock, end-organ failure, and loss of limb or life. Patients who are immunocompromised, such as those with human immunodeficiency virus (HIV) infections, diabetes mellitus, and alcoholism, are at increased risk of necrotizing fasciitis. Clinical signs of necrotizing fasciitis include tense edema and erythema that do not respond to antibiotics or elevation. Patients are usually febrile.

Osteomyelitis. Fever, local pain, edema, exudative drainage, and elevated leukocyte count and sedimentation rate are typical findings with osteomyelitis. Surgical treatment of patients with osteomyelitis consists of debridement of all necrotic and infected tissue and appropriate antibiotic therapy. Treatment may also include the use of antibiotic-impregnated methylmethacrylate beads, local or vascularized soft-tissue flaps, autogenous bone grafts, or vascularized bone grafts once the infection is eradicated.

Rheumatoid Arthritis

RA characteristically involves the synovial tissues of the small joints of the feet, rather than the talocrural or subtalar joint. Three times more women than men are affected. In 17% of cases, the disease first manifests in the foot.[466]

The early stage of the disease should be suspected in young women presenting with bilateral foot pain and a tendency for morning stiffness in the MTP joints of the feet.

Gout

About 60% of initial attacks of gout involve the great toe (podagra), which becomes swollen and excruciatingly painful.[466]

Pseudogout

Pseudogout involves joints in addition to the MTP joint, including the talonavicular or subtalar joints.[466]

Systemic Lupus Erythematosus

SLE is a systemic autoimmune disease with clinical features that include glomerulonephritis, rashes, serositis, hemolytic anemia, thrombocytopenia, and CNS involvement.[467] It is disease occurs most commonly in women of childbearing age.

The variety of neurologic presentations of SLE can include cranial neuropathies, stroke syndromes, movement disorders, spinal cord lesions, seizure disorders, dementias, cognitive disturbances, psychoses, and mood disorders. Peripheral nervous system (PNS) manifestations include symmetric polyneuropathies, mononeuritis multiplex, acute inflammatory demyelinating polyneuropathies, chronic relapsing inflammatory demyelinating polyneuropathies, and autonomic failure.

SLE is considered to be the prototypical human autoimmune disease mediated by pathogenic immune complexes.

Sickle-Cell Disease[468]

Sickle-cell disease is an inherited blood disorder that affects mostly African Americans. It leaves patients vulnerable to repeated crises that can cause severe pain, multisystem organ damage, and early death. Sickle-cell crises typically begin during the preschool or early elementary school years. How often they recur and how long each attack lasts vary considerably.

The crisis begins when a trigger—such as an acute infection (especially viral), stress, dehydration, or extremely hot or cold temperatures—causes the red blood cells to release oxygen. People with the sickle-cell disease have abnormal hemoglobin, called hemoglobin S (HbS), which forms long polymers upon deoxygenation. The rod-like polymers change the normally round and pliable red blood cells into stiff cells with a crescent, or sickle, shape.

Bundles of these deformed cells plug up the capillaries throughout the body, reducing blood flow. This vasoocclusion causes localized tissue hypoxia, which, in turn, promotes further sickling. Tissue infarction and necrosis soon follow.

Pain is usually the main symptom. It may be localized or diffuse, constant or intermittent. About half of all patients also have a fever, swelling in the joints of the hands or feet, long bone pain, tachypnea, hypertension, nausea, and vomiting. Hospitalization becomes necessary when these complications are severe. Acute chest syndrome and cerebrovascular accidents are life-threatening complications of sickle-cell disease. In addition, the patient may develop an infarct in a lung, causing acute chest syndrome, characterized by a combination of chest pain, dyspnea, fever, and leukocytosis.

Complex Regional Pain Syndrome

CRPS formerly known as RSD, is a regional, posttraumatic, neuropathic pain problem that most often affects one or more limbs (see Chapter 18 for CRPS of the upper extremity).[469]

Most patients with CRPS have an identifiable inciting or initiating injury, which may be trivial, such as a minor limb sprain, or severe, such as trauma involving a major nerve or nerves. Adults can present with CRPS after a fracture or trauma with immobilization. With children, CRPS occurs most often in athletic girls (1:6, boys to girls) with an average age of 12 years.[470]

Most of the cases of CRPS in the lower extremity, including the foot and ankle, have a history of minor trauma. T e key features are pain, allodynia, and hyperalgesia (see Chapter 3), abnormal vasomotor activity, and abnormal sudomotor activity persisting beyond the period of normal healing.

Patients with CRPS often adopt a protective posture to protect the affected extremity from mechanical and thermal stimulation. T ey may wear a stocking to guard the involved extremity. Allodynia may be so severe that the patient will not allow the clinician to examine or even touch the affected limb.

Successful treatment of CRPS depends on an aggressive and multidisciplinary approach. Because pain and limb dysfunction are the major clinical problems, physical rehabilitation, and pain control are the main treatment objectives. Early referral to a pain clinic for possible sympathetic nerve blocks or neurosuppressive medications may be indicated.

Peripheral Vascular Disease

PVD is common in the western world. PVD, typically begins its progression in midlife (for men, at approximately 45 years, and for women, 55–60 years).[471] Arteries generally have smooth linings, which allow blood to flow unimpaired. Arteriosclerosis is a degenerative arterial disease that refers to the so-called hardening of the arteries. In this condition, muscle and elastic tissue are replaced with fibrous tissue, and calcification may occur.

Atherosclerosis is the most common type of arteriosclerosis. It is characterized by the formation of atheromatous plaques, which are deposits of fatty material in the lining of medium- and large-sized arteries. T ese arteries then become narrowed and rough as more fat is deposited. Blood clots form more easily because of the roughness of the vessel wall, further narrowing the artery and, thus, potentially limiting blood flow. A reduction of blood supply to the organs and tissues prevents them from performing adequately. In addition, the plaques are liable to break down and form ulcers. T romboses may then develop as a result of the roughening and ulceration of the inner coat of the arteries.

A patient who is suffering from reduced blood supply to the lower limbs, often experiences effort-related cramp in the calves, thighs, and buttocks, which disappears at rest. T is condition is known as intermittent claudication.

PVD with claudication can be confused with neurogenic claudication and spinal stenosis. T e major difference is the response of the pain to rest or to the position of the spine. Unlike the pain from spinal stenosis, the pain from PVD is not relieved by trunk flexion or aggravated with sustained trunk extension (Table 5-26).

T e site of claudication indicates the most likely site of the narrowing or blockage. When severe, claudication can become debilitating, can limit mobility, and sometimes is associated with a worsened quality of life and loss of functional independence. Pain may occur at more regular intervals, as the disease process

TABLE 5-26 Differentiating Causes of Claudication

Vascular Claudication	Neurogenic Claudication	Spinal Stenosis
Pain[a] is usually bilateral	Pain is usually bilateral but may be unilateral	Usually bilateral pain
Occurs in calf (foot, thigh, hip, or buttocks)	Occurs in back, buttocks, thighs, calves, and feet	Occurs in back, buttocks, thighs, calves, and feet
Pain consistent in all spinal positions	Pain is decreased in spinal flexion and increased in spinal extension and with walking	Pain is decreased in spinal flexion and increased in spinal extension and with walking
Pain is brought on by physical exertion (e.g., walking), relieved promptly by rest (1–5 min), and increased by walking uphill	Pain is decreased by recumbency	Pain is relieved with prolonged rest (may persist hours after resting) and decreased when walking uphill
No burning or dysesthesia	Burning and dysesthesia from back to buttocks and leg(s)	Burning and numbness present in lower extremities
Decreased or absent pulses in lower extremities	Normal pulses	Normal pulses
Color and skin changes in feet; cold, numb, dry, or scaly skin; and poor nail and hair growth	Good skin nutrition	Good skin nutrition
Affects ages of 40–60 + years	Affects ages of 40–60 + years	Peaks in the seventh decade, affects men primarily

Data from Goodman CC, Snyder TE. Dif erentia! Diagnosis in Physical Therapy. Philadelphia, PA: WB Saunders; 1990.
[a]Pain associated with vascular claudication also may be described as an "aching," "cramping," or "tired" feeling.

continues to its end stage—critical limb ischemia—until finally it occurs when the patient is at rest (rest pain). At this stage, rest pain is usually worse when the legs are elevated and during sleep, with the patient gaining relief by hanging the foot over the side of the bed. The development of nonhealing wounds or gangrene (tissue death) may occur at this stage.

This disease process can lead to loss of limb and life; therefore, investigation and early diagnosis are important. The patient who presents with typical, reproducible, exertional discomfort in the buttocks, thighs, or calves that disappears during rest is likely to have claudication and symptomatic PVD.

Peripheral Polyneuropathy

Polyneuropathy is a syndrome with many different causes. Clinical features in painful neuropathies include sensory loss, paresthesia, paradox hyperalgesia, paroxysms, and increased pain with repetitive stimulation.

Systemic Disorders

The systemic disorders that can cause foot pain include:

- carcinoma;
- leukemia;
- lymphoma;
- myeloma;
- amyloidosis;
- connective tissue diseases (polyarteritis nodosa and SLE);
- renal failure;
- acquired immunodeficiency syndrome;
- sarcoidosis; and
- cutaneous disorders.

Nerve and Root Compression Syndromes

See Chapters 3 and 21.

Forefoot Pain

The causes of forefoot pain include those shown in Figure 5-5 and listed in Table 5-27.

Metatarsalgia

Metatarsalgia, in its broadest definition, includes discomfort around the metatarsal heads or the plantar aspects of the metatarsal heads. Metatarsalgia is discussed in Chapter 21.

TABLE 5-27 Potential Causes of Forefoot Pain

Metatarsalgia
Freiberg disease
Morton neuroma
Arthritis
Fracture
Forefoot sprain
Bursitis
Idiopathic synovitis
Arterial insufficiency

Freiberg Disease

Freiberg disease, an avascular necrosis of the second metatarsal epiphysis, is a source of metatarsalgia.[447] The disease is an osteochondrosis of congenital, traumatic, or vascular etiology that leads to eventual collapse and deformity of a lesser metatarsal head. It is unlikely that an athletic injury is the sole cause of Freiberg disease, although a mechanical stress to the forefoot may exacerbate a previously subclinical condition. The condition is most common in the second metatarsal head, with a predilection of 68–82%.[472,473] Less commonly, it may occur at the third, fourth, or fifth metatarsal heads.

The female-to-male ratio in Freiberg disease is 5:1 and the typical patient is a female adolescent aged 11–17 years.[474] The condition may be asymptomatic early in its course and manifest in young adulthood to middle age.

Physical examination usually reveals unilateral pain over the second metatarsal head; that is worse with activity, limited range of motion, periarticular swelling, and, occasionally, a plantar callosity under the second metatarsal head.[475]

This condition is usually self-limiting and requires only conservative treatment in the form of rest from high-impact activities, an orthosis to correct pronation,[476] a range-of-motion walking boot, or a short leg cast for more severe acute pain. Patients with severe antalgia should use crutches. Hoskinson[473] reported success with conservative treatment in 11 of 28 patients, although all had a restriction of joint motion.

The surgical intervention for Freiberg disease involves debridement of the joint, removal of loose bodies, and removal of metatarsal head osteophytes, with reshaping of the head.[477] A dorsiflexion osteotomy of the metatarsal head also has been advocated to rotate the healthy plantar cartilage up into articulation with the proximal phalanx.

Morton Neuroma

An interdigital neuroma, or Morton neuroma, is a mechanical entrapment neuropathy of the interdigital nerve. The entrapment may occur as the nerve courses on the plantar side of the distal aspect of the transverse intermetatarsal ligament, where it is vulnerable to traction injury and compression during the toe-off phase of running or during repetitive positions of toe rise.[478]

The most commonly involved nerve is the third interdigital nerve, between the third and fourth metatarsal heads, followed in incidence by the second interdigital nerve and, rarely, the first and fourth interdigital nerves.[478,479]

The individual with an interdigital neuroma will complain of symptoms of forefoot burning, cramping, tingling, and numbness in the toes of the involved interspace, with occasional proximal radiation in the foot.[478]

Morton neuroma is described further in Chapter 21.

Arthritis

See Chapter 21.

Fracture

See Chapter 21.

Forefoot Sprain

See Chapter 21.

Bursitis

See Chapter 21.

Medial Forefoot and Great Toe Pain

The causes of medial forefoot and great toe pain include those shown in Figure 5-5 and listed below.

Nail Lesions

See Chapter 21.

Hallux Valgus

See Chapter 21.

Hallux Rigidus

See Chapter 21.

Arthritis of the First MTP Joint

See Chapter 21.

Midfoot Pain

The causes of midfoot pain include those shown in Figure 5-5 and listed below.

Longitudinal Arch Strain

Aseptic Necrosis of the Navicular

Tendinopathy of the Flexor Hallucis Longus or Fibularis (Peroneal)

Subtalar Osteochondral Fracture

See Chapter 21.

Accessory Navicular

The accessory navicular is the most common accessory bone in the foot. It occurs on the medial plantar border of the navicular at the site of the tibialis posterior tendon insertion.[480] The incidence in the general population has been reported to be between 4% and 14%,[480,481] but few patients actually become symptomatic.[447] A histologic study by Grogan et al. in 1989[482] suggested that tensile failure in the cartilaginous synchondrosis was the cause of pain.

In the adolescent athletic population, symptoms may arise secondary to pressure over the bony prominence, a tear in the actual synchondrosis, or tibialis posterior tendinopathy.[481]

The patient usually presents with pain and a prominence of the navicular in a pronated foot. There is usually local tenderness to palpation and pain with resisted foot inversion.[480] It has been hypothesized that when the tibialis posterior tendon inserts into the accessory navicular, a weaker insertion point, it contributes to a drop in the medial arch of the foot and a pes planus.[483] However, Sullivan and Miller[484] found no difference in the longitudinal arches of those with an accessory navicular and those without.[447]

A physical examination can be supplemented by radiographic assessment. The anteroposterior view or a 45-degree eversion oblique view is usually diagnostic.[480]

The intervention for this condition consists of orthotics, trial of casting, range-of-motion exercises, and eventual removal if symptoms continue.[480–482,484–487]

Köhler Bone Disease

Köhler bone disease is an aseptic necrosis of unknown etiology that typically affects the tarsal navicular bone.[447] The condition is likely caused by repetitive microtrauma to the maturing epiphysis.[447] It is largely found in active boys aged 4–7 years.

Köhler bone disease is typically self-limiting and should not require any type of surgery. The initial intervention involves decreased activity or a short leg cast for 3–6 weeks.[488] Orthotics may be necessary to maintain the longitudinal arch.

Stress Fracture of the Navicular

See Chapter 21.

Acquired Flatfoot

See Chapter 21.

Osteoarthritis

See Chapter 21.

Plantar Fascial Pain

See Chapter 21.

Cuboid Subluxation Syndrome

See Chapter 21.

Posterior (Dorsal) Foot Pain

Tendinopathy of the Extensor Hallucis Longus, Extensor Digitorum Longus, or Tibialis Anterior

See Chapter 21.

Hindfoot Pain

The causes of generalized hindfoot pain include those shown in Figure 5-5 and are as follows.

Intraarticular Calcaneal Fractures

The calcaneus is the most frequently fractured tarsal bone, with calcaneal fractures accounting for 65% of tarsal injuries and approximately 2% of all fractures.[489] Acute complications include swelling, fracture blisters, and compartment syndromes. Late complications include arthritis; malunion, including calcaneofibular abutment; and heel pad problems. Complications associated with operative treatment include wound dehiscence, infection, and iatrogenic nerve injury.

Fat Pad Disorders

Calcaneus Stress Fracture

See Chapter 21.

Plantar Fasciitis

See Chapter 21.

Entrapment Neuropathy of the First Branch of the Lateral Plantar Nerve

See Chapter 21.

Flexor Tendinopathy

See Chapter 21.

Superficial Achilles Bursitis

See Chapter 21.

Retrocalcaneal Bursitis

See Chapter 21.

Haglund Syndrome

See Chapter 21.

Achilles Tendinopathy

See Chapter 21.

Achilles Tendon Rupture

See Chapter 21.

Calcaneal Osteomyelitis

Primary hematogenous osteomyelitis of the calcaneus is uncommon and accounts for 3–10% of all acute bone infections in children.[490] The calcaneus has a so-called metaphyseal equivalent region that borders the apophysis and is susceptible to hematogenous infection, as in long bones.[491] S. aureus has been found to be the most common bacterial agent in hematogenous calcaneal osteomyelitis.

Clinical findings include fever, pain, and swelling in the foot and ankle. The differential diagnosis may include septic arthritis of the ankle, cellulitis, stress fracture, calcaneal apophysitis, Achilles enthesopathy, and subcutaneous abscess.

Tibialis Posterior Tendinopathy

See Chapter 21.

Flexor Hallucis Longus Tendinopathy

See Chapter 21.

Tarsal Tunnel Syndrome

See Chapter 21.

Calcaneal Fracture

See Chapter 21.

Medial Ankle Sprain

See Chapter 21.

Fibularis (Peroneal) Muscle Strain or Tendinopathy

See Chapter 21.

Lateral Ankle Sprain

See Chapter 21.

Osteochondral Fracture of the Talar Dome

See Chapter 21.

Stress Fracture of the Lateral Malleolus

See Chapter 21.

CASE STUDY

neCK PUlsing

HISTORY

A 37-year-old woman presented to the office complaining that her head "wanted to go back." Her symptoms began approximately 6 months earlier, with painless "pulsing" on the left side of her neck that became worse with stressful situations and physical activity but was relieved by relaxation and sleep. She could briefly stop the pulsing by placing her hand on the right posterior aspect of the neck. Her symptoms had progressed to an extension of the neck with spasm, which caused her to lean forward to maintain eye contact with others. She also noted an occasional "eye tic," which seemed to come and go spontaneously. She denied any paresthesias, weakness, dysphasia, visual changes or hearing loss, or bowel or bladder changes. Although she had no family history of specific neurologic problems, the patient reported a maternal aunt who had "facial tics." The patient had a medical history notable for anxiety and several phobias for which she had received psychological counseling. Vascular studies had ruled out vascular disease and the presence of an aneurysm in the neck and trunk. Imaging studies had ruled out fracture or tumor.

Questions

1. What aspects of the history should alert the clinician to the possibility of a serious pathology?
2. What could be the significance of the pulsing?
3. Does this presentation/history warrant further investigation? Why or why not?

CASE STUDY

Groin Pain in a Middle-aged Female

HISTORY

A 56-year-old moderately obese woman presents with a prescription that reads "hip OA, evaluate, and treat."

Patient presented with left groin pain of an insidious onset that was worsening. The pain started approximately 3 months ago, when the patient commenced a walking program to lose some weight. The symptoms improve with rest, but worsen with activity, especially with walking and stair negotiation. The series of radiographs taken at the physician's office revealed slight degenerative changes at the hip joint.

Questions

1. What aspects of the history should alert the clinician to the possibility of a serious pathology?
2. What is the significance of an insidious onset?
3. Does this presentation/history warrant further investigation? Why or why not?

CASE STUDY

Back and Leg Pain

HISTORY

A 55-year-old man presented with complaints of an insidious onset of severe back and left leg pain. Progressively worsening symptoms of pain over the past few months were followed by left foot drop. An MRI examination was interpreted as mild lumbar spine degenerative disk disease without evidence of nerve–root compromise. The patient could report no specific aggravating or relieving activities but did report pain at night, not related to movement in bed. The patient's past medical history was significant for a renal transplantation approximately 20 years previously.

Questions

1. What aspects of the history should alert the clinician to the possibility of a serious pathology?
2. What is the significance of night pain that is unrelated to movement?
3. Does this presentation/history warrant further investigation? Why or why not?

CASE STUDY

Left-sided Low Back and Leg Pain

HISTORY

A 45-year-old man presented with complaints of intermittent variable left-sided LBP that extended into his left posterior thigh and intermittent variable tingling along the anterolateral aspect of his left lower extremity.[249] This was the patient's first visit to a healthcare facility for this condition; therefore, medical records were not available. The symptoms began about 2 months ago, with no specific mechanism of injury. The patient reported working as a quality control manager for a pharmaceutical lab. His job required sitting for approximately 50% of the day and occasional lifting of boxes weighing between 4.5 and 9.1 kg. Activities or positions that increased or aggravated all of the patient's symptoms included lying supine, coughing and sneezing, prolonged walking, and sitting for longer than an hour. Activities that decreased the patient's symptoms included applying a heating pad to his low back region and taking over-the-counter ibuprofen (200 mg) every 4 hours. The patient noted that his symptoms were most intense in the evening and into the night, with pain sometimes causing him difficulty with falling asleep. The patient also remarked that he would sometimes awaken because of pain but was able to fall asleep after finding a comfortable position. The patient's past medical history was unremarkable for cancer, bowel and bladder problems, hypertension, diabetes, or recent weight changes.

Questions

1. What aspects of the history should alert the clinician to the possibility of a serious pathology?
2. What types of conditions have an insidious onset?
3. Does this presentation/history sound like a neuromuscular problem or does this condition warrant further investigation? Why or why not?

CASE STUDY

r ig Ht BUt t o CK Pa in

HISTORY

A 55-year-old woman presented for physical therapy with a physician diagnosis of "right lumbosacral radiculitis." The patient had a 10-month history of right buttock pain with radiation to the posterolateral right lower limb, which was associated with intermittent numbness and tingling of the distal lower limb and foot. She denied any LBP or any radiation of pain down her left lower limb. The pain was exacerbated by walking uphill, by lying on her right side, and after exercise. It was not worse with bending or with Valsalva maneuver. Past medical history was significant for chronic LBP, lymphoma (diagnosed at age of 23 years and treated successfully with local radiation to the neck and axillae), status postmeningioma resection, status postbilateral modified radical mastectomy for carcinoma in situ, and hypothyroidism.[490] An MRI of the lumbosacral spine revealed multilevel degenerative disk disease from L3 and L4 through L5–S1, with mild foraminal narrowing bilaterally. There was no evidence of focal herniation or canal stenosis.

Questions

1. What structure(s) could be the cause of these symptoms?
2. Does the history of the symptoms follow a pattern associated with a musculoskeletal disorder? If not, why not?
3. What in the patient's past medical history needs to be noted?
4. What tests or questions would you use to help rule out the potentially serious causes of these symptoms such as cauda equina compression?
5. What impairment could cause an increase in these symptoms when walking uphill and lying on the right side?
6. Why would the patient's symptoms increase after exercise?
7. What is your working hypothesis at this stage based on the various diagnoses that could manifest with leg pain and paresthesia, and what tests you would use to rule out each one?
8. Does this presentation/history warrant a scanning examination? Why or why not?

CASE STUDY

in t er Mit t ent l eg n UMBn ess

HISTORY

A 46-year-old man presented to the clinic with a 10-year history of sensations that he described as a mixture both of pins and needles and of cotton wool around the second and third toes of his feet. The symptoms developed suddenly while at work and had progressed to intermittent numbness of both legs from the waist down. Over the following 10 years, the patient suffered momentarily from electric-type sensations radiating down into his legs, more so on the right than on the left. In addition, he noticed stiffness in his gait and reduced sensation on passing urine, and an aching sensation had developed in the buttocks. He had a history of infrequent LBP over a number of years. The patient's physician had given him a workup for MS, but the results were negative.

Questions

1. What aspects of the history should alert the clinician to the possibility of a serious pathology?
2. What is the significance of the gait stiffness?
3. What is the significance of the reduced sensation on passing urine?
4. Does this presentation/history warrant a scanning examination? Why or why not?

CHAPTER 6

Gait and Posture Analysis

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Summarize the various components of the gait cycle.
2. Apply the knowledge of gait components to gait analysis.
3. Perform a comprehensive gait analysis.
4. Categorize the various compensations of the body and their influences on gait.
5. Recognize the manifestations of abnormal gait and develop strategies to counteract these abnormalities.
6. Describe and demonstrate a number of abnormal gait syndromes.
7. Make an accurate judgment when recommending an assistive device to improve gait and function.
8. Describe and demonstrate the various gait patterns used with assistive devices.
9. Evaluate the effectiveness of an intervention for a gait dysfunction.
10. Summarize the components of a postural assessment.
11. Perform a thorough posture assessment.
12. Recognize the most common manifestations of abnormal posture.
13. Make an accurate judgment when recommending postural adjustments.
14. Evaluate the effectiveness of a postural adjustment.

OVERVIEW

T e assessment of symmetry within locomotion and posture is critical in the evaluation of neuromusculoskeletal dysfunction. For most individuals, gait or posture is an innate characteristic, as much a part of their personality as their smile. Indeed, many people can be recognized in a group by their gait or posture. T e purpose of this chapter is to describe the various components of gait and posture and to provide the clinician with the necessary tools for the analysis of each.

Gait and the Gait Cycle

T e lower kinetic chain has two main functions: to provide a stable base of support (BOS) in standing, and to propel the body through space with gait. During gait, the body follows the least restrictive pathway in the most efficient manner.[1] In order to maintain this efficiency, the body attempts to maintain a level center of gravity (COG) in all planes.[1] While maintaining a static equilibrium of forces, the objective with mobility is to create and control dynamic, unbalanced forces to produce movement.[2] Gait is thus an example of controlled instability. It is not clear whether gait is learned or is preprogrammed at the spinal cord level. However, once mastered, gait allows us to move around our environment in an efficient manner, requiring little in the way of conscious thought, at least in familiar surroundings. T e evolution of bipedal gait has allowed the arms and hands to be free for exploration of the environment. Even though gait appears to be a simple process, it is prone to breakdown. Despite individual gait patterns being characterized by significant variation, only three essential requirements are necessary for efficient locomotion: progression, postural control, and adaptation:[3]

- Progression. T e fall that occurs at the initiation of gait so that an individual must take the first step is controlled by the central nervous system (CNS).[4] T e CNS computes in advance the required size and direction of this fall toward the supporting foot. Progression of the head, arms, and the trunk is initiated and terminated in the brainstem that maintains a central pattern generator (CPG) through the spinal cord (see Chapter 3). T e locomotor CPG produces self-sustaining patterns of stereotype motor output resulting in gait-like movements. In addition, gait relies on the control of the limb movements by reflexes. Two such reflexes include the stretch reflex and the extensor thrust. T e stretch reflex is involved in the extremes of joint motion, whereas the extensor thrust may facilitate the extensor muscles of the lower extremity during weight bearing.[5] Both the CPG and the reflexes that mediate afferent input to the spinal cord are under the control of the brainstem and are therefore subconscious.[6] T is would tend to indicate that verbal coaching (i.e., feedback that is

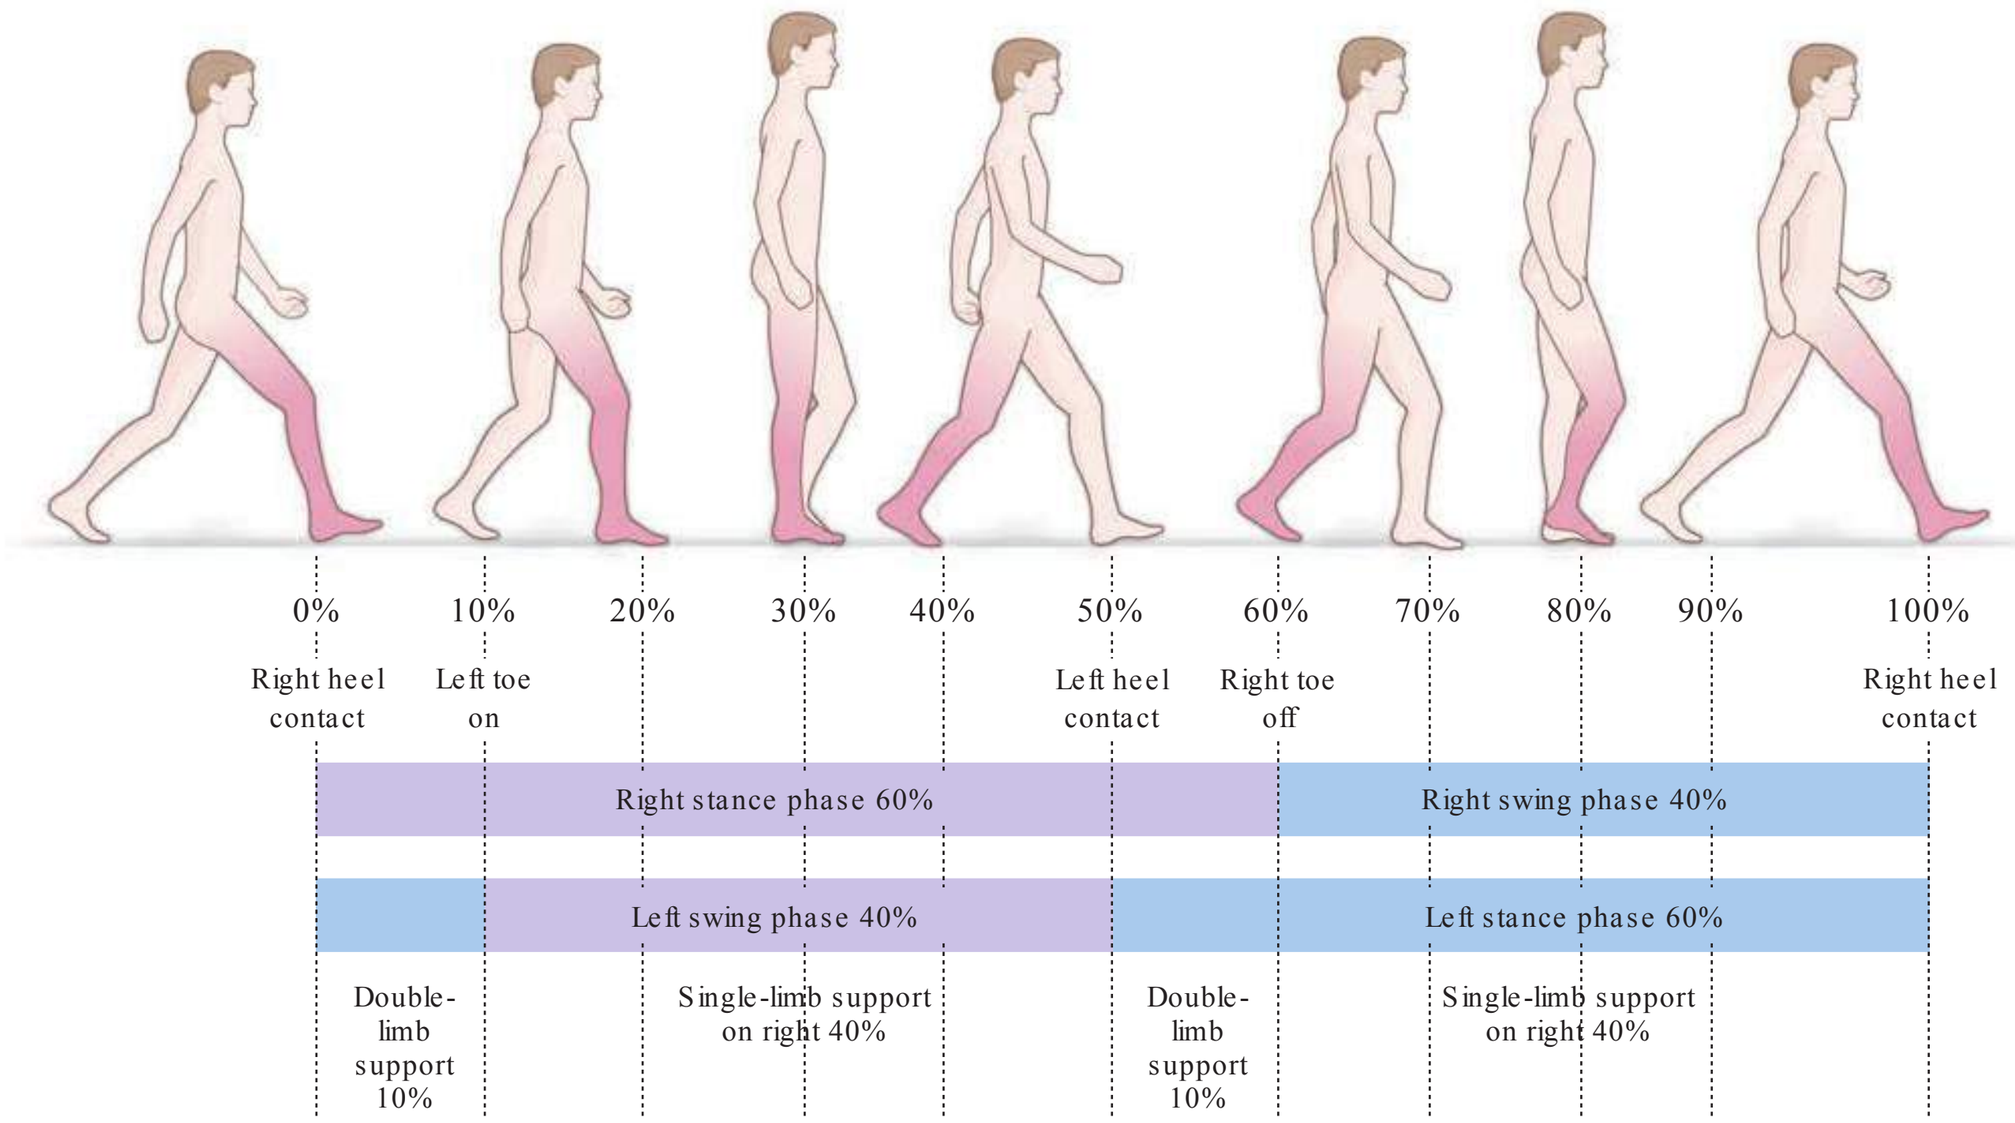

FIGURE 6-1 The two phases of gait.

processed in the cortex) regarding an aberrant gait pattern might be less effective than a sensory input that will elicit a brainstem-mediated postural response.[2]

- Postural control. Postural control is dynamically maintained to appropriately position the body for efficient gait.
- Adaptation. Although central pattern generation occurs independent of any sensory input, afferent information from the periphery can influence the CPG. Adaptation is achieved by adjusting the central pattern generated to meet task demands and environmental demands.

Gait, therefore, is initiated grossly in the spinal cord and then fine-tuned by the higher brain centers.[2] In patients who have developed dysfunctional gait patterns, physical therapy can help to restore this exquisite evolutionary gift.[7] Pain, weakness, and disease can all cause a disturbance in the normal rhythm of gait. However, except in obvious cases, abnormal gait does not always equate with impairment.

In addition to neural input, normal human gait also involves a complex synchronization of the cardiopulmonary and muscular systems in which the cardiopulmonary system produces the energy required for gait. Normal gait requires concentric, eccentric, and isometric contractions of the foot, ankle, knee, hip, and trunk as well as training to maintain an upright posture.[1]

Walking involves the alternating action of the two lower extremities. T is walking pattern is studied as a gait cycle. A gait cycle is defined as the interval of time between any of the repetitive events of walking. Such an event could include the point when the foot first contacts the ground to the point when the same foot contacts the ground again. T e seven intervals that occur during the gait cycle include:

1. Loading response
2. Midstance
3. Terminal stance
4. Preswing
5. Initial swing
6. Midswing
7. Terminal swing

T ese intervals occur during two phases, the stance phase and the swing phase (Fig. 6-1). Four of the intervals occur in the stance phase, and the remaining three occur during the swing phase (Fig. 6-2).

1. Stance. T e stance phase (Fig. 6-1) takes about 0.6 seconds during an average walking speed. T is phase constitutes approximately 60% of the gait cycle (Fig. 6-1) and describes the entire time the foot is in contact with the ground and the limb is bearing weight. T e stance phase begins when the foot makes contact with the ground (initial contact) and concludes when the ipsilateral foot leaves the ground (toe-off) (Fig. 6-2). T e initial contact interval accounts for the first 10% of the gait cycle and describes the phase when one foot is coming off the floor while the other foot is accepting body weight and absorbing the shock of initial contact (Fig. 6-2). Because both feet are in contact with the floor, this phase is referred to as double support (Fig. 6-1). T e phase of double support occurs twice during a single gait cycle and accounts for approximately 20% of the gait cycle (Fig. 6-1). T e four intervals which occur in this phase include the loading response, midstance, terminal stance, and preswing (see Fig. 6-2).

   a. Loading response. T e loading response interval begins as one limb bears weight while the other leg begins to go through its swing phase. T e extent to which eccentric muscle tension counteracts the effect of gravity on the body mass during the loading response to ground contact

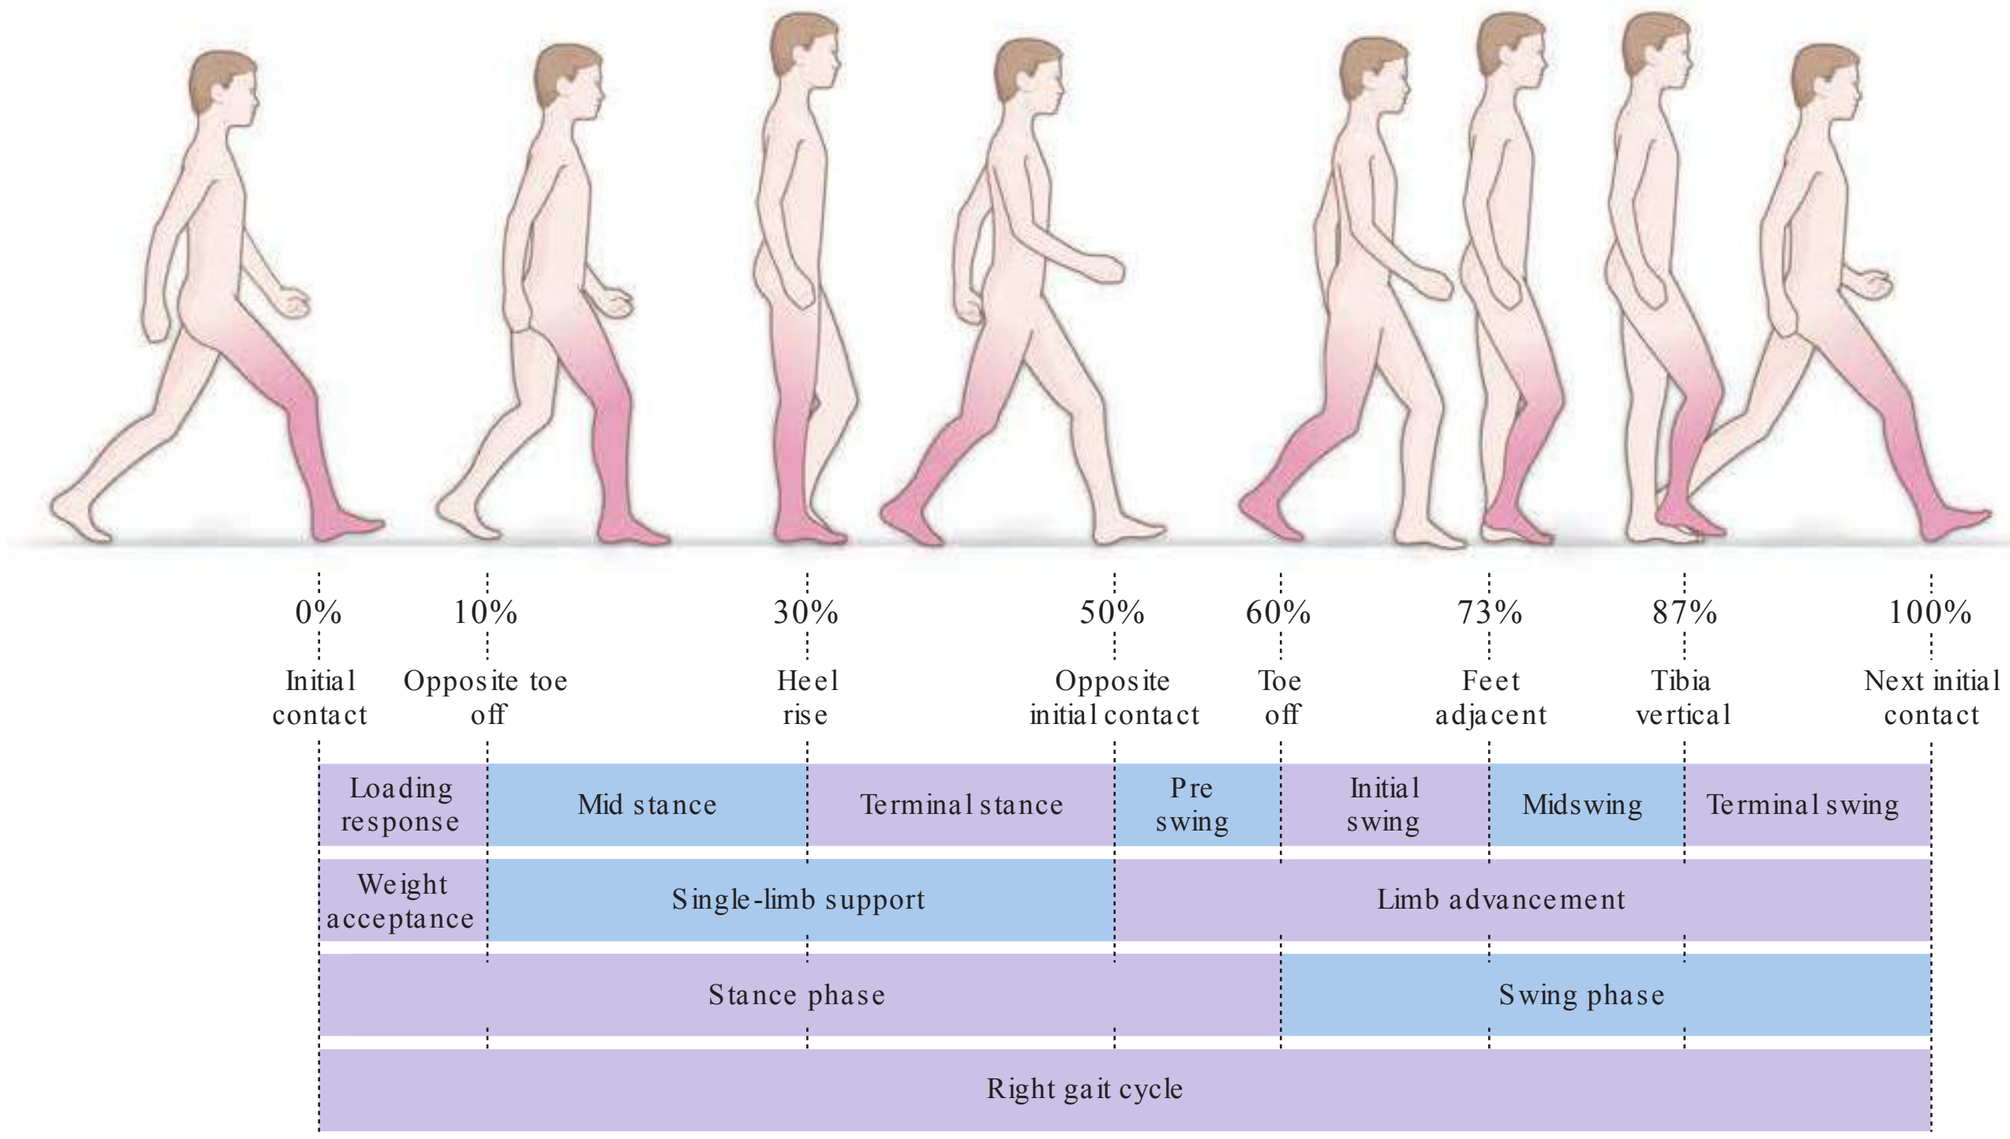

FIGURE 6-2 The intervals of gait.

determines both the velocity and amplitude of motion that occurs at any given joint in the lower extremity.[8]

b. The midstance interval, representing the first half of the single-limb support task (Fig. 6-2), begins as one foot is lifted and continues until the body weight is aligned over the forefoot.

c. The terminal stance interval (Fig. 6-2) is the second half of the single-limb support task. It begins when the heel of the weight-bearing foot lifts off the ground and continues until the contralateral foot strikes the ground.

d. The preswing interval (Fig. 6-2) begins with the initial contact of the contralateral limb and ends with the ipsilateral toe-off. During this phase, the stance leg is unloading the body weight to the contralateral limb and preparing the leg for the swing phase.

2. Swing. Gravity and momentum are the primary sources of motion for the swing phase.[5] The swing phase constitutes approximately 40% of the gait cycle (Fig. 6-2) and describes the phase when the foot is not in contact with the ground. The swing phase begins as the foot is lifted from the ground and ends when the ipsilateral foot makes contact with the ground again. The three intervals which occur in this phase include initial swing, midswing, and terminal swing:

   a. Initial swing (Fig. 6-2). This interval begins with the lifting of the foot from the floor and ends when the swinging foot is opposite the stance foot. It represents the 60–73% phase of the gait cycle (Fig. 6-2).

   b. Midswing (Fig. 6-2). This interval begins as the swinging limb is opposite the stance limb and ends when the swinging limb is forward, and the tibia is vertical. It represents the 73–87% phase of the gait cycle (Fig. 6-2).

   c. Terminal swing (Fig. 6-2). This interval begins with a vertical tibia of the swing leg with respect to the floor and ends the moment the foot strikes the floor. It represents the last 87–100% of the gait cycle (Fig. 6-2).

CLINICAL PEARL

In terms of energy expenditure, the swing phase requires relatively little, relying heavily on passive, soft tissue tension, gravity, and momentum to accelerate and decelerate individual segments.[2] In contrast, stance requires more dynamic activity, with muscles in the stance limb support and the body propelling it forward.

The precise duration of the gait cycle intervals depends on a number of factors including, but not limited to, age, degree of impairment, attention to another task, health status, motor control, muscle performance, endurance and habitual activity levels, walking environment, and the patient's walking velocity.[9] Walking velocity is defined as the distance a body moves in a given time and is thus calculated by dividing the distance traveled by the time taken. Normal free gait velocity on a smooth and level surface averages about 1.2–1.4 m/s for adults, with speed varying by gender, age and anthropometrics, with men being about 5% faster than women.[10]

Running involves both a stance phase (30%) and a swing phase (70%), with increased speed showing an increase in the swing to stance ratio. Running also involves a float phase, during which there is no foot contact with the ground, and potential energy is greatest, and which comprises 30% of the running cycle.[11]

CLINICAL PEARL

An increase in self-selected walking speed is associated with clinically meaningful improvement in quality of life.[12]

GAIT PARAMETERS

A normal gait pattern is a factor of a number of parameters.

Step Width

The step width is the distance between both feet. The normal step width, which is considered to be between 5 and 10 cm (2–4 in), forms the BOS during gait. The size of the BOS and its relation to the COG are important factors in the maintenance of balance (see Chapter 1) and, thus, the stability of an object. As the COG moves forward with each step, it briefly passes beyond the anterior margin of the BOS, resulting in a temporary loss of balance.[13] This is temporary loss of equilibrium is counteracted by the advancing foot at initial contact, which establishes a new BOS. A larger than normal step width or BOS is observed in individuals who have muscle imbalances of the lower limbs and trunk, as well as those who have problems with overall static and dynamic balance.[14] Assistive devices, such as crutches or walkers, can be prescribed to increase the BOS and, therefore, enhance stability. The step width should be seen to decrease to around zero with increased speed. If the step width decreases to a point below zero, crossover occurs, whereby one foot lands where the other should, and vice versa.

CLINICAL PEARL

When walking, the body's COG is elevated to its highest position during midstance, and then it falls anteriorly.[15] When running, knee and hip flexion produce downward displacement of the COG that reaches its lowest position during midstance, but which subsequently begins to move in a superior and anterior direction as the knee and hip extend during the terminal portion of the stance phase.[8]

Step Length

Step length is measured as the distance between the point of initial contact of one foot and the point of initial contact of the opposite foot. The average step length is about 72 cm (28 in). The measurement should be equal for both legs.

Stride Length

Stride length is the distance between successive points of foot-to-floor contact of the same foot. A stride is one full lower extremity cycle. Two step lengths added together make the stride length. The average stride length for normal adults is 144 m (56 in).[10]

Typically, the step and stride lengths do not vary more than a few centimeters between tall and short individuals. Men typically have longer step and stride lengths than women. Step and stride lengths decrease with age, pain, disease, fatigue, and as the speed of gait decreases.[16,17] A decrease in step or stride length may also result from a forward head posture, a stiff hip, or a decrease in the availability of motion at the lumbar spine. The decrease in step and stride length that occurs with aging is thought to be the result of a number of factors including an overall decrease in joint range of motion (ROM), and the increased likelihood of falling during the swing phase of ambulation, caused by diminished control of the hip musculature.[16,17] This is lack of control prevents the aged person from being able to intermittently lose and recover the same amount of balance that the younger adult can lose and recover.

Cadence

Cadence is defined as the number of separate steps taken in a certain time. Normal cadence is between 90 and 120 steps per minute.[10] The cadence of women is usually six to nine steps per minute slower than that of men.[13] Cadence is also affected by age, decreasing from the age of 4 to the age of 7 years, and then again in advancing years.[18]

CLINICAL PEARL

Compared to men, women generally have narrower shoulders, greater valgus at the elbow, greater varus at the hip, and greater valgus at the knee.[19] Women also have a smaller Achilles tendon, a narrower heel in relationship to the forefoot, and a foot that is narrower than a man's in length. On average, women walk at a higher cadence than men (six to nine steps higher), but at lower speeds.[20–24] Women also have slightly shorter stride lengths,[20,21,23–27] although when normalized for height, women tend to have the same or slightly greater stride lengths.[24–26]

Velocity

The primary determinants of gait velocity are the repetition rate (cadence), physical conditioning, and the length of the person's stride.[10]

CLINICAL PEARL

A mathematical relationship exists between cadence, stride length, and velocity, such that if two of them are directly measured, the third may be derived by calculation (Table 6-1).[28]

As gait speed increases, it develops into jogging at approximately 2.0–2.7 m/s,[29] and then running, with changes in each of the intervals. For example, as speed increases, the stance phase decreases and the terminal double stance interval disappears altogether, so that there are alternating single extremity support intervals that are separated by a period of

TABLE 6-1 Gait Parameters

Cadence (steps/min) = velocity (m/s) × 120/stride length (m)
Stride length (m) = velocity (m/s) × 120/cadence (steps/min)
Velocity (m/s) = cadence (steps/min) × stride length (m)/120

Data from Levine D, Whittle M. Gait Analysis: The Lower Extremities. La Crosse, WI: Orthopaedic Section, APTA, Inc.; 1992.

no ground contact by either extremity. T is produces a double unsupported interval.[30] Initial contact with the ground is normally made by the heel when walking, which is also the case for more than 75% of individuals while running.[31] Normal running gait begins with lateral heel strike, followed by foot pronation during midstance, and foot supination during pushoff. T e rear foot strike running pattern is facilitated by the elevated and cushioned heels of modern running shoes during which ground reaction forces (GRFs) (see next section) reach 1.5–3 times body weight.[32] A current trend in rehabilitation has centered on modifying running technique to prevent, treat, and reduce running injuries. Different running styles are defined by the portion of the foot segment the makes initial contact with the ground. T ese patterns include rear foot strike, midfoot strike, and forefoot strike.[33] Runners tend to use a heel strike or midfoot strike, whereas sprinters typically use a forefoot strike. Barefoot, or evolution, running, with its emphasis on forefoot striking, has increased in popularity due to its claim that the style produces a significant reduction in GRFs, stride length, and ground contact time. As with walking, running economy can be affected by physiological and biomechanical factors. While forefoot strikers rely more heavily on musculature to aid in cushioning during stance, traditional runners demonstrate a heel strike pattern, secondary to a heavy reliance on footwear and skeletal structures to absorb GRFs.[34] While it has been demonstrated that barefoot forefoot strike runners generate smaller impact forces than shorter rear foot strikers, there is no evidence to date that either confirms or refutes improved performance and reduced injuries in barefoot runners, although there is some evidence that the former improves running efficiency.[34]

Although the motion occurring at each of the lower extremity joints is similar for walking and for running, the required ROM increases with the speed of the activity. As the speed of walking or running increases, so do the forces that act on the various joints, and the joints themselves have to produce greater excursions with greater muscle activity.

Humans have the capacity to run at a broad spectrum of speeds.[35] Elite athletes have the ability to achieve maximal running speeds greater than 10 m/s (36 km/h).[36] Gait speed can be increased by pushing on the ground more forcefully, pushing on the ground more frequently, or a combination of the two. When speed is initially increased, the priority appears to be pushing on the ground more forcefully as this results in a longer stride length because the body spends more time in the air.[37] T e lower limb muscles that are responsible for pushing on the ground forcefully during running are the major ankle plantarflexors (soleus and gastrocnemius). At speeds beyond approximately 7.0 m/s, the dominant strategy shifts toward the goal of increasing stride frequency and pushing on the ground more frequently, which results in the force generating capacity of these muscles becoming less effective.[35] Instead, as more power at the hip joint is required, the proximal lower limb muscles such as the iliopsoas, gluteus maximus, rectus femoris, and hamstrings become dominant.[35]

Due to its repetitive nature, running has the potential to create lower extremity pathology. For example, at the hip, they may be microinstability due to repeated hip extension and stretching of the anterior capsule.[38]

Ground Reaction Forces

An analysis of GRFs is important to quantify the magnitude of forces sustained by body structures during movements and exercise. Newton's third law states that for every action there is an equal and opposite reaction. GRFs can be influenced by several factors, such as the environment in which the movement is executed (e.g., on land or in water), movement speed, and the weight of the individual performing the exercise. T e center of pressure (COP) is the location of the vertical projection of the GRF, and is equal and opposite to the weighted average of all the downward forces acting on the area of contact with the ground.[39] T e COP is considered to be a reflection of the body's neuromuscular responses to imbalances of the COG. During gait, vertical GRFs are created by a combination of gravity, body weight, and the firmness of the ground. For example, during running, joint reactive forces through the hip have been demonstrated at five times body weight during single-limb support. Even when immersed in water, stationary running still involves contact forces (see Chapter 8). Under normal conditions, we are mostly unaware of these forces. However, in the presence of joint inflammation or tissue injury, the significance of these forces becomes apparent. T e GRF during gait begins with an impact peak of less than body weight and then exceeds body weight at the end of the initial contact interval, dropping during midstance and rising again to exceed the body weight, reaching its highest peak during the terminal stance interval. T us, there are two peaks of GRF during the gait cycle: the first at maximum limb loading during the loading response and the second during terminal stance.

T e GRF vector changes from quite far anterior to the hip joint at initial contact to a progressively posterior position at late stance, when the GRF is posterior to the hip.[10,40,41] Peak flexion torque occurs at initial contact but gradually declines, changing to an extension torque in midstance. T e extension torque remains until terminal stance.[10,40,41] In the frontal plane, a hip abduction moment is generated to counteract the relative hip adduction angle at initial contact.

During the gait cycle, the tibiofemoral joint reaction force has two peaks: the first immediately following initial contact (two to three times body weight) and the second during preswing (three to four times body weight).[42] Tibiofemoral joint reaction forces increase to five to six times body weight for running and stair climbing, and eight times body weight with downhill walking.[42,43]

It is well established that joint angles and GRF components increase with walking speed.[44] T is is not surprising, because the dynamic force components must increase as the body is subjected to increasing deceleration and acceleration forces when walking speed increases.

CLINICAL PEARL

Because leg-length in women is 51.2% of total body height compared with 56% in men, women must strike the ground more often to cover the same distance.[45] Furthermore, because their feet are shorter, women complete the heel-to-toe gait in a shorter time than men do. Therefore, the cumulative GRFs may be greater in women.[19]

Mediolateral Shear Forces

Mediolateral shear in walking gait begins with an initial medial shear (occasionally lateral) force after initial contact, followed by lateral shear for the remainder of the stance phase.[10] At the end of the stance phase, the shear shifts to a medial direction because of propulsion forces.

Anteroposterior Shear Forces

Anteroposterior shear forces in gait begin with an anterior shear force at initial contact and the loading response intervals, and a posterior shear at the end of the terminal stance interval.

CHARACTERISTICS OF NORMAL GAIT

Much has been written about the criteria for normal and abnormal gait.[10,20,28,40,46–52] Although the presence of symmetry in gait appears to be important, asymmetry in itself does not guarantee impairment. It must be remembered that the definition of what constitutes the so-called normal gait is elusive. Unlike posture, which is a static event, gait is dynamic and as such is protean.

CLINICAL PEARL

Good alignment of the weight-bearing segments of the body:

- Reduces the likelihood of strain and injury by reducing joint friction and tension in the soft tissues.
- Improves the stability of the weight-bearing limb and the balance of the trunk. The stability of the body is directly related to the size of the BOS. In order to be stable, the intersection of the line of gravity with the BOS should be close to the geometric center of the base.[53]
- Reduces excess energy expenditure.

Gait involves the displacement of body weight in a desired direction, utilizing a coordinated effort between the joints of the trunk and extremities and the muscles that control or produce these motions. Any interference that alters this relationship may result in a deviation or disturbance of the normal gait pattern. T is, in turn, may result in increased energy expenditure or functional impairment.

Perry and Burnfield[10] list four priorities of normal gait:

1. Stability of the weight-bearing foot throughout the stance phase.
2. Clearance of the NWB foot during the swing phase.
3. Appropriate prepositioning (during terminal swing) of the foot for the next gait cycle.
4. Adequate step length.

Gage et al.[18] added a fifth priority, energy conservation. T e typical energy expended in normal gait (2.5 kcal/min) is less than twice that spent while sitting or standing (1.5 kcal/min).[18] Two-dimensional kinetic data have revealed that approximately 85% of the energy for normal walking comes from the plantarflexors of the ankle, and 15% from the flexors of the hip.[54] It has been proposed that the type of gait selected is based on metabolic energy considerations.[55] Current commonly used parameters to measure walking efficiency include oxygen consumption, heart rate, and comfortable speed of walking.[56–58] T e economy of mobility is a measurement of submaximal oxygen uptake (submax VO_2) for a given speed.[59,60] A decline in functional performance may be evidenced by an increase in submax VO_2 for walking.[61] T is change in the economy of mobility may be indicative of an abnormal gait pattern.[61] Some researchers have reported no gender differences for economy of mobility,[62–64] whereas others suggest that men are more economical or have lower-energy costs than women at the same work.[65–67] Age-related declines in the economy of mobility also have been reported in the literature, with differing results. Some researchers reported that older adults were less economical than younger adults while walking at various speeds.[59,68,69] Conversely, economy of mobility appears to be unaffected by aging for individuals who maintain higher levels of physical activity.[70–72]

Some authors have claimed that a limb-length discrepancy leads to mechanical and functional changes in gait[73] and increased energy expenditure.[74] Intervention has been advocated for limb-length discrepancies of less than 1 cm to discrepancies greater than 5 cm, [73–75] but the rationale for these recommendations has not been well defined, and the literature contains little substantive information regarding the functional significance of these discrepancies.[76] For example, Gross found no noticeable functional or cosmetic problems in a study of 74 adults who had less than 2 cm of discrepancy and 35 marathon runners who had as much as 2.5 cm of discrepancy.[75]

CLINICAL PEARL

The cardiovascular benefits derived from increases in gait speed may be acceptable for a normal population, or an advanced rehabilitation program, but should be used cautiously with postsurgical patients.[77]

For gait to be efficient and to conserve energy, the COG must undergo minimal displacement:

- Any displacement that elevates, depresses, or moves the COG beyond normal maximum excursion limits wastes energy.
- Any abrupt or irregular movement will waste energy even when that movement does not exceed the normal maximum displacement limits of the COG.

CLINICAL PEARL

The COG in men is at a point that corresponds to 56.18% of their height. In women, the COG is at a point that corresponds to 55.44% of their height.[78]

To minimize the energy costs of walking, the body uses a number of biomechanical mechanisms. In 1953, Saunders et al.[79] proposed that six kinematic features—the Six Determinants—have the potential to reduce the energetic cost of human walking. T e six determinants are as follows:[80]

- Lateral displacement of the pelvis: To avoid significant muscular and balancing demands, the pelvis shifts side to side (approximately 2.5–5 cm or 1–2 in) during the gait cycle in order to center the weight of the body over the stance leg. If the lower extremities dropped directly vertical from the hip joint, the COG would be required to shift 3–4 in to each side to be positioned effectively over the supporting foot. T e combination of femoral varus and anatomical valgum at the knee permits a vertical tibial posture with both tibias in close proximity to each other. T is narrows the step width to 5–10 cm (2–4 in) from heel center to heel center, thereby reducing the lateral shift required of the COG toward either side.
- Pelvic rotation: T e rotation of the pelvis normally occurs about a vertical axis in the transverse plane toward the weight-bearing limb. T e total pelvic rotation is approximately 4 degrees to each side.[18] Forward rotation of the pelvis on the swing side prevents an excessive drop in the body's COG. T e pelvic rotation also results in a relative lengthening of the femur by lessening the angle of the femur with the floor, and thus step length, during the termination of the swing interval.[81]
- T e vertical displacement of the pelvis: Vertical pelvic shifting keeps the COG from moving superiorly and inferiorly more than 5 cm (2 in) during normal gait. Due to the shift, the high point occurs during midstance, and the low point occurs during initial contact. T e amount of vertical displacement of the pelvis may be accentuated in the presence of a leg-length discrepancy, fusion of the knee, or hip abductor weakness, the latter of which results in a Trendelenburg sign. T e Trendelenburg sign is said to be positive if, when standing on one leg, the pelvis drops on the side opposite to the stance leg. T e weakness is present on the side of the stance leg—the gluteus medius is not able to maintain the COG on the side of the stance leg.
- Knee flexion in stance: Knee motion is intrinsically associated with foot and ankle motion. At initial contact before the ankle moves into a plantarflexed position, and thus is relatively more elevated, the knee is in relative extension. Responding to a plantarflexed posture at loading response, the knee flexes. Midstance knee flexion prevents an excessive rise in the body's COG during that period of the gait cycle. If not for the midstance knee flexion, the COG's rise during midstance would be larger, as would its total vertical displacement. Passing through midstance as the ankle remains stationary with the foot flat on the floor, the knee again reverses its direction to one of extension. As the heel comes off the floor in terminal stance, the heel begins to rise as the ankle plantarflexes and the knee flexes. In preswing, as the forefoot rolls over the metatarsal heads, the heel elevates even more as further plantarflexion occurs, and flexion of the knee increases.
- Ankle mechanism: For normal foot function and gait, the amount of ankle joint motion required is approximately 10 degrees of dorsiflexion (to complete midstance and begin terminal stance) and 20 degrees of plantarflexion (for full push-off in preswing). At initial contact, the foot is in relative dorsiflexion due to the muscle action of the pretibial muscles and the triceps surae. T is muscle action produces a relative lengthening of the leg, resulting in a smoothing of the pathway of the COG during stance phase.
- Foot mechanism: T e controlled lever arm of the forefoot at preswing is particularly helpful as it rounds out the sharp downward reversal of the COG. T us, it does not reduce a peak displacement period of the COG as the earlier determinants did but rather smooths the pathway. An adaptively shortened gastrocnemius muscle may produce movement impairment by restricting normal dorsiflexion of the ankle from occurring during the midstance to heel raise portion of the gait cycle. T is motion is compensated for by increased pronation of the subtalar joint, increased internal rotation of the tibia, and resultant stresses to the knee joint complex.

CLINICAL PEARL

A decrease in flexibility or joint motion, or both, may result in an increase in both "internal resistance" and the energy expenditure required.

Joint Motions

During the gait cycle, the swing of the arms is out of phase with the legs. As the upper body moves forward, the trunk twists about a vertical axis. T e thoracic spine and the pelvis rotate in opposite directions to each other to enhance stability and balance. In contrast, the lumbar spine tends to rotate with the pelvis. In addition, the pelvis tilts anteriorly and posteriorly (Fig. 6-3). T e shoulders and trunk rotate out of phase with each other during the gait cycle.[82] Unless they are restrained, the arms tend to swing in opposition to the legs,

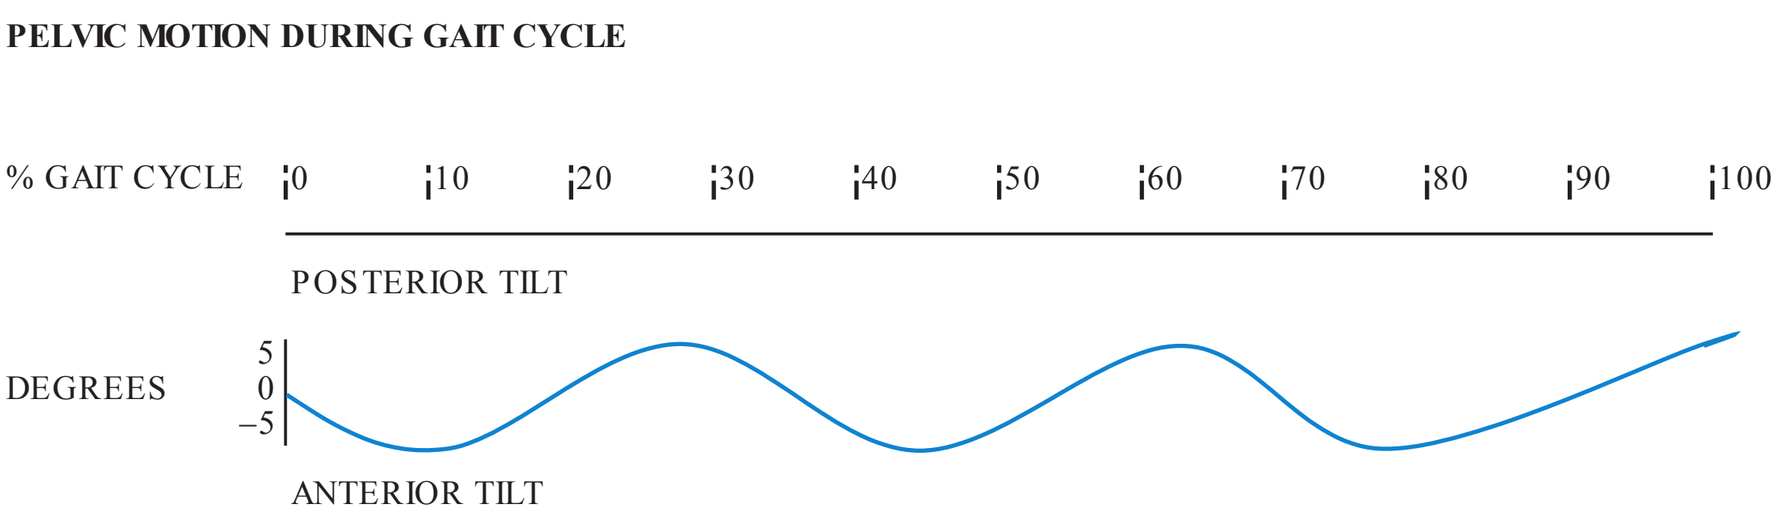

FIGURE 6-3 Pelvic motion during normal gait.

the left arm swinging forward as the right leg swings forward, and vice versa.[5] When the arm swing is prevented, the upper trunk tends to rotate in the same direction as the pelvis, producing an awkward gait.

CLINICAL PEARL

Different patterns of interlimb coordination between arms and legs have been observed within the human walking mode.[83,84] At lower walking speeds, the arms are synchronized to the stepping frequency (2:1 ratio of arm to leg), whereas at higher walking velocities, the arms are synchronized to the stride frequency (1:1 ratio of arm to leg). These results also suggest that at lower speeds, the resonant frequency of the arms dominates the interlimb coupling, whereas at higher speeds, the resonant frequency of the legs is dominant.[85]

Maximum flexion of both the elbow and the shoulder joints occurs at the initial contact interval of the opposite foot, and maximum extension occurs at the initial contact of the foot on the same side.[86]

Although the majority of the arm swing results from momentum, the pendular actions of the arms are also produced by gravity and muscle action.[5,87]

- The posterior deltoid and teres major appear to be involved during the backward swing.
- The posterior deltoid serves as a braking mechanism at the end of the forward swing.
- The middle deltoid is active in both the forward and the backward swing, perhaps to prevent the arms from brushing against the sides of the body during the swing.

The motions that occur at each of the lower extremity joints during the stance phase of the gait cycle are outlined in Table 6-2 and Figure 6-4.

Hip

The function of the hip is to extend the leg during the stance phase and flex the leg during the swing phase (Table 6-2). Although movement of the hip during gait predominately occurs in the sagittal plane, the hip motion also occurs in the frontal and transverse planes during the gait cycle.

TABLE 6-2 Joint Motions in the Lower Extremities During Gait

Phase	Hip	Knee and Tibia	Ankle and Foot
Initial contact	Hip begins to move toward extension from a position of 20–40 degrees of flexion; slight adduction and external rotation Reaction force anterior to hip joint creating flexion moment moving toward extension	Knee positioned in full extension before initial contact but flexes as heel makes contact Tibia positioned in slight external rotation Reaction force behind knee rapidly increases causing flexion moment	Foot positioned in supination (rigid) at heel contact, with the ankle moving into plantarflexion Reaction forces behind the joint axis; plantarflexion moment at heel strike
Loading response	Hip moves into extension, adduction, and internal rotation. Flexion moment	Knee in 20 degrees of knee flexion, moving toward extension Tibia into internal rotation Flexion moment	Foot positioned in pronation to adapt to support surface, with the ankle moving from plantarflexion to dorsiflexion over a fixed foot Maximum plantarflexion moment; reaction force is beginning to shift anteriorly, producing a dorsiflexion moment
Midstance	Hip moves through neutral position with the pelvis rotating posteriorly Reaction force now posterior to hip joint creating extension moment	Knee in 15 degrees of flexion, moving toward extension Tibia in neutral rotation Maximum flexion moment	Foot in neutral and ankle in 3 degrees of dorsiflexion Slight dorsiflexion moment
Terminal stance	Hip positioned in 10–15 degrees of hip extension, abduction, and external rotation Extension moment decreases after double-limb support begins	Knee in 4 degrees of flexion, moving toward extension Tibia in external rotation Reaction forces moving anterior to the joint; extension moment	Foot in supination becoming rigid for push-off Ankle in 15 degrees dorsiflexion toward plantarflexion Maximum dorsiflexion moment
Preswing	Hip moving toward 10 degrees of extension, abduction, and external rotation Continued decrease of extension moment	Knee moving from near full extension to 40 degrees of flexion. Tibia in external rotation Reaction forces moving posterior to knee as knee flexes; flexion moment	Foot in supination and ankle in 20 degrees of plantarflexion Dorsiflexion moment

Data from Giallonardo LM. Gait. In: Myers RS, ed. Saunders Manual Physical Therapy Practice. Philadelphia, PA: WB Saunders; 1995:1108–1109.

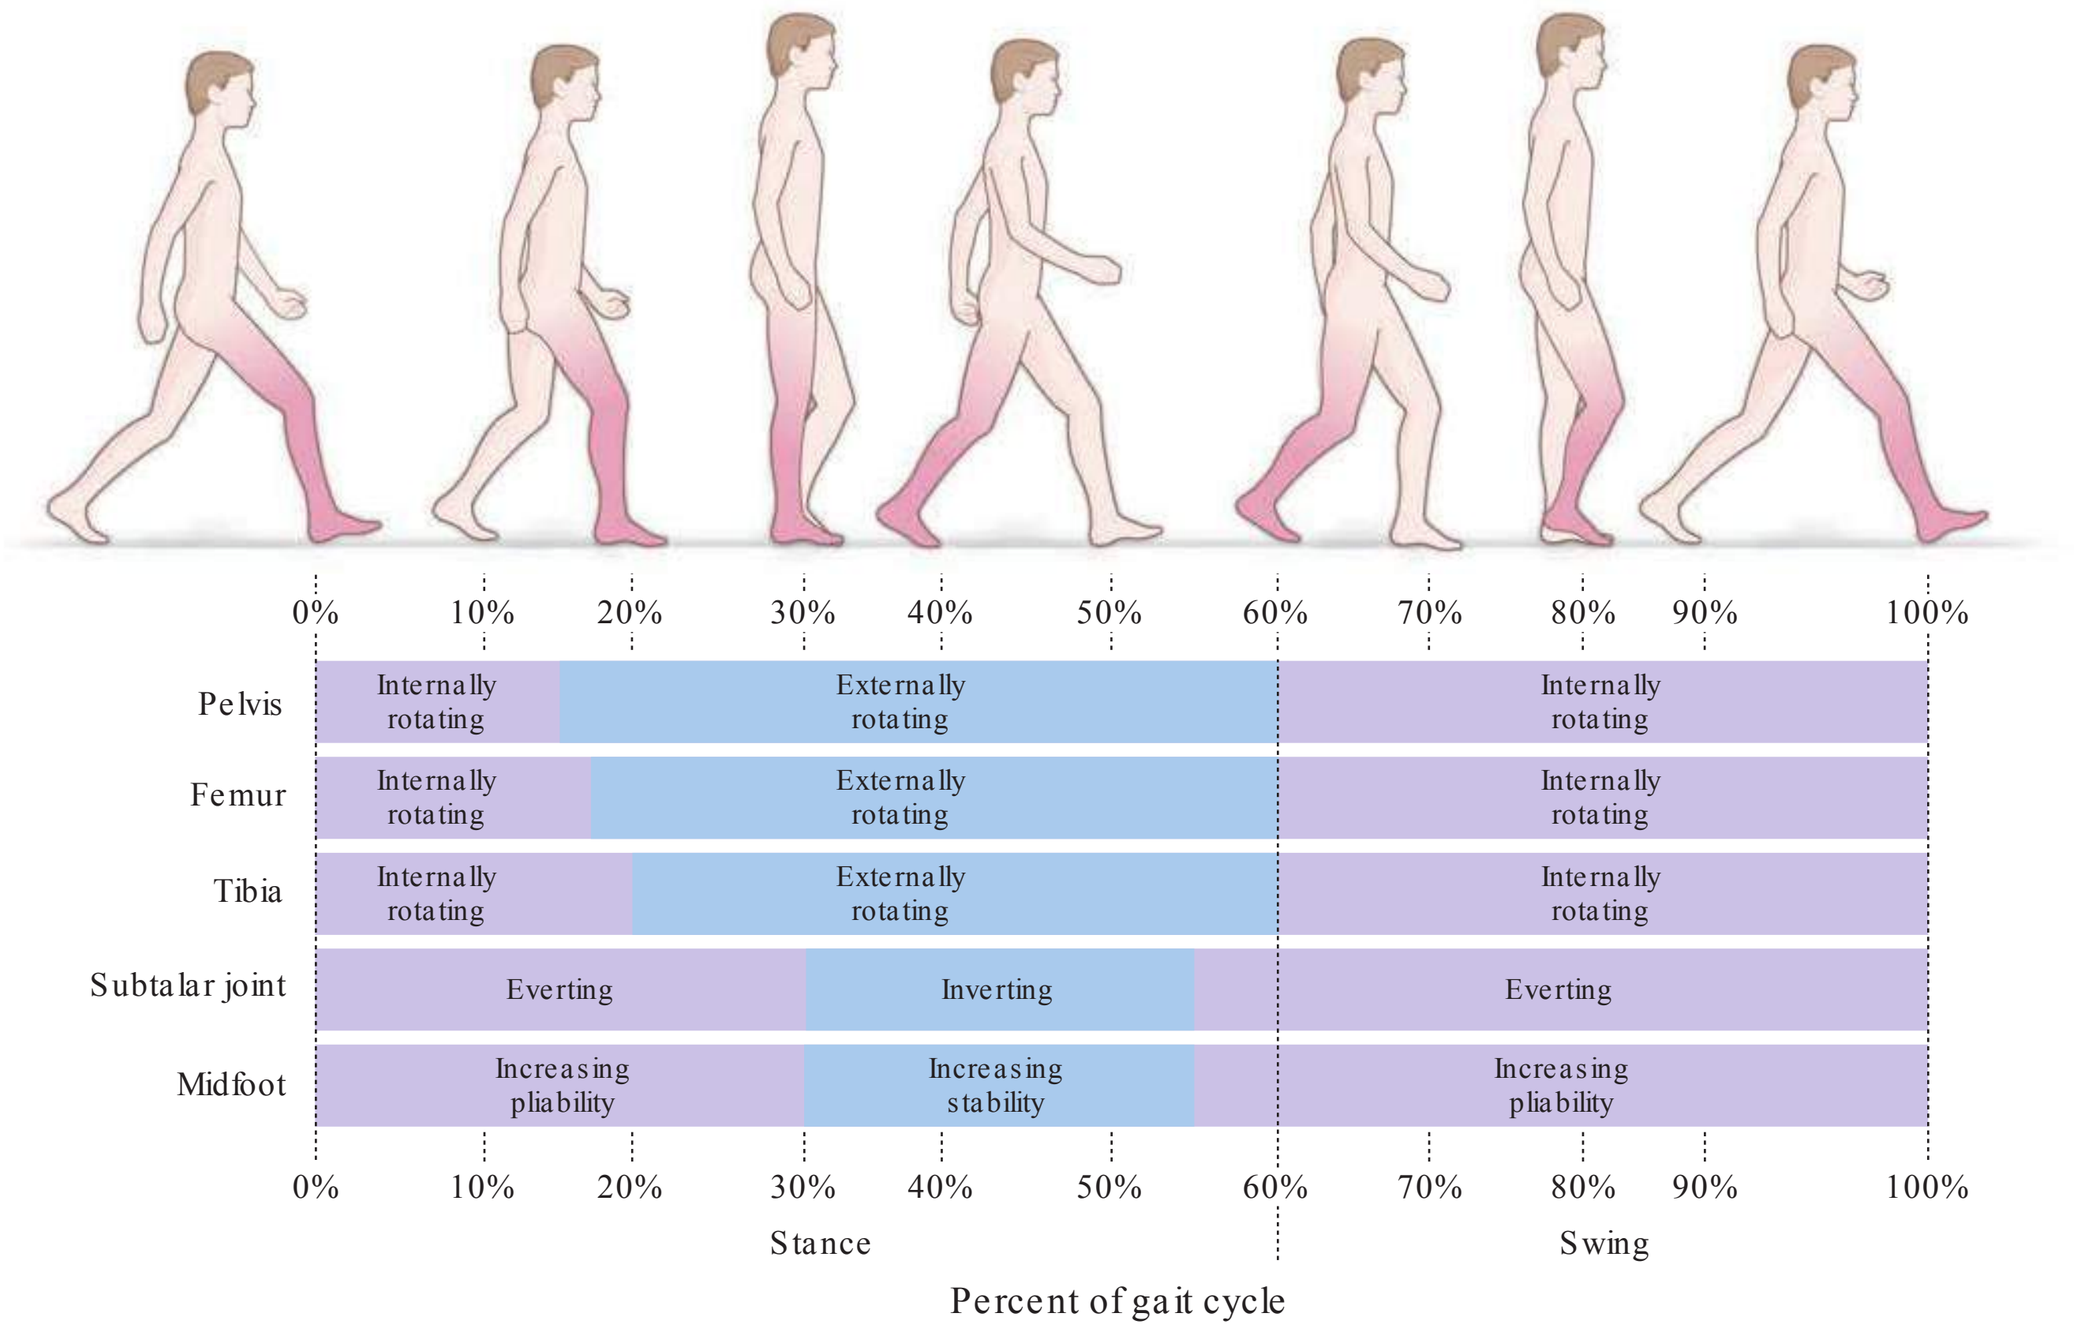

FIGURE 6-4 Joint kinematics in the horizontal plane during gait.

During swing, the hip flexes to advance the limb, while, during stance, the hip extends to move the trunk forward until toe-off.[88]

- The hip flexes and extends once during the gait cycle, with the limit of flexion occurring at the middle of the swing phase, and the limit of extension being achieved before the end of the stance phase (Table 6-2). The hip goes through a total excursion of 40–50 degrees during stance, with maximum hip flexion of 30–35 degrees occurring just before the initial contact, at about 85% of the gait cycle. After maximum hip flexion has been obtained, there is often a small movement toward extension (i.e., the hip become slightly less flexed) as the leg adjusts for placement or prepositioning of the foot just prior to initial contact.[88] Maximum extension of approximately 10–20 degrees is reached near toe-off at approximately 60% of the cycle.[10,40,41,89] The ligaments of the hip helps to stabilize the joint in extension.
- In the coronal plane, the hip is slightly abducted at initial contact before hip adduction occurs throughout early stance as the limb is loaded, and the body is supported and reaches a maximum at 40% of the cycle.[89] Much of the hip adduction is a result of the pelvic angle so that adduction during stance occurs, in part, due to the dropping of the pelvis on the contralateral unsupported limb. The hip then moves into abduction as the pelvis levels out, and the body progresses over the stance limb, reaching maximum abduction shortly after toe-off.[88] The total ROM is near 15 degrees, with equal amounts of abduction and adduction. During the swing phase, hip adduction totaling 5–7 degrees occurs in early swing phase, which is followed by slight hip abduction at the end of the swing phase, especially if a long stride is taken.[10,40,41,89]

CLINICAL PEARL

Women naturally have a larger Q-angle than men (see Chapter 20). In addition, women have increased hip adduction, hip internal rotation, knee valgus, and the internal rotation during functional activities such as running and walking as compared to men.[90,91]

- The hip rotates internally and externally approximately 40–45 degrees in the transverse plane during a normal stride, beginning in approximately 10 degrees of external rotation at initial contact.[10] The hip begins to internally rotate during the loading response to approximately 5 degrees of internal rotation. Maximum internal rotation occurs around the time of initial contact on the contralateral side.[88] The hip externally rotates during the swing phase, with maximal external rotation occurring in terminal swing.[40]

The greatest force on the hip occurs during midstance. Painful hip, knee, or ankle conditions cause this interval to be shortened to decrease the time spent in the painful position.

CLINICAL PEARL

The movements of the thigh and lower leg occur in conjunction with the rotation of the pelvis. The pelvis, thigh, and lower leg normally rotate toward the weight-bearing limb at the beginning of the swing phase.[82]

Knee

The knee flexes twice and extends twice during each gait cycle: once during weight bearing and once during NWB.

Normal sagittal plane excursion of the knee joint during a gait cycle is approximately 60 degrees with the knee near full extension at initial contact and midstance. At initial contact during normal gait, the GRF initially passes anterior to the knee joint and gives rise to an external knee extension moment, which is counterbalanced by an internal knee flexion moment created by the hamstrings and passive posterior knee structures.[9] Immediately after initial contact, the GRF passes behind the knee joint causing an external knee flexion moment as the knee flexes to about 20 degrees during the loading response interval, which acts as a shock-absorbing mechanism. After midstance, the GRF passes in front of the knee again as the knee begins to extend until toe-off and, as the heel rises during the terminal stance interval, the knee is almost fully extended, but flexes again as the swing phase begins. The GRF does not act upon the swing limb. The flexion occurs so that the lower limb can be advanced during the swing phase with a minimum vertical displacement of the COG. The knee then continues to flex as the leg moves into the swing phase. During initial to midswing, the knee continues to flex to a maximum of 60 degrees, before extending again prior to initial contact.[28] During terminal swing, the hamstrings act to slow the progression of the tibia in preparation for contact with the ground. Although movements in the frontal and transverse planes can occur at the knee during gait, the magnitude of the excursion is much smaller, making these motions harder to analyze visually. In individuals without joint pathology, there is very little movement in the frontal plane, although there is slight knee varus excursion during the loading response of approximately 4 degrees of tibial abduction range relative to the femur during stance phase.[92] The motion of the knee in the transverse plane has been termed the screw home or locking mechanism and is considered a key element in knee joint stability (see Chapter 20).

In normal walking, about 60 degrees of knee flexion is required for adequate clearance of the foot during the swing phase. This is peak flexion is required immediately after toe-off because at that point in the gait cycle, the toe is still pointed toward the ground.[18]

CLINICAL PEARL

The most common problem at the knee during the stance phase is excessive flexion. During the swing phase, the most common error results from inadequate motion.

- When the GRF acts to collapse the knee joint during stance, producing an external joint moment, an equal and opposite angular force, or internal joint moment, needs to be produced by the individual to maintain an upright position.[9] If excessive flexion at the knee occurs in midstance, the GRF moves posteriorly to the knee and generates a flexion rather than an extension moment. This change at the moment requires the hip, knee, and ankle to maintain stability. The sharing of these forces between the hip, knee, and ankle are known as the total support moment; the redistribution of forces among these joints can result in visible gait compensations.[9]
- Excessive flexion at the knee results in excessive flexion occurring at the hip. This, in turn, increases the magnitude of the load on both the hip and the knee joints.[93]

The arthrokinematics involved during the loading response include an anterior gliding of the femoral condyles, which serves to "unlock" the knee. This forward gliding is controlled by the passive restraint of the posterior cruciate ligament (PCL) and by the active contraction of the quadriceps muscles.

CLINICAL PEARL

Because ACL-reconstructed patients may experience patellofemoral pain,[94–96] especially those with patella tendon autografts, it is important to prescribe exercises that decrease ACL strain through increased flexion, and minimize patellofemoral pain by exercising with the knee near full extension.[77] This has been recognized as a "paradox",[97,98] exercises performed between the two extremes, approximately 30–60 degrees of knee flexion, may avoid excessive ACL strain and limit patellofemoral pain.[77] However, patellofemoral contact pressures can increase dramatically with increased knee flexion.[99–101] As a result, patellofemoral pain is exacerbated but can be avoided and treated by strengthening the quadriceps in the 0–30 degrees knee flexion range.[102]

A loss of knee extension, which can occur with a flexion deformity, results in the hip being unable to extend fully, which can alter the gait mechanics. Patients with patellofemoral dysfunction demonstrate less knee flexion than normal during the stance phase of gait, combined with increased external rotation of the femur during the swing phase.[49] Excessive compensatory internal rotation of the femur of the weight-bearing leg during the stance phase may result in abnormal stresses being placed on the patellofemoral joint.[49]

CLINICAL PEARL

Studies using a forward dynamic analysis show a strong relationship between tibial advancement and the movement during the first half of the stance phase of gait.[103] By decelerating the tibia after midstance, the gastrocnemius muscle contributes to knee extension.

In late stance, plantarflexion at the ankle contributes to support (vertical forces acting on the trunk) and forward progression (horizontal forces acting on the trunk).[104]

Ankle and Foot

Ankle joint motions during the gait cycle occur primarily in the sagittal plane and are associated with balance and forward progression. During normal gait, the initial contact with the ground is made by the heel, with the ankle in

a relatively neutral or slightly dorsiflexed position, the heel slightly inverted, and the subtalar joint slightly supinated.[105]. In individuals with poor control of dorsiflexion (e.g., in cases of hemiplegia), the initial contact is made with the lower part of the heel and forefoot simultaneously. T is is usually accompanied by a toe drag during the swing phase. A knee flexion contracture or spasticity may cause the same alteration. Similarly, if the quadriceps are weak, the patient may extend the knee by using the hand or may hit the heel hard on the ground to whip the knee into extension. If heel pain occurs at initial contact, this pain may cause increased flexion of the knee, with early plantarflexion to relieve the stress or pressure on the painful tissues.[10]

CLINICAL PEARL

The ability of the foot to perform both as a rigid lever for propulsion and as a flexible structure for shock absorption during gait depends on a number of structural mechanisms within the foot. Midfoot locking is associated with the axes of the talonavicular and calcaneocuboid joint changing according to whether the foot is pronated or supinated (see Chapter 21). When the hindfoot is pronated, the axes of these two joints are parallel to each other which allows for movement (flexible foot). When the hind foot is inverted, the axes are not parallel, which results in decreased movement and enhanced function of the foot as a rigid lever.[104]

T e immediate impact of the initial contact is taken through the lateral tubercle of the calcaneus, a structure unique to humans that is designed to tolerate the shock via the calcaneal fat pad. T e calcaneus quickly moves into approximately 5 degrees of valgus as the limb is loaded to dissipate the high GRF that is generated at impact. During the loading response, the ankle moves from neutral dorsiflexion at initial contact to about 5–8 degrees of plantarflexion at midstance. During the loading response interval, the valgus displacement of the calcaneus within the frontal plane induces pronation at the subtalar joint, which in turn results in external rotation of the calcaneus and internal rotation of the talus within the transverse plane.[105]

CLINICAL PEARL

Tiberio[106] has proposed that prolonged pronation during gait can lead to increased knee internal rotation and subsequent patellofemoral problems.

T e subtalar joint moves into pronation from initial contact to midstance, then rapidly inverts and supinates during terminal stance (after 50% of stance) and peaks near 90% of stance. T e pronation of the subtalar joint unlocks the foot and allows maximal ROM of the midtarsal joint, which brings the articulating surfaces of the cuboid and navicular to a position relatively parallel to the weight-bearing surface and allows the forefoot to become supple.[107,108] T is increase in midtarsal joint mobility enhances the foot's ability to adapt to the support surface. Abnormal responses during this interval include excessive, or no knee motion, as a result of weak quadriceps, plantarflexor contractures, or spasticity.[10]

CLINICAL PEARL

There are two broad types of errors at the foot and ankle joints in the stance and swing phases:

1. Malrotation. The malrotation in stance rotates the plane of the foot outside of the plane of progression, resulting in the COG prematurely passing outside of the BOS. This alteration, in turn, results in a shortening of the contralateral step length. In addition, if the foot is malrotated significantly into external rotation, a valgus moment and an external rotation moment are introduced at the knee.
2. Varus or valgus deformity. Varus and valgus deformities produce a loss of stability throughout the stance phase because they introduce large external moments in the frontal plane that must be balanced by large muscle moments, if stability is to be maintained.

In the stance phase, these deviations may interfere with the first and fourth of Perry's priorities of gait (stability in stance and adequate step length). In the swing phase, these deviations may interfere with priorities 2 and 3 (clearance of the foot in swing and prepositioning of the foot in terminal swing).

At the end of the midstance interval, as the leg segment advances over the fixed foot, the ankle moves into dorsiflexion, and the subtalar joint begins to supinate. T is subtalar joint movement may play a key role in assisting the foot to become a rigid lever and increase the height of the medial longitudinal arch. During preswing, the ankle plantarflexes approximately 20 degrees, which serves to lengthen the limb and preserve the vertical position of the COG. In order to perform this function, the foot must become a rigid lever. However, if the pain is elicited during this interval, the heel may lift off the floor early. From the midstance to the terminal stance interval, the foot is in supination.[107] Supination at the subtalar joint locks the foot into a rigid lever[105,109] by promoting supination at the midtarsal joint, which results in the articulating surfaces of the cuboid and calcaneus adopting a position that is perpendicular to one another, thus stabilizing their articulation.[108] T e fixed cuboid acts as a fulcrum for the fibularis (peroneus) longus muscle, facilitating plantarflexion of the first metatarsal in pushing off.[107]

CLINICAL PEARL

An adaptively shortened gastrocnemius muscle may produce movement impairment by restricting normal dorsiflexion of the ankle from occurring during the midstance to heel raise portion of the gait cycle. This motion is compensated for by increased pronation of the subtalar joint, increased internal rotation of the tibia, and resultant stresses to the knee joint complex.

Once the ankle is fully close packed, the heel is lifted by a combination of passive force and contraction from the taut gastrocnemius and the soleus. T e lifting of the heel accentuates the force applied to the mid- and forefoot, reinforcing the close-packing of this area while simultaneously reducing the close-packing of the ankle joint.

T e hallux, or first MTP joint, undergoes considerable ROM while walking (in excess of 40 degrees of extension),[110] particularly at the end of stance, as the ankle is plantarflexing and the hallux remains in contact with the ground.[110] As ankle plantarflexion reaches its peak at the end of the terminal stance interval; the first MTP joint is passively extended. T is extension of the first MTP joint places tension on the plantar fascia and helps to elevate the medial longitudinal arch through the windlass mechanism of the plantar fascia (see Chapter 21). T is windlass mechanism creates a dynamic stable arch and, hence, a more rigid lever for push-off.[107] However, if the pain is elicited during this interval, the patient is unable to push off on the medial aspect of the foot and instead compensates by pushing off on the lateral aspect of the foot.

While the forefoot is on the ground, and the heel is off, the heel is inverted, and the foot is supinated.[105] T e plantarflexion action helps to smooth the pathway of the COG. T e heel rise coincides with the opposite leg swinging by the stance leg.[111] Approximately 40% of the body weight is borne by the toes in the final stages of foot contact.[112,113] Muscle activity during push-off is designed to initiate propulsion.[107] However, if the plantarflexors are weak, the push-off may be absent.

CLINICAL PEARL

Bojsen-Möller[114] describes the heel rise and the push-off as taking place at the MTP joints around two primary axes: one oblique and one transverse. The heel rise occurs first around the oblique axis, which passes through the MTP joints of the second through the fifth toes. This is followed by the push-off around the transverse axis passing through the MTP joints of the first and second toes. The resistance arm offered against the force arm of the triceps surae while the push-off varies and is 20% longer when the push-off is being performed along the transverse axis. Bojsen-Möller characterizes the motion around the oblique MTP joint axis as a low-gear motion, and the motion around the transverse axis as a high-gear motion.[112,114,115] High-gear motion is used for sprinting, and low-gear motion is used for uphill walking with loads, and in the first step of a sprint.

From initial contact to early midstance, the tibia moves anteriorly, internally rotating within the ankle mortise, and producing talar adduction and plantarflexion, and calcaneal eversion (weight-bearing pronation of the subtalar joint).[107] T e forward tibial advancement requires approximately 10 degrees of ankle joint dorsiflexion to prevent excessive pronation at the subtalar and oblique midtarsal joints.[52,108,116]

During the swing phase, the ankle must dorsiflex in order for the forefoot to clear the ground. After the toes clear the ground, the ankle moves into a position of dorsiflexion, which is maintained throughout the remainder of the swing phase.[117] However, if the ankle dorsiflexor muscles are weak, the patient must utilize a steppage gait, manifested by excessive flexion at the hip so that the toes can clear the ground. Prior to the next initial contact, the ankle adopts a neutral position in terms of dorsiflexion and plantarflexion.

Muscle Actions During Gait

T e musculotendinous units that span the lower extremity joints act as torsional springs, which produce a forward translation of the body mass in a manner similar to that of a bouncing ball.[118] T e efficiency of locomotion (i.e., walking or running) is greatly enhanced by the stretch shortening cycle of the skeletal muscles (i.e., recoil of the stretched parallel and series elastic components, combined with a rapid transition from an eccentric to a concentric contraction mode).[8] During the swing phase, the semispinalis, rotatores, multifidus, and external oblique muscles are active on the side toward which the pelvis rotates.[5] T e erector spinae and internal oblique abdominal muscles are active on the opposite side. T e psoas major and quadratus lumborum help to support the pelvis on the side of the swinging limb, with the contralateral hip abductors also providing support.

T e ankle and hip muscles are responsible for the majority of positive work performed while walking (54% of the hip and 36% of the ankle).[119] T e knee contributes the majority of the negative work (56%).[119] T e muscle actions that occur during the stance phase of gait are depicted in Table 6-3.[120]

Hip

T e hip is unique in that it controls motions of the sagittal, frontal, and transverse planes during the gait cycle, with the majority occurring in the sagittal plane.[1] During the initial contact, the gluteal muscles and the hamstrings contract isometrically with moderate intensity. T e passive hip extension moment at initial contact has been calculated to be approximately 60–100% of the total moment occurring during the stance phase, suggesting that passive elastic energy is stored and released during gait.[121] T e loading response interval is accompanied by hamstring and gluteus maximus activity, which aids hip extension.[10,41,89,122] T e adductor magnus muscle supports hip extension and also rotates the pelvis externally toward the forward leg. In midstance, frontal plane muscle activity is greatest, as the abductors stabilize the pelvis by isometrically and eccentrically contracting.[123–127] T e muscle activity initially is eccentric, as the pelvis shifts laterally over the stance leg.

T e gluteus medius and minimus remain active in terminal stance for lateral pelvic stabilization. T e iliacus and anterior fibers of the tensor fasciae latae (TFL) are also active in the terminal stance and preswing intervals.[10] Notable, but inconsistent, muscle activity of the rectus femoris is described by several authors.[10,41,89,122] T e only muscles of the hip that contract significantly during the last part of the stance phase are the adductor magnus, longus, and possibly brevis.[5]

During the early to midportion of the swing phase, the iliopsoas is the prime mover, with assistance from the rectus femoris, sartorius, gracilis, adductor longus, and possibly the TFL, pectineus, and short head of the biceps femoris during the initial swing interval.[5] Perry notes the adductor longus muscle to be "the first and most persistent hip flexor."[10] In terminal

TABLE 6-3 Muscle Actions in the Lower Extremities During the Stance Phase of Gait

Phase	Hip	Knee and Tibia	Ankle and Foot
Initial contact	Gluteus maximus and hamstrings work eccentrically to resist flexion moment and decelerate the leg	Quadriceps femoris contracts eccentrically to control rapid knee flexion and to prevent buckling	The dorsiflexors (tibialis anterior, extensor digitorum longus, and extensor hallucis longus) contract eccentrically to slow plantarflexion.
Loading response	Gluteus maximus and hamstrings contract concentrically to bring the hip into extension	After the foot is flat, quadriceps activity becomes concentric to bring the femur over the tibia	Dorsiflexion activity decreases; tibialis posterior, flexor hallucis longus, and flexor digitorum longus work eccentrically to control pronation
Midstance	Iliopsoas works eccentrically to resist extension; gluteus medius contracts in reverse action to stabilize opposite pelvis	Quadriceps activity decreases; gastrocnemius works eccentrically to control excessive knee extension	Plantarflexor muscles (gastrocsoleus and fibularis [peroneal] muscles) are activated to control dorsiflexion of the tibia and fibula over a fixed foot by contracting eccentrically
Terminal stance	Iliopsoas activity continues	Gastrocnemius begins to work concentrically to start knee flexion	Plantarflexor muscles begin to contract concentrically to prepare for push-off
Preswing	Adductor magnus works eccentrically to control or stabilize the pelvis; iliopsoas activity continues	Quadriceps femoris contracts eccentrically	Plantarflexor muscles at peak activity but become inactive as the foot leaves the ground

Data from Giallonardo LM. Gait. In: Myers RS, ed. Saunders Manual Physical Therapy Practice. Philadelphia, PA: WB Saunders; 1995:1108–1109.

swing, there is no appreciable action of the hip flexors when ambulating on level ground. Instead, the hamstrings and gluteus maximus are strongly active to decelerate hip flexion and knee extension.[10] Both these superficial muscles and their deeper counterparts, such as the hip adductors, gemelli, and short rotators, certainly contribute.[51] In rapid walking, there is increased activity of the sartorius and the rectus femoris during the swing phase.[5]

CLINICAL PEARL

- The hip flexors (primarily the iliopsoas muscle) contract to slow down hip extension, whereas the hip extensors (primarily the hamstring muscles) contract to slow down hip flexion.
- The hip abductor muscles provide stability during single-leg support, a critical event for the hip.[51]

CLINICAL PEARL

The major problems that occur at the hip during gait are inadequate power, an inadequate or inappropriate ROM, and malrotation.

A weakness of the hip flexors is best seen during the preswing and initial swing intervals. A weakness of the hip abductors is noted during the single support phase of stance because the hip abductors are required to prevent the collapse of the pelvis toward the unsupported side (Trendelenburg sign).

A weakness of the hip extensors is usually seen at initial contact and during loading response. If the hamstrings are weak, the initial contact may be excessively harsh to lock the knee into extension.

As the flexors, adductors, and internal rotators of the hip are dominant over their antagonists, flexion, adduction, and internal rotation deformities tend to be the rule.

Malrotation of the hip usually results from conditions such as femoral anteversion.

Knee

The functions of the knee during gait are to absorb shock, reduce vertical displacement of the COG, maintain the stride length, bear weight, and allow the foot to move through its swing. In a normal gait cycle, the loading response interval begins with the knee slightly flexed as the heel initially contacts the ground. Throughout the loading response interval, the knee continues to flex to about 20 degrees, at which time the knee is under maximum weight-bearing load.[9] The loading response phase requires large amounts of eccentric quadriceps force. Midstance corresponds with concentric loading of the knee extensors as the knee begins to extend following its role in absorbing the body's weight during the loading response.[9] During the swing phase, there is very little activity from the knee flexors. The knee extensors contract slightly at the end of the swing phase prior to initial contact. During level walking, the quadriceps achieve peak activity during the loading response interval (25% maximum voluntary contraction) and are relatively inactive by midstance as the leg reaches the vertical position and locks,

making quadriceps contraction unnecessary.[46,128–130] In a graded exercise, Brandell[131] examined the effect of speed and grade on electromyographic (EMG) activity of the quadriceps and calf musculature. The author concluded that increases in speed and grade resulted in a relative increase in EMG activity of the quadriceps compared with the calf musculature. More recently Ciccotti et al.[132] noted similar magnitudes and profiles of EMG activity in the quadriceps during level walking (1.5 m/s) and ascending a ramp of 10% grade at the same speed as level walking. Although minimal data were presented for comparison, the authors did note a decrease in vastus lateralis activity from 16% to less than 10% of maximum manual muscle test, with the addition of a grade. Therefore, it remains questionable whether graded walking actually facilitates quadriceps activity.[77]

CLINICAL PEARL

If the quadriceps muscles are weak, the trunk muscles thrust the pelvis forward to provide forward momentum to the leg.

Hamstring involvement is also important to normal knee function. The hamstrings provide dynamic stability to the knee by resisting both mediolateral and anterior translational forces on the tibia.[133] The coactivation of the antagonist muscles about the knee during the loading response interval aids the ligaments in maintaining joint stability by equalizing the articular surface pressure distribution and controlling tibial translation.[134,135] EMG activity of the hamstrings during level walking has shown that the hamstrings decelerate the leg prior to heel contact and then act synergistically with the quadriceps during the stance phase to stabilize the knee.[129,136] The hamstrings also demonstrate activity at the end of the stance phase. Hamstring activity during graded walking and increased speed demonstrates increased activity and for a longer duration.[5]

CLINICAL PEARL

Not only is quadriceps and hamstrings training important in knee rehabilitation, but proper ROM must also be considered.[77]

Ankle and Foot

The extensor hallucis longus (EHL) and extensor digitorum longus (EDL), which are both innervated by the deep fibular (peroneal) nerve containing fibers from L4–S1, eccentrically assist the forefoot in controlling the deceleration of the foot at heel strike. At initial contact, the tibialis anterior is active. Following initial contact, the tibialis anterior works eccentrically to control the speed of plantarflexion to lower the foot to the ground during the loading response interval.[137,138] Loss of this plantarflexion control can result in an inability to transfer weight to the anterior foot, increased ankle dorsiflexion, and increased knee flexion. Eccentric tension within the tibialis posterior musculotendinous unit restrains excessive distraction (pronation) of the medial articular surfaces of the subtalar joint and transverse tarsal joints during impact loading, and subsequent isometric and concentric tension generated by the tibialis posterior provide the midfoot stabilizing effect that is essential for body mass propulsion.[139] Indeed, the tibialis posterior is required to act during the full weight-bearing phase of the gait cycle and is thus active from initial contact to shortly after the heel raises before toe-off. The anterior movement of the tibia and talus is limited by the eccentric action of the gastrocnemius and soleus muscle groups as the foot moves toward midstance.[120]

CLINICAL PEARL

The tibialis posterior muscle is active during 45–80% of the gait cycle, and the interdependent closed chain displacements of the various foot, and ankle joints are heavily influenced by this muscle.[139] Indeed, the tibialis posterior muscle likely plays an important role in controlling hindfoot pronation and supination while providing secondary control of abduction and adduction of the midfoot during gait.[104] In addition, the tibialis posterior plays an integral role in maintaining the integrity of the longitudinal arch of the foot (see Chapter 21).

Eccentric contractions dominate gastrocnemius function during normal walking; therefore, rehabilitation should emphasize eccentric movement.[140]

Pronation, which is eccentrically controlled by the tibialis posterior also occurs in this phase to allow for shock absorption, ground terrain changes, and equilibrium.[108,141] The triceps surae become active again from midstance to the late stance phase, contracting eccentrically to control ankle dorsiflexion, as the COG continues to move forward. In late stance phase, the Achilles tendon is stretched, as the ankle dorsiflexes.[142] In addition, the tibialis posterior is the initiator of inversion of the hindfoot at the subtalar joint. At the end of the stance phase, the heel rises off the ground, and the action of the plantarflexors changes from one of eccentric contraction to one of concentric contraction as they provide an active "pushoff."[143,144] The contribution of muscles other than the triceps surae muscles to perform ankle plantarflexion is extremely small.[104] The energy stored in the stretched tendon helps to initiate plantarflexion and the initiation of propulsion.[142] At the same time, concentric contraction of the tibialis posterior muscle induces supination of both the rearfoot and forefoot by adducting the transverse tarsal joint. This action has two beneficial effects on the gastrocnemius–soleus complex: it locks the transverse tarsal joint allowing maximal plantarflexion at the ankle joint, and it shifts the pull of the Achilles tendon further medially.[145] Weakness of the tibialis posterior muscle will limit the ability to actively supinate the foot during the latter portion of the stance phase of gait, which is essential to convert it into a rigid lever for a forcible pushoff.[8] Thus, the interlocking of the supinated articular surfaces of each of the adjacent hind foot, midfoot, and forefoot joints, combined with powerful action that the triceps surae muscles exert to the Achilles tendon to elevate the heel, results in a forefoot varus thrust that facilitates generation of a propulsive GRF beneath the forefoot.[146]

During the beginning of the swing phase, the tibialis anterior, EDL, EHL, and possibly the fibularis (peroneus) tertius contract concentrically with slight-to-moderate intensity to provide clearance for the foot and toes, tapering off during the middle of the swing phase.[5,137,138] As the swing phase begins, the fibularis (peroneus) longus also contracts concentrically to evert the entire foot and bring the sole of the foot parallel to the substrate. At the point where the leg is perpendicular to the ground during the swing phase, the tibialis anterior, EDL, and EHL group of muscles contract concentrically to dorsiflex and invert the foot in preparation for the initial contact.[5,137,138] There is very little activity, if any, from the plantarflexors during the swing phase. The fibularis (peroneus) brevis acts to evert the foot and unlock the transverse tarsal joints in the nonweight-bearing swing phase of gait.[147]

CLINICAL PEARL

A three-stage process of transferring ground contact from the rear foot to the forefoot, which involves interaction between the anatomic structure and muscle actions, has been described as consisting of three "rocker" mechanisms[15]:

1. The first rocker occurs between the initial contact with the convex undersurface of the heel and when the foot is flat on the floor. This rocker, which acts in a manner similar to the base of a rocking chair to facilitate a forward rolling of the rear foot, involves the ankle dorsiflexors, working eccentrically to control plantarflexion to gradually permit the foot to come into full contact with the ground.[8]
2. During the second rocker, the foot remains flat on the ground, while the tibia anteriorly rotates over the talus. This motion, which is a combination of articular surface rolling and sliding of the concave plafond of the tibia over the convex dome of the talus, results from the plantarflexors, working eccentrically to control the ankle dorsiflexion displacement that occurs.[8]
3. The third rocker is produced during terminal stance by the convex contour of the under surface beneath the heads of the metatarsals, which results in elevation of the rear foot as the leg and foot segments roll forward. This is the phase of power generation. During rapid walking with a long stride, contraction of the ankle plantarflexors contributes to forward propulsion immediately prior to toe-off.[8] Subsequent concentric contraction (see Chapter 1) of the ankle dorsiflexors prevents the toes from contacting the ground during the swing phase.[148,149]

Thus, the first two rockers are deceleration rockers, in which the respective muscles are working eccentrically by undergoing a lengthening contraction with energy absorption. The third rocker is an acceleration rocker and aids in propulsion. Abnormal muscle moments at the ankle during the stance phase can manifest as a weakness of the tibialis anterior, resulting in a "foot slap" at initial contact during the first rocker. The weakness of the triceps surae allows the tibia to progress too rapidly during the second rocker, causing the GRF to fall behind the knee, and inducing knee flexion. Abnormal muscle moments during the swing phase include the excessive activity of the plantarflexors and insufficient strength of the dorsiflexors, resulting in foot drop and poor foot clearance.

As the first MTP joint is dorsiflexing during gait, and especially at heel rise, the flexor hallucis longus (FHL) muscle is lengthening across the first MTP joint while it is shortening at ankle joint, resulting in a near isometric contraction.[150]

CLINICAL EXAMINATION OF GAIT

The clinical examination of gait can be performed using methods ranging from observation to computerized analysis (Table 6-4). Computerized gait analysis measures gait parameters more precisely than is possible with clinical observation alone,[151,152] and is used in the evaluation and treatment planning for patients with gait abnormalities.[153] However, computerized gait analysis is often cost prohibitive and, thus, not practical for most clinicians, who must, therefore, rely on their powers of observation. Many spatiotemporal variables, like speed, cadence, and step length, are easily assessed in the clinical setting, and provide some useful information on gait deficiencies. Walking speed reflects underlying physiologic processes and is advocated as a vital sign due to its ability to predict future health status.[154] Self-selected gait speeds below 1.0 m/s imply a need for rehabilitation[9] and speeds below 0.6 m/s are associated with a high risk of falls.[155] The reliability and agreement both between and within raters for gait problems detected by observation alone has been reported. Krebs et al.[152] found moderate reliability within and between physical therapists observing children's gait from videotape. Eastlack et al.[156] found only slight-to-moderate reliability between raters in the assessment of deviations at a single joint from a videotape.[153]

Perhaps, the most commonly used gait analysis chart is the one designed by the Rancho Los Amigos Medical Center (Fig. 6-5), which allows the clinician to determine deviations and their effect on gait in a user-friendly format.

Several other examination tools are available. Some of these tools are specific to a particular population. For example, the modified version of the Gait Abnormality Rating Scale (Table 6-5) can be used with community-dwelling frail older persons to help predict individuals who are at high risk for falling.[157]

Dysfunction of the vestibular system may lead to gait abnormalities.[158,159] The Functional Gait Assessment (Table 6-6) is a 10-item test that comprises 7 of the 8 items from a previous test called the Dynamic Gait Index, which was developed to assess postural stability during gait tasks in the older adult (greater than 60 years of age) at risk for falling.[160] According to the designers of the Functional Gait Assessment, the tool demonstrates acceptable reliability, internal consistency, and concurrent validity with other balance measures used for patients with vestibular disorders.[159] Intervention strategies for vestibular dysfunction are described in Chapter 14.

Observational Analysis

Observational analysis of gait should focus on one gait interval at a time. For example, the clinician should observe the

TABLE 6-4 Strengths and Limitations of Gait Analysis Methods

Method	Strengths	Limitations
Observational analysis	1. Widely available 2. Can be enhanced by simple videotaping 3. Allows classification of gross gait patterns 4. Inexpensive	1. Subjective 2. Unable to measure more subtle phenomena
Stride analysis	1. Provides quantitative information regarding time–distance parameters 2. Easy and fast 3. Low space requirements 4. Relatively inexpensive	1. Does not permit angular kinematic and kinetic analysis 2. Requires that patients have distinct swing phase involving removal of floor contact
Angular kinematic analysis	1. Permits precise measurement of joint angular excursions 2. Objective and quantitative	1. Requires technically trained personnel for measurement and interpretation of results 2. High space requirements 3. Limited portability 4. Expensive
Force plate and pressure plate analyses	1. Permits precise measurement of external loads 2. Permits analysis of inverse dynamics 3. Provides information regarding load patterns and distributions on stance limb	1. Limited usefulness in isolation 2. Typically requires permanent installation (gait lab) 3. Requires technically trained personnel for measurement and interpretation of results 4. Expensive
Electromyographic analysis	1. Provides measurement of motor performance and functional role of musculature 2. Enhances interpretation of kinematic and kinetic parameters	1. Requires technical expertise for measurement and interpretation 2. Subject to interference and artifact during sampling 3. Invasiveness of intramuscular technique poses risk to patients 4. Expensive

Data from Spivak JM, DiCesare PE, Feldman DS, et al., eds. Orthopaedics: A Comprehensive Study Guide. New York, NY: McGraw-Hill; 1999:209.

pattern of initial contact with the floor at the ankle, knee, hip, pelvis, trunk, and upper extremities and then, in turn, study the same actions throughout the loading response interval.

A paper walkway, approximately 25-ft long, on which the patient's footprints can be recorded, is very useful for gait analysis.[48,161] To assess gait, knowledge of what is deemed abnormal and the reasons for those abnormalities are prerequisite (Table 6-7).

Gait is assessed by having the patient walk barefoot and with footwear. Barefoot walking provides information about foot function without support and can highlight painful areas on the sole, and compensations, such as excessive pronation, and foot deformities, such as claw toes.[162] For example, metatarsalgia is indicated if the metatarsal heads are made more painful with barefoot walking. Pain at initial contact may indicate a heel spur, bone contusion, calcaneal fat pad injury, or bursitis. The patient's foot is also examined for callus formation, blisters, corns, and bunions. Callus formation on the sole of the foot can be an indicator of dysfunction and provides the clinician with an index to the degree of shear stresses applied to the foot, and a clear outline of abnormal weight-bearing areas.[163] Adequate amounts of calluses may provide protection, but in excess amounts they may cause pain. Callus formation under the second and third metatarsal heads could indicate excessive pronation in a flexible foot, or Morton neuroma, if just under the former. A callus under the fifth, and sometimes the fourth, metatarsal head may indicate an abnormally rigid foot.

Having the patient walk with footwear can provide information about the effectiveness of the footwear to counteract the compensations. The patient's footwear is examined for patterns of wear. The greatest amount of wear on the sole of the shoe should occur beneath the ball of the foot and in the area corresponding to the first, second, and third MTP joints, and slight wear to the lateral side of the heel. The upper portion of the shoe should demonstrate a transverse crease at the level of the MTP joints. A stiff first MTP joint can produce a crease line that runs obliquely, from forward and medial to backward and lateral.[164] Scuffing of the top of the shoe at its front might indicate tibialis anterior weakness or adaptively shortened heel cords.[162]

The patient should be asked to walk on the toes and then on the heels. An inability to perform either of these actions could be the result of pain, weakness, or a motion restriction, or a combination of all.

The patient is asked to walk in his or her usual manner and at the usual speed. The clinician begins the gait assessment with an overall look at the patient while they walk and noting the cadence, stride length, step length, and velocity. The arms

GAIT ANALYSIS: FULL BODY

RANCHO LOS AMIGOS MEDICAL CENTER
PHYSICAL THERAPY DEPARTMENT

Reference Limb:

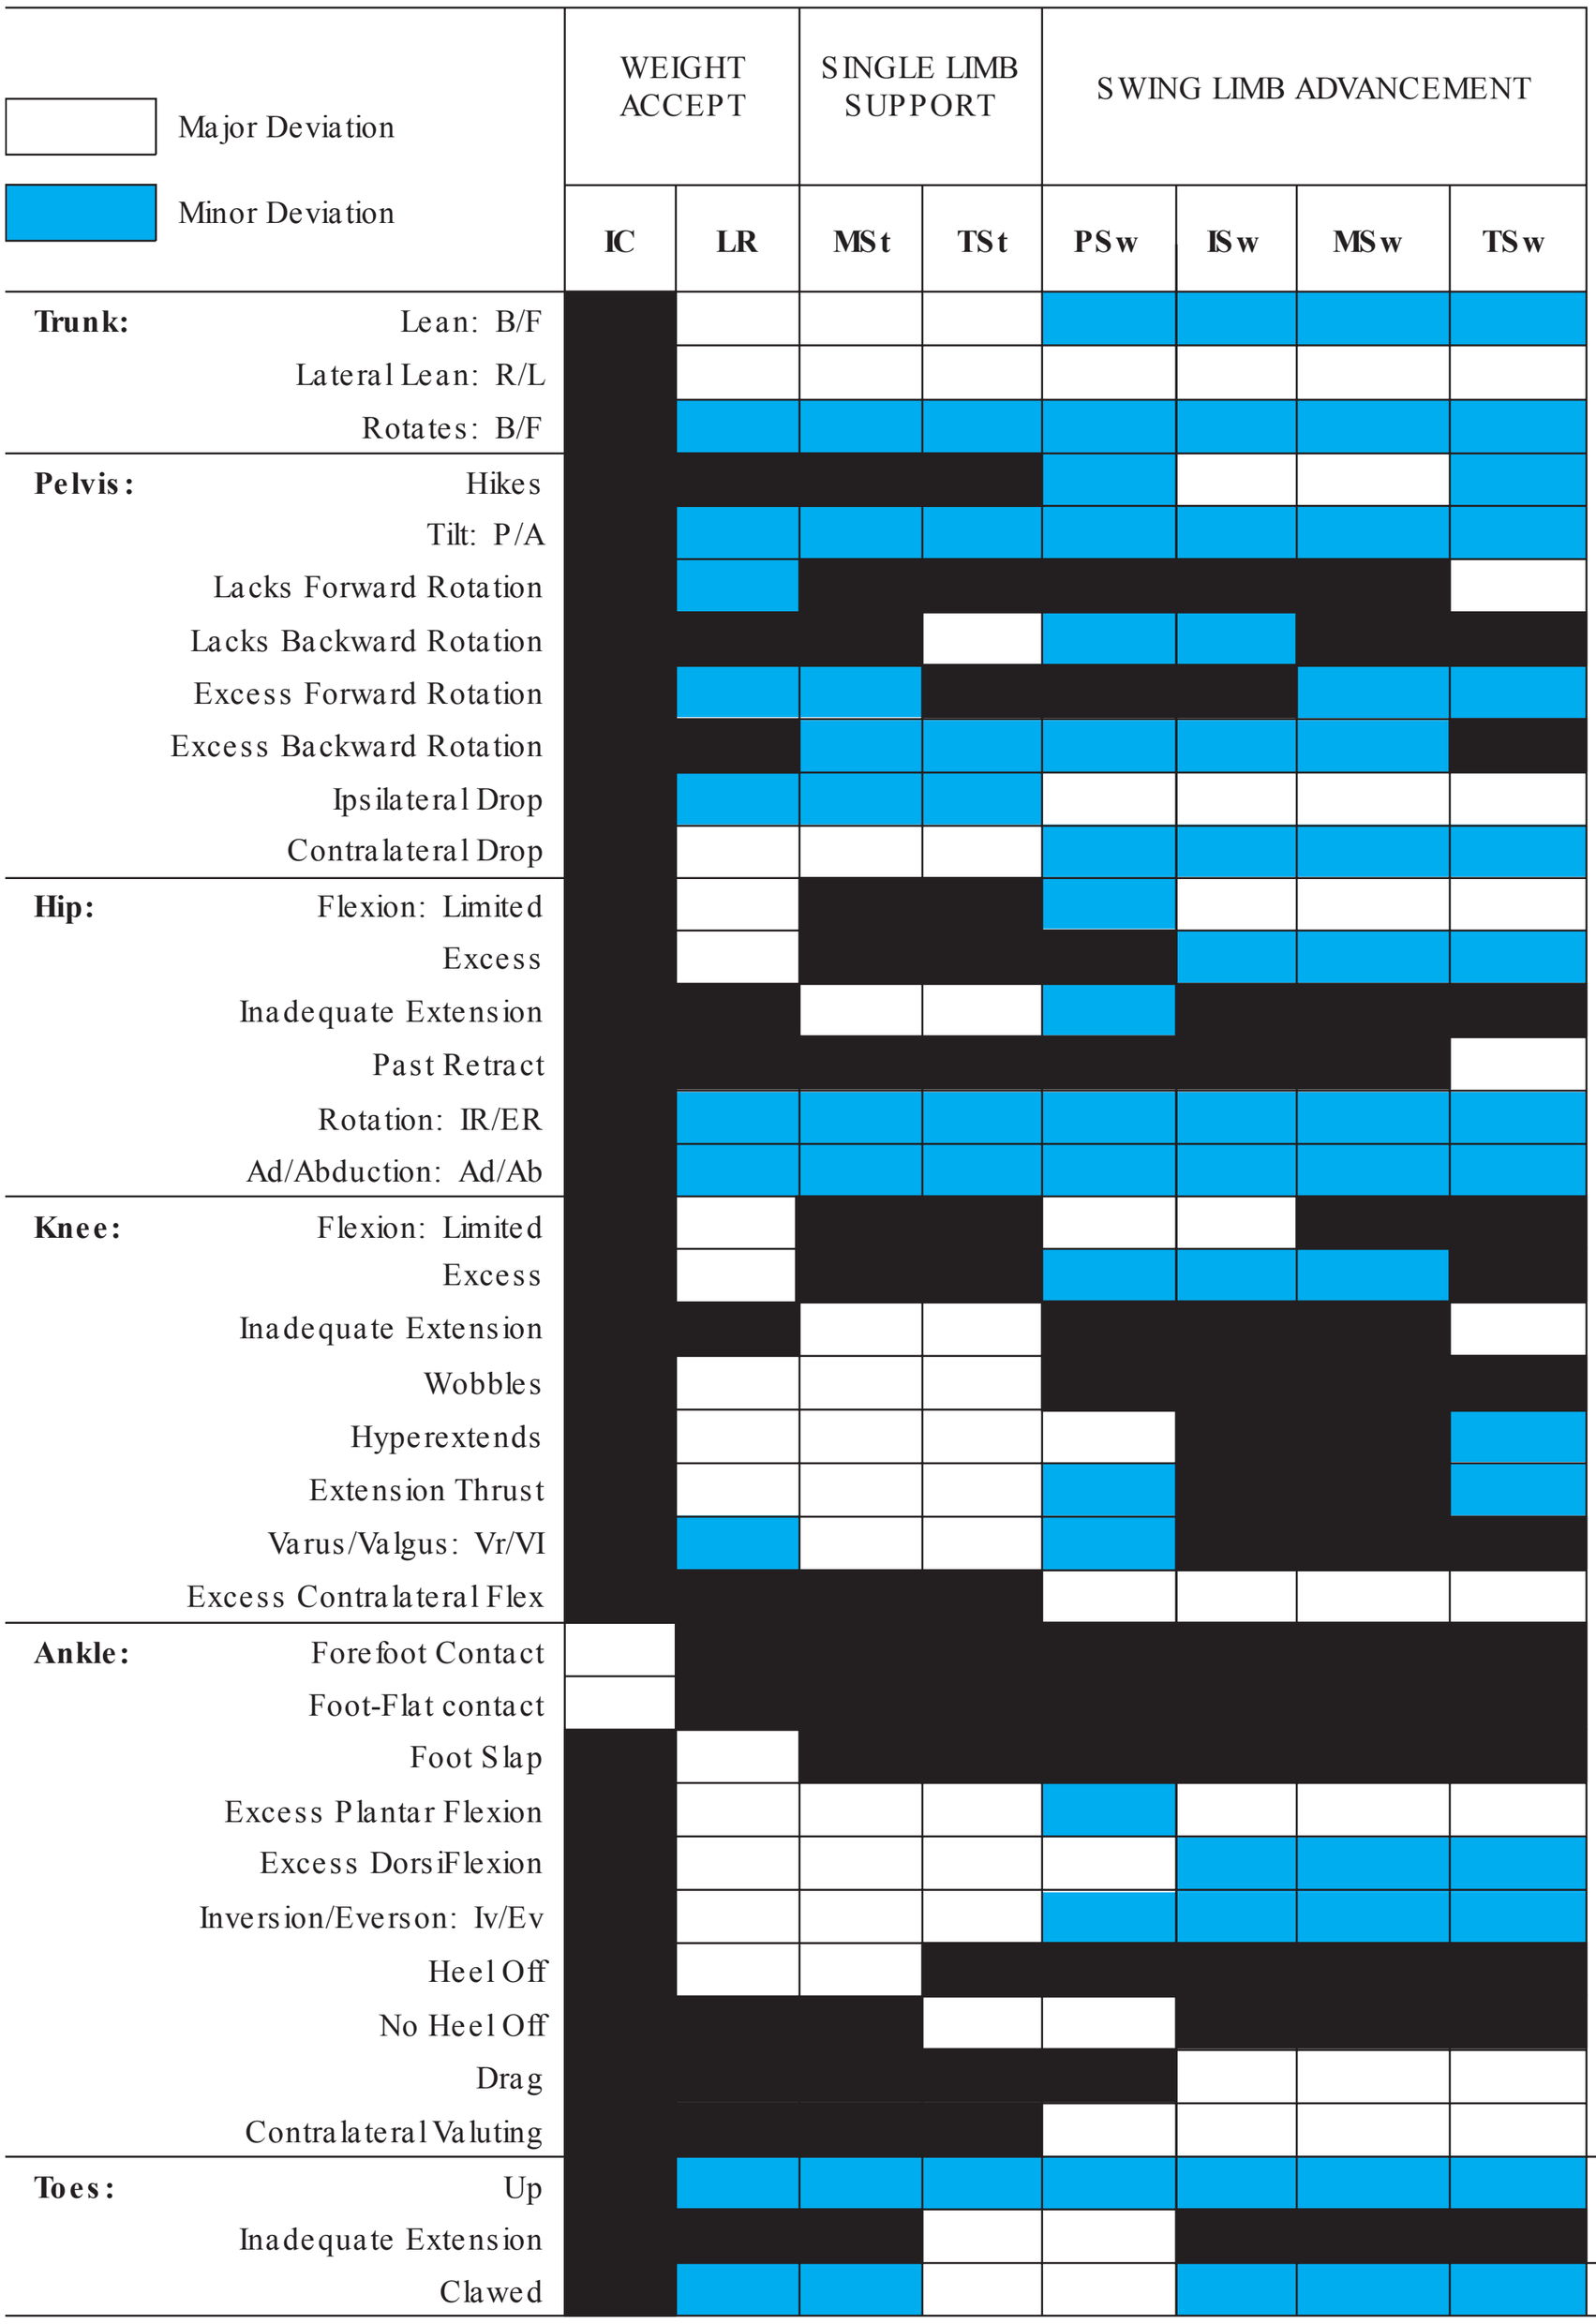

FIGURE 6-5 Rancho Los Amigos gait analysis chart.

TABLE 6-5 Modified Gait Abnormality Rating Scale

Name _____ No. _____ Visit _____ Date _____

1. Variability—a measure of inconsistency and arrhythmicity of stepping and of arm movements
0 = fluid and predictably paced limb movements
1 = occasional interruptions (changes in velocity), approximately 25% of time
2 = unpredictability of rhythm approximately 25–75% of time
3 = random timing of limb movements

2. Guardedness—hesitancy, slowness, diminished propulsion, and lack of commitment in stepping and arm swing
0 = good forward momentum and lack of apprehension in propulsion
1 = center of gravity of head, arms, and trunk (HAT) projects only slightly in front of push-off, but still good arm–leg coordination
2 = HAT held over anterior aspect of foot, and some moderate loss of smooth reciprocation
3 = HAT held over rear aspect of stance-phase foot, and great tentativity in stepping

3. Staggering—sudden and unexpected laterally directed partial losses of balance
0 = no losses of balance to side
1 = a single lurch to side
2 = two lurches to side
3 = three or more lurches to side

4. Foot contact—the degree to which the heel strikes the ground before the forefoot
0 = very obvious angle of impact of heel on ground
1 = barely visible contact of heel before forefoot
2 = entire foot lands flat on ground
3 = anterior aspect of foot strikes ground before heel

5. Hip ROM—the degree of loss of hip range of motion seen during a gait cycle
0 = obvious angulation of thigh backward during double support (10 degrees)
1 = just barely visible angulation backward from vertical
2 = thigh in line with vertical projection from ground
3 = thigh angled forward from vertical at maximum posterior excursion

6. Shoulder extension—a measure of the decrease of shoulder ROM
0 = clearly seen movement of upper arm anterior (15 degrees) and posterior (20 degrees) to vertical axis of trunk
1 = shoulder flexes slightly anterior to vertical axis
2 = shoulder comes only to vertical axis, or slightly posterior to it during flexion
3 = shoulder stays well behind vertical axis during entire excursion

7. Arm–heel strike synchrony—the extent to which the contralateral movements of an arm and leg are out of phase
0 = good temporal conjunction of arm and contralateral leg at apex of shoulder and hip excursions all of the time
1 = arm and leg slightly out of phase 25% of the time
2 = arm and leg moderately out of phase 25–50% of time
3 = little or no temporal coherence of arm and leg

ROM, range of motion.

TABLE 6-6 Functional Gait Assessment Requirements: A Marked 6 m (20 ft) Walkway That is Marked with a 13.48 cm (12 in) Width

1. Gait level surface

Instructions: Walk at your normal speed from here to the next mark (6 m/20 ft)

Grading: Mark the highest category that applies

(3) Normal: Walks 6 m/20 ft, in less than 5.5 s, no assistive devices, good speed, no evidence for imbalance, normal gait pattern, deviates no more than 15.24 cm (6 in) outside of the 30.48 cm (12 in) walkway width

(2) Mild impairment: Walks 6 m/20 ft, in less than 7 s but greater than 5.5 s, uses assistive device, slower speed, mild gait deviations, or deviates 15.24–25.4 cm (6–10 in) outside of the 30.48 cm (12 in) walkway width

TABLE 6-6 Functional Gait Assessment Requirements: A Marked 6 m (20 ft) Walkway That is Marked with a 13.48 cm (12 in) Width (Continued)

(1) Moderate impairment: Walks 6 m/20 ft, slow speed, abnormal gait pattern, evidence for imbalance, or deviates 25.4–38.1 cm (10–15 in) outside of the 30.48 cm (12 in) walkway width. Requires more than 7 s to ambulate 6 m (20 ft)

(0) Severe impairment: Cannot walk 6 m/20 ft without assistance, severe gait deviations or imbalance, deviates greater than 38.1 cm (15 in) outside of the 30.48 cm (12 in) walkway width, or reaches and touches the wall

---

2. Change in gait speed

Instructions: Begin walking at your normal pace (for 1.5 m/5 ft). When I tell you "go," walk as fast as you can (for 1.5 m/5 ft). When I tell you "slow," walk as slowly as you can (for 1.5 m/5 ft)

Grading: Mark the highest category that applies

(3) Normal: Able to smoothly change walking speed without loss of balance or gait deviation. Shows a significant difference in walking speeds between normal, fast, and slow speeds. Deviates no more than 15.24 cm (6 in) outside of the 30.48 cm (12 in) walkway width

(2) Mild impairment: Is able to change speed but demonstrates mild gait deviations, deviates 15.24–25.4 cm (6–10 in) outside of the 30.48 cm (12 in) walkway width, or no gait deviations but unable to achieve a significant change in velocity, or uses an assistive device

(1) Moderate impairment: Makes only minor adjustments to walking speed, or accomplishes a change in speed with significant gait deviations, or changes speed but has significant gait deviations, deviates 25.4–38.1 cm (10–15 in) outside of the 30.48 cm (12 in) walkway width, or changes speed but loses balance but is able to recover and continue walking

(0) Severe impairment: Cannot change speeds, deviates greater than 38.1 cm (15 in) outside of the 30.48 cm (12 in) walkway width, or loses balance and has to reach for wall or be caught

---

3. Gait with horizontal head turns

Instructions: Walk from here to the next mark (6 m/20 ft) away. Begin walking at your normal pace. Keep walking straight; after three steps, turn your head to the right and keep walking straight while looking to the right. After three more steps, turn your head to the left and keep walking straight while looking left. Continue alternating looking right and left every three steps until you have completed two repetitions in each direction

Grading: Mark the highest category that applies

(3) Normal: Performs head turns smoothly with no change in gait velocity. Deviates no more than 15.24 cm (6 in) outside of the 30.48 cm (12 in) walkway width

(2) Mild impairment: Performs head turns smoothly with slight change in gait velocity, i.e., minor disruption to smooth gait path, deviates 15.24–25.4 cm (6–10 in) outside of the 30.48 cm (12 in) walkway width, or uses assistive device

(1) Moderate impairment: Performs head turns with moderate change in gait velocity, slows down, deviates 25.4–38.1 cm (10–15 in) outside of the 30.48 cm (12 in) walkway width but recovers, can continue to walk

(0) Severe impairment: Performs task with severe disruption of gait, i.e., staggers outside of the 30.48 cm (12 in) walkway width, loses balance, stops, or reaches for wall

---

4. Gait with vertical head turns

Instructions: Walk from here to the next mark (6 m/20 ft) away. Begin walking at your normal pace. Keep walking straight; after three steps, tip your head up and keep walking straight while looking up. After three more steps, tip your head down, keep walking straight while looking down. Continue alternating looking up and down every three steps until you have completed two repetitions in each direction

Grading: Mark the highest category that applies.

(3) Normal: Performs head moves smoothly with no change in gait. Deviates no more than 15.24 cm (6 in) outside of the 30.48 cm (12 in) walkway width

(2) Mild impairment: Performs task with slight change in gait velocity, i.e., minor disruption to smooth gait path, deviates 15.24–25.4 cm (6–10 in) outside of the 30.48 cm (12 in) walkway width, or uses assistive device

(1) Moderate impairment: Performs task with moderate change in gait velocity, slows down, deviates 25.4–38.1 cm (10–15 in) outside of the 30.48 cm (12 in) walkway width but recovers, can continue to walk

(0) Severe impairment: Performs task with severe disruption of gait, i.e., staggers outside of the 30.48 cm (12 in) walkway width, loses balance, stops, or reaches for wall

---

5. Gait and pivot turn

Instructions: Begin walking at your normal pace. When I tell you, "turn and stop," turn as quickly as you can to face the opposite direction and stop

Grading: Mark the highest category that applies

(3) Normal: Pivot turns safely within 3 s and stops quickly with no loss of balance

(2) Mild impairment: Pivot turns safely in >3 s and stops with no loss of balance, or pivot turns safely within 3 s and stops with mild imbalance, requires small steps to catch balance

(1) Moderate impairment: Turns slowly, requires verbal cueing, or requires several small steps to catch balance following turn and stop

(0) Severe impairment: Cannot turn safely, requires assistance to turn and stop

---

(Continued)

TABLE 6-6 **Functional Gait Assessment Requirements: A Marked 6 m (20 ft) Walkway That is Marked with a 13.48 cm (12 in) Width** (Continued)

6. Step over obstacle

Instructions: Begin walking at your normal speed. When you come to the shoebox, step over it, not around it, and keep walking

Grading: Mark the highest category that applies

(3) Normal: Is able to step over two stacked shoe boxes taped together (22.86 cm/9 in total height) without changing gait speed, no evidence of imbalance

(2) Mild impairment: Is able to step over one shoebox (11.43 cm/4.5 in total height) without changing gait speed; no evidence of imbalance

(1) Moderate impairment: Is able to step over one shoe box (11.43 cm/4.5 in total height) but must slow down and adjust steps to clear box safely. May require verbal cueing

(0) Severe impairment: Cannot perform without assistance

7. Gait with narrow base of support

Instructions: Walk on the floor with arms folded across the chest, feet aligned heel to toe in tandem for a distance of 3.6 m (12 ft). The number of steps taken in a straight line are counted for a maximum of 10 steps

Grading: Mark the highest category that applies

(3) Normal: Is able to ambulate for 10 steps heel to toe with no staggering

(2) Mild impairment: Ambulates 7–9 steps

(1) Moderate impairment: Ambulates 4–7 steps

(0) Severe impairment: Ambulates less than 4 steps heel to toe or cannot perform without assistance

8. Gait with eyes closed

Instructions: Walk at your normal speed from here to the next mark (6 m/120 ft) with your eyes closed. Grading: Mark the highest category that applies

(3) Normal: Walks 6 m/20 ft, no assistive devices, good speed, no evidence of imbalance, deviates no more than 15.24 cm (6 in) outside of the 30.48 cm (12 in) walkway width. Ambulates 6 m/20 ft in less than 7 s

(2) Mild impairment: Walks 6 m/20 ft, uses assistive devices, slower speed, mild gait deviations, deviates 15.24–25.4 cm (6–10 in) outside of the 30.48 cm (12 in) walkway width. Ambulates 6 m/20 ft in less than 9 s but greater than 7 s

(1) Moderate impairment: Walks 6 m/20 ft, slow speed, abnormal gait pattern, evidence for imbalance, deviates 25.4–38.1 cm (10–15 in) outside of the 30.48 cm (12 in) walkway width. Requires more than 9 s to ambulate 6 m/20 ft

(0) Severe impairment: Cannot walk 6 m/20 ft without assistance, severe gait deviations or imbalance, deviates greater than 38.1 cm (15 in) outside 30.48 cm (12 in) walkway width, or will not attempt task

9. Ambulating backward

Instructions: Walk backward until I tell you to stop

Grading: Mark the highest category that applies

(3) Normal: Walks 6 m/20 ft, no assistive devices, good speed, no evidence of imbalance, normal gait and, deviates no more than 15.24 cm (6 in) outside of the 30.48 cm (12 in) walkway width

(2) Mild impairment: Walks 6 m/20 ft, uses assistive devices, slower speed, mild gait deviations, deviates 15.24–25.4 cm (6–10 in) outside of the 30.48 cm (12 in) walkway width

(1) Moderate impairment: Walks 6 m/20 ft, slow speed, abnormal gait pattern, evidence for imbalance, deviates 25.4–38.1 cm (10–15 in) outside of the 30.48 cm (12 in) walkway width

(0) Severe impairment: Cannot walk 6 m/20 ft without assistance, severe gait deviations or imbalance, deviates greater than 38.1 cm (15 in) outside 30.48 cm (12 in) walkway width, or will not attempt task

10. Steps

Instructions: Walk up these stairs as you would at home, i.e., using the railing if necessary. At the top, turn around and walk down

Grading: Mark the highest category that applies

(3) Normal: Alternating feet, no rail

(2) Mild impairment: Alternating feet, must use rail

(1) Moderate impairment: Two feet to a stair, must use rail

(0) Severe impairment: Cannot do safely

TOTAL SCORE: _____ /30

Data from Wrisley DM, Marchetti GF, Kuharsky DK, et al. Reliability, internal consistency, and validity of data obtained with the functional gait assessment. Phys Ther. 2004;84:906–918.

TABLE 6-7 Some Gait Deviations and Their Causes

Gait Deviations	Reasons
Slower cadence than expected for person's age	Generalized weakness Pain Joint motion restrictions Poor voluntary motor control/weakness of lower limb muscles
Shorter stance phase on involved side and decreased swing phase on uninvolved side Shorter stride length on uninvolved side Decrease lateral sway over involved stance limb Decrease in velocity	Antalgic gait, resulting from painful injury to lower limb and pelvic region
Stance phase longer on one side	Pain Lack of trunk and pelvic rotation Restrictions in lower limb joints Increased muscle tone
Lateral trunk lean (purpose is to bring center of gravity of trunk nearer to hip joint)	Ipsilateral lean (toward the stance leg)—marked hip abductor weakness (compensated gluteus medius/Trendelenburg gait) Contralateral lean—decreased hip flexion in swing limb—mild hip abductor weakness (gluteus medius/Trendelenburg gait) Painful hip Abnormal hip joint (congenital dysplasia, coxa vara, etc.) Wide walking base Unequal leg length Adaptive shortening of quadratus lumborum on swing side Contralateral hip adductor spasticity
Anterior trunk leaning at initial contact (occurs to move line of gravity in front of axis of knee) Anterior trunk leaning during mid and terminal stance, as the hip is moved over the foot	Weak or paralyzed knee extensors or gluteus maximus Hip pain Hip flexion contracture Pes equinus deformity
Posterior trunk leaning during initial contact to loading response (occurs to bring line of external force behind axis of hip)	Weak or paralyzed hip extensors, especially gluteus maximus (gluteus maximus gait) Hip pain Hip flexion contracture Inadequate hip flexion in swing Decreased knee range of motion
Increased lumbar lordosis in terminal stance	Inability to extend hip, usually due to hip flexion contracture or ankylosis
Excessive posterior horizontal pelvic rotation	Adaptively shortened/spasticity of hip flexors on same side Limited hip joint flexion
Hip circumduction during swing (ground contact can be avoided by swinging leg if it is swung outward for natural walking to occur; leg that is in its stance phase needs to be longer than leg that is in its swing phase to allow toe clearance of swing foot)	Functional leg-length discrepancy (shortening of the swing leg secondary to reduced hip flexion, reduced knee flexion, and/or lack of ankle dorsiflexion) Arthrogenic stiff hip or knee
Hip hiking (pelvis is lifted on side of swinging leg, by contraction of spinal muscles and lateral abdominal wall)	Functional leg-length discrepancy (shortening of the swing leg secondary to reduced hip flexion, reduced knee flexion, and/or lack of ankle dorsiflexion) Functionally or anatomically short-stance leg Hamstring weakness Quadratus lumborum shortening
Vaulting (ground clearance of swinging leg will be increased if the patient goes up on toes of stance phase leg)	Functional leg-length discrepancy. Vaulting occurs on shorter limb side

(Continued)

TABLE 6-7 Some Gait Deviations and Their Causes (Continued)

Gait Deviations	Reasons
Abnormal internal hip rotation (produces "toe-in" gait)	Adaptive shortening of iliotibial band Weakness of hip external rotators Femoral anteversion Adaptive shortening of hip internal rotators
Abnormal external hip rotation (produces "toe-out" gait)	Adaptive shortening of hip external rotators Femoral retroversion Weakness of hip internal rotators
Increased hip adduction (scissors gait), which results in excessive hip adduction during swing (scissoring), decreased base of support, and decreased progression of opposite foot	Spasticity or contracture of ipsilateral hip adductors Ipsilateral hip adductor weakness Coxa vara
Inadequate hip extension/excessive hip flexion, which results in loss of hip extension in midstance (forward leaning of trunk, increased lordosis, and increased knee flexion and ankle dorsiflexion) and late stance (anterior pelvic tilt), and increased hip flexion in swing	Hip flexion contracture Iliotibial band contracture Hip flexor spasticity Pain Arthrodesis (surgical or spontaneous ankylosis) Loss of ankle dorsiflexion
Inadequate hip flexion, which results in decreased limb advancement in swing, posterior pelvic tilt, circumduction, and excessive knee flexion to clear foot	Hip flexor weakness Hip joint arthrodesis
Decreased hip swing through (psoatic limp), which is manifested by exaggerated movements at pelvis and trunk to assist hip to move into flexion	Legg–Calvé–Perthes disease Weakness or reflex inhibition of psoas major muscle
Excessive knee extension/inadequate knee flexion, which results in decreased knee flexion at initial contact and loading response, increased knee extension during stance, and decreased knee flexion during swing	Pain Anterior trunk deviation/bending Weakness of quadriceps; hyperextension is a compensation and places body weight vector anterior to knee Spasticity of the quadriceps; noted more during the loading response and during initial swing intervals Joint deformity
Excessive hip and knee flexion during swing	Lack of ankle dorsiflexion of the swing leg Functionally or anatomically short contralateral stance leg
Excessive knee flexion/inadequate knee extension at initial contact or around midstance; results in increased knee flexion in early stance, decreased knee extension in midstance and terminal stance, and decreased knee extension during swing	Knee flexion contracture, resulting in decreased step length and decreased knee extension in stance Increased tone/spasticity of hamstrings or hip flexors Decreased range of motion of ankle dorsiflexion in swing phase Weakness of plantarflexors, resulting in increased dorsiflexion in stance Lengthened limb
Inadequate dorsiflexion control ("foot slap") during initial contact to midstance. Steppage gait during the acceleration through deceleration of the swing phase. The exaggerated knee and hip flexion are used to lift foot higher than usual, for increased ground clearance resulting from foot drop	Weak or paralyzed dorsiflexors Lack of lower limb proprioception Weak or paralyzed dorsiflexor muscles Functional leg-length discrepancy
Increased walking base/step width (>20 cm)	Deformity such as hip abductor muscle contracture Genu valgus Fear of losing balance Leg-length discrepancy
Decreased walking base/step width (<10 cm)	Hip adductor muscle contracture Genu varum

TABLE 6-7 Some Gait Deviations and Their Causes (Continued)

Gait Deviations	Reasons
Excessive eversion of calcaneus during initial contact through midstance	Excessive tibia vara (refers to frontal plane position of the distal one-third of leg, as it relates to supporting surface) Forefoot varus Weakness of tibialis posterior Excessive lower extremity internal rotation (due to muscle imbalances and femoral anteversion)
Excessive pronation during midstance through terminal stance	Insufficient ankle dorsiflexion (<10 degrees) Increased tibial varum Compensated forefoot or rearfoot varus deformity Uncompensated forefoot valgus deformity Pes planus Long limb Uncompensated medial rotation of tibia or femur Weak tibialis anterior
Excessive inversion and plantarflexion of the foot and ankle during swing and at initial contact	Pes equinovarus (spasticity of the plantarflexors and invertors)
Excessive supination during initial contact through midstance	Limited calcaneal eversion Rigid forefoot valgus Pes cavus Uncompensated lateral rotation of tibia or femur Short limb Plantarflexed first ray Upper motor neuron muscle imbalance
Excessive dorsiflexion during initial contact through toe-off	Compensation for knee flexion contracture Inadequate plantarflexor strength Adaptive shortening of dorsiflexors Increased muscle tone of dorsiflexors Pes calcaneus deformity
Excessive plantarflexion during midstance through toe-off	Increased plantarflexor activity Plantarflexor contracture
Excessive varus during initial contact through toe-off	Contracture Overactivity of muscles on medial aspect of foot
Excessive valgus during initial contact through toe-off	Weak invertors Foot hypermobility
Decreased or absence of propulsion (plantarflexor gait) during midstance through toe-off	Inability of plantarflexors to perform function, resulting in a shorter step length on the involved side

swing during gait should also be observed. If an individual has a problem with the foot or ankle on one side, the opposite arm swing is often decreased.

T e patient is observed from head to toe and then back again, from the side, from the front, and then from the back.

In addition to observing the patient walking at his or her normal pace, the clinician should also observe the patient walking at varying speeds. T is can be achieved on a treadmill by adjusting the speed or by asking the patient to change the walking speed.

Once an overall assessment has been made of the patient's gait, the clinician can focus attention on the various segments of the kinetic chain of gait that appear abnormal.

Attempts are made to determine the primary cause of any gait deviations or compensations (see Table 6-7).

Anterior View

When observing the patient from the front, the clinician can note the following:

- Head position—the subject's head should remain fairly stationary during the gait cycle and should not move too much in a lateral or vertical direction. A "bouncing" gait is characteristic of adaptively shortened gastrocnemii or increased tone of the gastrocnemius and soleus.
- T e amount of lateral tilt of the pelvis.
- T e amount of lateral displacement of the trunk and pelvis.
- Whether there is excessive swaying of the trunk or pelvis.
- Reciprocal arm swing—movements of the upper trunk and limbs usually occur in the opposite direction to the pelvis and the lower limbs.
- Whether the shoulders are depressed, retracted, or elevated.
- Whether the elbows are abnormally flexed or extended.
- T e amount of hip adduction or abduction that occurs. Causes of excessive adduction include an excessive angle of the coxa vara, hip abductor weakness, hip adductor contracture or spasticity, and contralateral hip abduction contracture. Excessive hip abduction may be caused by an abduction contracture, a short leg, obesity, impaired balance, or hip flexor weakness.[165]
- T e amount of valgus or varus at the knee—during gait, there may be an obvious varus-extension thrust. According to Noyes et al., this gait pattern is characteristic of chronic injuries to the posterolateral structures of the knee.[166]
- T e amount of knee effusion. Knee joint effusion and knee pain may lead to quadriceps muscle inhibition.[167] In one study, when intraarticular effusion was induced in healthy individuals, gait patterns worsened with increased effusion levels.[168] T e knee effusion caused an increase in knee flexion angle and a decrease in external knee flexion moment, impulse, and joint work. While knee effusion caused a decrease in quadriceps activity during gait, it resulted in an increase in hamstring activity.[168]
- T e width of the BOS, or step width.
- T e degree of "toe-out"—the term toe-out refers to the angle formed by the intersection of the line of progression of the foot and the line extending from the center of the heel through the second metatarsal. T e normal toe-out angle is approximately 7 degrees, and this angle decreases as the speed of gait increases.
- Whether any circumduction of the hip occurs. Hip circumduction can indicate a leg-length discrepancy, a decreased ability of the knee to flex, or a hip abductor shortening or overuse.
- Whether any hip hiking occurs. Hip hiking can indicate a leg-length discrepancy, hamstring weakness, or shortening of the quadratus lumborum.
- Evidence of thigh atrophy.
- T e degree of rotation of the whole lower extremity. Because positioning the lower extremity in external rotation decreases the stress on the subtalar joint complex, an individual with a foot or ankle problem often adopts this position during gait.[111] Excessive internal or external rotation of the femur can indicate adaptive shortening of the medial or lateral hamstrings, respectively, resulting in anteversion or retroversion, respectively.

Lateral View

When observing the patient from the side, the clinician can note the following:

- T e amount of thoracic and shoulder rotation. Each shoulder and arm should swing reciprocally, with equal motion.
- T e orientation of the trunk. T e trunk should remain erect and level during the gait cycle, as it moves in the opposite direction to the pelvis. Compensation can occur in the lumbar spine for a loss of motion at the hip. A backward lean of the trunk may result from weak hip extensors or inadequate hip flexion. A forward lean of the trunk may result from a pathology of the hip, knee, or ankle; abdominal muscle weakness; decreased spinal mobility; or hip flexion contracture. Forward leaning during the loading response and early midstance intervals may indicate hip extensor weakness.[10]
- T e orientation of the pelvic tilt. An anterior pelvic tilt of > 10 degrees is considered normal. Excessive anterior tilting can be caused by weak hip extensors, hip flexion contracture, or hip flexor spasticity. Excessive posterior pelvic tilting during gait usually occurs in the presence of hip flexor weakness.
- T e degree of hip extension. Causes of an inadequate amount of hip extension include hip flexion contracture, iliotibial band contracture, hip flexor spasticity, or pain.[10]
- T e degree of hip flexion. Common causes of inadequate hip flexion include hip flexor weakness or hip joint arthrodesis.[10]
- Knee flexion and extension. T e knee should be extended during the initial contact interval, followed by slight flexion during the loading response interval. During the swing phase, there must be sufficient knee flexion. Stride length and cadence have recently been shown to be related to load rate and risk for injury at the knee.[169] By increasing step rate and proportionately decreasing step length to maintain a constant speed, there is a reduction in impact loading, with the greatest effect occurring at the knee.[170] Causes of excessive knee flexion and inadequate knee extension include inappropriate hamstring activity, knee flexion contracture, soleus weakness, and excessive ankle plantarflexion. Causes of inadequate knee flexion and excessive extension at the knee include quadriceps weakness, pain, quadriceps spasticity, excessive ankle plantarflexion, hip flexor weakness, and knee extension contractures.[10] Individuals with genu recurvatum may have a functional strength deficit in the quadriceps muscle or gastrocnemius that allows knee hyperextension.[171] It is important to assess spatiotemporal measurements in the elderly who have knee injuries because this population

walk slowly, have a longer stride time and spend more time in double support, which puts them at a greater risk of falls.[172]

- Ankle dorsiflexion and plantarflexion. During midstance, the ankle dorsiflexes, and the body pivots on the stationary foot. At the end of the stance phase, the ankle should be seen to plantarflex to raise the heel. At the beginning of the swing phase, the ankle is plantarflexed, moving into dorsiflexion as the swing phase progresses and reaches a neutral position at the time of heel contact at the termination of the swing. Excessive plantarflexion in midswing, initial contact, and loading response may be caused by pretibial, especially the anterior tibialis, weakness. Excessive plantarflexion also may be caused by plantarflexion contracture, soleus and gastrocnemius spasticity, or weak quadriceps.[10] Excessive dorsiflexion may be caused by soleus weakness, ankle fusion, or persistent knee flexion during the midstance phase.[10]
- T e stride length of each limb. Each leg should swing reciprocally, with equal motion.
- Cadence. T e cadence should be normal for the patient's age (Table 6-7).
- Heel rise. An early heel rise could indicate an adaptively shortened Achilles tendon. Delayed heel rise may indicate a weak gastrocnemius–soleus complex.
- Heel contact. A low heel contact during initial contact may be caused by plantarflexion contracture, tibialis anterior weakness, or premature action by the calf muscles.[10]
- Preswing. An exaggerated preswing is manifested by the patient walking on the toes. Causes include pes equines deformity, adaptive shortening or increased tone of the triceps surae, weakness of the dorsiflexors, and knee flexion occurring at midstance. A decreased preswing is often characterized by a lack of plantarflexion at terminal stance and preswing. Causes for this can include ankle or foot pain or weakness of the plantarflexor muscles.

Posterior View

When observing the patient from the back, the clinician can note the following:

- T e amount of subtalar inversion (varus) or eversion (valgus). Excessive inversion or eversion usually relates to abnormal muscular control. Generally speaking, varus tends to be the dominant dysfunction in spastic patients, whereas valgus tends to be more common with flaccid paralysis.[10]
- BOS/step width.
- Pelvic list.
- T e degree of hip rotation—as in standing, excessive femoral internal rotation past the midstance of gait will accentuate genu recurvatum. Causes of excessive external hip rotation may include gluteus maximus overactivity and excessive ankle plantarflexion.[10] Causes of excessive internal hip rotation include medial hamstring overactivity, hip adductor overactivity, anterior abductor overactivity, and quadriceps weakness.[10]
- T e amount of hip adduction or abduction.
- T e amount of knee/tibial rotation.

ABNORMAL GAIT SYNDROMES

Each of the attributes of normal gait described earlier under "Characteristics of Normal Gait" is subject to compromise. In general, gait deviations fall under four headings: those caused by weakness, those caused by abnormal joint position or ROM, those caused by muscle contracture, and those caused by pain.[18,173]

- Weakness implies that there is inadequate internal joint movement, or loss of the natural force–couple relationship.
- Neuromuscular conditions may be associated with abnormalities of muscle tone, timing of muscle contractions, and proprioceptive and sensory disturbances, the latter of which can profoundly affect reflex postural balance.
- T e abnormal joint position can be caused by an imbalance of flexibility and strength around a joint or by contracture.
- Contractures, changes in the length of the connective tissue of muscles, ligaments, and the joint capsule, may produce changes in gait. If the contracture is elastic, the gait changes are apparent in the swing phase only. If the contractures are rigid, the gait changes are apparent during the swing and the stance phases.
- Pain can alter gait, as the patient attempts to use the position of minimal articular pressure (see "Antalgic Gait"). Pain may also produce muscle inhibition and eventual atrophy.

Antalgic Gait

T e antalgic gait is characterized by a decrease in the stance phase on the painful extremity in an attempt to minimize the amount of weight bearing of the injured body part as much as possible. T e antalgic gait pattern can result from numerous causes (Table 6-8), including disease, joint inflammation (Table 6-9), or an injury to the muscles, tendons, and ligaments of the lower extremity. T e knee stiffening strategy, which occurs during the loading response interval, includes reduced sagittal plane knee motion, reduced internal knee extensor moments, and altered muscle activation patterns, all of which serve to avoid positions of maximal intraarticular pressure, and to seek the position of minimum articular pressure.[9]

- Minimum articular pressure occurs at the ankle at 15 degrees of plantarflexion.
- Minimum articular pressure occurs at the knee at 30 degrees of flexion. With a painful knee, the gait is characterized by a decrease in knee flexion at initial contact and the loading response interval, and an increase in knee extension during the remainder of the stance phase.

TABLE 6-8	Some Causes of Antalgic Gait
Cause	**Examples**
Bone disease	Fracture Infection Tumor Avascular necrosis (Legg–Calvé–Perthes disease, Osgood Schlatter disease, and Köhler bone disease)
Muscle disorder	Traumatic rupture and contusion Cramp secondary to fatigue, strain, malposition, or claudication Inflammatory myositis
Joint disease	Traumatic arthritis Infectious arthritis Rheumatoid arthritis Crystalline arthritis (gout and pseudogout) Hemarthrosis Bursitis
Neurologic disease	Lumbar spine disease with nerve root irritation or compression
Other	Hip, knee, or foot trauma Corns, bunions, blisters, or ingrown toenails

Data from Judge RD, Zuidema GD, Fitzgerald FT. Musculoskeletal system. In: Judge RD, Zuidema GD, Fitzgerald FT, eds. Clinical Diagnosis. 4th ed. Boston, MA: Little, Brown and Company; 1982:365–403.

- Minimum articular pressure occurs at the hip at 30 degrees of flexion. One of the most common causes of an antalgic gait at the hip is OA, which is associated with pain, stiffness, and functional limitation, the extent of which depends on the amount of structural disease progression and associated symptoms, as well as sensorimotor adaptations to the disease.[174] Perhaps not surprisingly, individuals with hip OA walk at a slower speed and exhibit greater gait asymmetry than controls.[174]

Perhaps surprisingly, recent studies have shown that the gait pattern is altered in individuals with low back pain.[175] These individuals exhibit a cautious gait exemplified by a reduction in cycle duration as well as hip flexion–extension excursion.[176] When compared to healthy controls, patients with back pain exhibit similar patterns of activation across the gait cycle, but with premature activity in the lumbar spine and hip extensor muscles, and prolonged activity of the gluteus maximus and spine extensors.[175] This raises the question as to what role the CNS plays in this alteration of gait.[177]

Equinus Gait

The equinus gait demonstrates premature firing of the calf muscle in the swing phase of gait with EMG resulting in a toe-walking gait pattern.[178] A toe-walking gait pattern describes dynamic ankle deviations that include[179]:

- a loss of heel strike at initial contact, with disruption of the first ankle rocker;

TABLE 6-9	Gait Abnormalities in Arthritic Disease and Associated Conditions and Treatment Examples				
	Gait Abnormalities				
Disorder	**Observational**	**Time–Distance**	**Angular**	**Kinetic and EMG**	**Treatment**
Osteoarthritis of the hip, unilateral involvement	Lateral lurch gait pattern	1. ↑ Stance time, uninvolved side 2. ↑ Double-limb support 3. ↑ Step time, involved side 4. ↓ Step length, involved side 5. ↓ Velocity	↓ Hip flexion–extension excursion, involved side	↓ Hip abductor moment	Assistive device (cane or crutches)
Rheumatoid arthritis with hindfoot pain and deformity	1. Antalgic gait pattern 2. Flat-foot gait pattern	1. ↓ Velocity 2. ↓ Single-limb support, involved side 3. ↓ Cadence 4. ↓ Stride length 5. Delayed heel rise	1. ↑ Knee flexion during stance 2. ↑ Dorsiflexion during stance 3. ↓ Plantarflexion during terminal stance 4. ↑ Subtalar eversion during terminal stance	↑ Tibialis anterior activation during terminal stance and preswing	Cane Rigid AFO or hindfoot orthoses Rocker bottom shoes
Total knee arthroplasty, unilateral		1. ↓ Single-limb support, involved side 2. ↓ Stride length	↓ Knee flexion during stance	↓ Knee extensor moment	N/A

EMG, electromyography.
Data from Spivak JM, DiCesare PE, Feldman DS, et al., eds. Orthopaedics: A Comprehensive Study Guide. New York, NY: McGraw-Hill; 1999:213.

- disruption of the second rocker, with ankle plantarflexion(instead of dorsiflexion) occurring at midstance;
- variable disruption of the third rocker in terminal stance;
- variable ankle alignment during swing phase.

Equinus gait, one of the more common abnormal patterns of gait in patients with spastic diplegia (see also "Spastic Gait"), is characterized by forefoot strike to initiate the gait cycle, and premature plantarflexion in the loading response interval to midstance.[180] In this patient population, motor impairment occurs as a result of a number of deficits, including poor muscle control, weakness, impaired balance, hypertonicity, and spasticity.[181] However, reduced joint motion as a consequence of spasticity is perhaps the most noticeable and recorded impairment. As a consequence, muscle–tendon units frequently become contracted over time, contributing to malalignment of the extremity during gait.

Toe-walking may be a primary gait deviation, which is the consequence of excessive myostatic contracture of the triceps surae, excessive dynamic contraction of the ankle plantarflexors, or a combination of both factors. In addition, toe-walking may be a compensatory deviation for myostatic deformity or dynamic overactivity of the ipsilateral hamstring muscles, which directly limits knee alignment and secondarily compromises foot and ankle position during the stance phase. For the clinician, the challenge is to distinguish between changes that are the direct consequence of such an underlying neuromuscular disorder and are, therefore, primary, and those changes that result from biomechanical constraints of toe-walking and are, therefore, secondary or compensatory. It is not unusual for normal children to display intermittent tiptoe gait when they first begin to walk; however, a more mature heel-toe gait pattern should become consistent by the age of 2 years.[182] Older children with persistent tiptoe gait are often labeled idiopathic toe walkers. Toe-walking that begins after a mature heel–toe gait pattern has been established may signify muscular dystrophy, diastematomyelia, fibularis muscular atrophy, or spinal cord tumor. Toe-walking has been associated with premature birth, developmental delay, schizophrenia, autism, and various learning disorders.[183]

Associated gait deviations are frequently seen in the knees, hips, and pelvis in children with cerebral palsy who are walking on their toes:[179]

- Deviations seen at the knees include increased flexion in the stance phase at initial contact and in midstance, and delayed and diminished peak knee flexion in the swing phase.
- T e hips often show diminished extension in the sagittal plane at terminal stance.
- A common deviation seen in the pelvis in children with cerebral palsy who are toe-walking is an increased anterior tilt.

Gluteus Maximus Gait

T e gluteus maximus gait, which results from weakness of the gluteus maximus, is characterized by a posterior thrusting of the trunk at initial contact in an attempt to maintain the hip extension of the stance leg. T e hip extensor weakness also results in an anterior tilt of the pelvis, which eventually translates into hyperlordosis of the spine to maintain posture.

Quadriceps Gait

Quadriceps weakness can result from a peripheral nerve lesion (femoral), spinal nerve root lesion (L2–4), trauma, or disease (muscular dystrophy). Although often appearing to have a normal gait pattern when walking on a level surface, the patient with quadriceps weakness/paralysis often demonstrates difficulty walking on rough or inclined surfaces and stairs, and is unable to run. In such instances, forward motion is propagated by circumducting each leg. To compensate, the patient leans the body toward the uninvolved side, to balance the COG, and swings the involved leg like a pendulum.

Hip Flexor Gait

T is type of gait is commonly seen in patients with a hip flexion contracture secondary to decreased mobility or disease processes that result in increased tone. Hip flexion contractures have been associated with decreased gait efficiency and compensations including increased anterior pelvic tilting, increased lumbar lordosis, excessive knee flexion, decreased hip extension, and reduced contralateral step length.[184] While the iliopsoas muscle has been identified as the main contributor to contracture; it rarely occurs without the involvement of other anterior hip structures such as the rectus femoris, TFL, or sartorius.[185] A hip flexion contracture reduces hip extension during gait due to decreased flexibility and greater passive tension of the iliopsoas and other anterior hip structures.[186] T e decrease in dynamic hip extension during terminal stance causes a decrease in single-leg support time on the affected limb, which in turn leads to a shorter step length on the contralateral side and overall decreased gait efficiency.[88] Increased knee flexion during stance is another compensation for reduced hip extension excursion during stance as it allows the foot to remain flat on the floor without the need for an exaggerated lumbar lordosis.[187]

Steppage Gait

T is type of gait occurs in patients with weakness or paralysis of the dorsiflexor muscles resulting from an injury to the muscles, the peripheral nerve supply, or the nerve roots supplying the muscles (Table 6-10).[188] T e result is an inability to control the dorsiflexion that is supposed to occur at initial contact. Instead, the foot "drops" into plantarflexion. To compensate for this, the patient lifts the leg high enough to clear the flail foot off the floor, by flexing excessively at the hip and knee, and then slaps the foot to the floor.

Trendelenburg Gait

T is type of gait results from weakness of the hip abductors (gluteus medius and minimus), with a loss of the normal stabilizing effect of these muscles, such that the patient demonstrates an excessive lateral list, in which the trunk is thrust laterally in an attempt to keep the COG over the stance leg. A positive Trendelenburg sign is also present (Table 6-10).

TABLE 6-10 Gait Abnormalities Associated with Muscle Weakness and Treatment Examples

Disorder	Gait Abnormalities: Observational	Gait Abnormalities: Time–Distance	Gait Abnormalities: Angular	Gait Abnormalities: Kinetic and EMG	Treatment
Dorsiflexor paresis or paralysis	1. Steppage gait pattern 2. Foot slap gait pattern	1. ↓ Time to foot flat 2. ↓ Step length	1. Ankle plantarflexion during swing 2. ↑ Hip and knee flexion during swing	↓ Dorsiflexor moment	AFO
Hip abductor weakness	1. Trendelenburg gait pattern 2. Lateral lurch gait pattern	1. ↑ Double-limb support 2. ↓ Step length 3. ↓ Velocity	1. ↑ Hip adduction during midstance, with Trendelenburg 2. ↑ Lateral trunk tilt with lateral lurch 3. ↓ Pelvic tilt during swing, involved side, with Trendelenburg	Hip abductor ↓ moment during stance with lateral lurch	Assistive device (cane and crutches)
Plantar flexor paresis or paralysis	No pattern discernible	1. Prolonged midstance 2. ↓ Step length, uninvolved side 3. ↓ Single-limb support, involved side	1. ↑ Stance phase knee flexion 2. ↑ Stance phase dorsiflexion	1. ↓ Plantar flexor power during late stance. 2. Prolonged stance phase quadriceps activation	AFO

EMG, electromyography; AFO, ankle–foot orthosis.

Spastic Gait

A spastic gait may result from either unilateral or bilateral upper motor neuron (UMN) lesions. A number of types are recognized.

Spastic Hemiplegic (Hemiparetic) Gait

T is type of gait results from a unilateral UMN lesion. Spastic hemiplegic gait is frequently seen following a completed stroke. Spasticity of all muscles on the involved side is noted, but it is more marked in some muscle groups. During gait, the leg tends to circumduct in a semicircle, rotating outward or is pushed ahead, with the foot dragging and scraping the floor. T e upper limb typically is carried across the trunk for balance (Table 6-11).

Spastic Paraparetic Gait

T is type of gait results from bilateral UMN lesions (e.g., cervical myelopathy in adults and cerebral palsy in children). Spastic paraparetic gait is characterized by slow, stiff, and jerky movements. Spastic extension occurs at the knees, with adduction at the hips (scissors gait).

Ataxic Gait

T e ataxic gait is seen in two principal disorders: cerebellar disease (cerebellar ataxic gait) and posterior column disease (sensory ataxic gait) (Table 6-11).

Cerebellar Ataxic Gait

T e nature of the gait abnormality with a cerebellar lesion is determined by the site of the lesion. In vermal lesions, the gait is broad based, unsteady, and staggering, with an irregular sway. T e patient is unable to walk in tandem, or in a straight line. T e ataxia of gait worsens when the patient attempts to stop suddenly or to turn sharply, resulting in a tendency to fall.

In hemispheral lesions, the ataxia tends to be less severe, but there is persistent lurching or deviation toward the involved side.

Sensory Ataxic Gait

With this type of ataxia, because the patient is unaware of the position of the limbs, the gait is broad based, and the patient tends to lift the feet too high and slap on the floor in an uncoordinated and abrupt manner. T e patient tends to watch the floor and the feet to maximize the opportunities for visual correction, and may have difficulty walking in the dark.

Parkinsonian Gait

T e Parkinsonian gait is characterized by a flexed and stooped posture, with flexion of the neck, elbows, metacarpophalangeal joints, trunk, hips, and knees (Table 6-11). T e patient has difficulty initiating movements and walks using short steps, with the feet barely clearing the ground. T is results in a shuf ing type of gait with rapid steps. As the patient gets going, he or she may lean forward and walk progressively faster, as though chasing the COG (propulsive or festinating gait). Less commonly, deviation of the COG backward may cause retropulsion. T ere is also a lack of associated arm movement during the gait because the arms are held stif y.

Hysterical Gait

T e hysterical gait is nonspecific and bizarre. It does not conform to any specific organic pattern, with the abnormality

TABLE 6-11 Gait Abnormalities Associated with Neurologic Disorders and Treatment Examples

Disorder	Gait Abnormalities: Observational	Gait Abnormalities: Time–Distance	Gait Abnormalities: Angular	Gait Abnormalities: Kinetic and EMG	Treatment
Ataxia	"Ataxic" gait pattern	Variable stride to stride	Variable stride to stride	Variable stride to stride	1. Orthotic stabilization to control movement variability 2. Walking aids (e.g., crutches and walker)
Hemiplegia from stroke	1. "Stiff-legged" gait pattern 2. Equinus or equinovarus gait pattern 3. Circumduction	1. ↑ Double-limb support 2. ↓ Step length, involved side 3. Delayed heel rise 4. ↓ Velocity 5. ↓ Stride length 6. ↓ Cadence 7. Absent heel contact 8. Toe drag during swing	1. ↑ Plantar flexion during swing 2. ↓ Knee flexion during stance and swing	1. ↑ Knee flexor moment during stance 2. ↓ Amplitude of joint powers 3. Abnormal timing of muscle activation (i.e., mass synergy patterns)	1. Ankle–foot orthosis 2. Rectus femoris release 3. Tendo-Achilles lengthening 4. Tendon transfer, foot and ankle 5. Functional electrical stimulation
Parkinson disease	1. "Shuf ing" gait pattern 2. "Frozen" gait pattern	1. ↓ Stride length 2. ↓ Step length 3. ↓ Step width 4. ↓ Cadence 5. ↓ Velocity	↓ Angular excursions throughout	Agonist–antagonist coactivation with "frozen" pattern	Pharmaceutical/ medical management

Data from Spivak JM, DiCesare PE, Feldman DS, et al., eds. Orthopaedics: A Comprehensive Study Guide. New York, NY: McGraw-Hill; 1999:214.

varying from moment to moment and from one examination to another. T ere may be ataxia, spasticity, inability to move, or other types of abnormality. T e abnormality is often minimal or absent when the patient is unaware of being watched or when distracted. However, although all hysterical gaits are bizarre, all bizarre gaits are not hysterical.

Pregnancy

Substantial hormonal and anatomic changes occur during pregnancy, which dramatically alter body mass, body mass distribution, and joint laxity. During pregnancy, musculoskeletal disorders are common and may cause problems ranging from mild discomfort to serious disability. It is widely presumed that pregnant women exhibit marked gait deviations. T e results of a recent study appear to refute that notion.[189] T e study concluded that velocity, stride length, and cadence during the third trimester of pregnancy were similar to those measured 1 year postpartum and that only small deviations in pelvic tilt and hip flexion, extension, and adduction were observed during pregnancy.[189] T e study found significant increases ($p < 0.05$) in hip extensor, hip abductor, and ankle plantarflexor kinetic gait parameters, which suggests an increased use of hip extensor, hip abductor, and ankle plantarflexor muscles to compensate for increases in body mass and changes in body mass distribution during pregnancy. T ese increases keep speed, stride length, cadence, and joint angles relatively unchanged.[189] However, these compensations may result in overuse injuries to the muscle groups about the pelvis, hip, and ankle, including low back, pelvic, and hip pain; calf cramps; and other painful lower extremity musculoskeletal conditions associated with pregnancy.[189] It was unclear from this study whether the women examined had gained normal amounts of weight associated with pregnancy. It would seem obvious that obesity associated with pregnancy may have differing effects on gait.

Obesity

As obesity is reaching epidemic proportions in the United States and is a growing problem in developed countries, the clinician needs to be aware of its effects on the normal gait pattern to help discriminate compensatory patterns as opposed to pathologic manifestations. Obesity is associated with a number of comorbidities, such as coronary artery disease, type 2 diabetes, gall bladder disease, and sleep apnea. Given a normal body mass index (defined as the weight in kilograms divided by the square of the height in meters) ranging from 18.5 to 24.9, 34% of the adult population in the United States is overweight (body mass index of 25–29.9) and another 27% is obese (body mass index of 30 or more).[190]

T e gait used by the obese patient is often described as a waddling gait. Depending on the degree of obesity, the waddling gait is characterized by increased lateral displacement, pelvic obliquity, hip circumduction, increased knee valgus, external foot progression angle, over-pronation, and increases in the normalized dynamic BOS. Nantel et al.[191] compared the biomechanical parameters between obese and nonobese

children during self-paced walking. Kinematics were captured with eight VICON optoelectronic cameras (Oxford Metrics Limited, Oxford, UK) recording at 60 Hz. Findings from the study revealed that obese children modified their hip motor pattern by shifting from an extensor to a flexor moment earlier in the gait cycle. T is led obese children to significantly decrease the mechanical work done by the hip extensors during the loading response interval and significantly increase the mechanical work done by the hip flexors, compared with nonobese children. Finally, there was a significant decrease in the single support duration in the obese group compared with nonobese. Gushue et al.[192] attempted to quantify the three-dimensional knee joint kinematics and kinetics while walking in children with varying body mass and to identify effects associated with obesity. T e study found that the overweight group walked with a significantly lower peak knee flexion angle during early stance, but no significant differences in peak internal knee extension moments were found between groups. However, the overweight group showed a significantly higher peak internal knee abduction moment during early stance. T ese data suggest that although overweight children may develop a gait adaptation to maintain a similar knee extensor load, they may not be able to compensate for alterations in the frontal plane, which may lead to increased medial compartment joint loads.[192] Finally, in a study by de Souza et al.,[193] an outpatient population (age 47.2 ±12.9 years, 94.1% females, BMI 40.1 ± 6.0 kg/m^2, n = 34) had their gait analyzed by an experienced physical therapist. Variables included speed, cadence, stride length, step width, and foot angle, which were compared to reference values. All variables were significantly lower in the obese patients, except for step width, which was increased. Speed was 73.3 ± 16.3 versus 130 cm/s, cadence was 1.4 ± 0.2 versus 1.8 steps/s, stride length was 106.8 ± 13.1 versus 132.0 cm, and step width was 12.5 ± 3.5 versus 10.0 cm ($p < 0.05$). T e authors concluded that these findings were consistent with poor skeletal muscle performance, high metabolic expenditure, and constant physical exhaustion.[193]

CLINICAL PEARL

Obese adults demonstrate a longer stance time, decreased stride length, a step width that is double that of the nonobese, an increased support period (double and single), altered hip abduction angles, and decreased gait velocity (1.09 m/s).[194]

Obesity also impacts other areas of mobility such as sit-to-stand transfers. In obese adults, sit to stand is performed by placing the feet further under the body and utilizing less hip flexion than in the nonobese.[177] While this results in a decreased torque at the hip, it also results in an increased torque demand and joint stress at the knee.[195] Perhaps more alarmingly is the finding that obese children have significant difficulty with the sit-to-stand task.[177] In one study, 69% of obese children required assistance to perform a sit-to-stand transfer.[196]

Although the functional comorbidities of excess body weight such as gait problems are perhaps clinically insignificant compared to those associated with certain metabolic sequelae, they may interfere with the quality of life and also act to increase muscle, bone, and joint stress. For example, the changes in the natural alignment of the weight-bearing segments may result in overuse injuries such as tendonitis and bursitis and eventual osteoarthritis of the hip or knee, or both.

Joint Replacement Surgery

Individuals undergoing knee replacement and hip replacement surgery demonstrate impaired gait patterns[177]:

- Knee replacement. T e gait tends to present with slower preoperative and postoperative cadence than age-matched normals, as well as shorter step length both preoperatively and postoperatively.[197] T ese changes remain stable for 1–2 years after surgery.[197] Individuals with knee replacement surgery also continue to exhibit reduced knee excursion during gait before and after surgery throughout all time periods.[197] Muscle activation also remains altered with a stiff knee gait pattern that involves coactivation during the stance phase predominating up to 2 years postoperatively.[198]
- Hip replacement. Individuals undergoing both the posterolateral and the anterolateral surgical total hip arthroplasty (THA) approaches have demonstrated altered gait parameters at 6–18 months postoperative.[199] Typical findings following a THA include significantly decreased gait speed, cadence, step length, and stride length.[200] Two separate studies[201,202] have suggested that the decreased stride length is due to failure to fully extend the involved hip during the stance phase, thus decreasing gait speed. Whether this loss of hip extension is the result of an increase in passive resistance, or contracture of the anterior hip structures, or hip extensor weakness, is not known.[203,204] T e anterolateral approach tends to lead to greater trunk forward inclination and a Trendelenburg gait pattern.[199] T e ipsilateral trunk side bending associated with the Trendelenburg is considered to be a strategy to decrease demand on the hip abductors to stabilize the pelvis in the frontal plane during single-leg stance by moving the COG closer to the axis of rotation at the hip.[205] Early maximal strength training, combined with conventional rehabilitation, may improve muscle strength and work efficiency in patients following THA more effectively than conventional rehabilitation programs alone.[206,207]

ASSISTIVE DEVICES

T e most common cause of the breakdown of the normal gait cycle is an injury to one or both of the lower extremities. Such an injury usually results in an antalgic gait. If the injury is severe enough, an assistive device is needed. Assistive devices are designed to make ambulation as safe and as painless as possible. However, it must be remembered that there is an energy cost associated with the use of assistive devices. Energy expenditure during walking with assistive devices such as crutches or a walker has generally been examined only in younger people with contrasting results. One study[208] showed that walking with crutches resulted in lower VO_2

compared with walking with a rollator or a standard walker. Compared with unassisted walking, walking with a wheeled walker resulted in more oxygen use. Another study[209] found that subjects 75 years of age or older, consumed an average of 2.8 METS when walking while using a wheeled walker; this corresponds to a moderate level of intensity according to the ACSM scale for the very old.[210–212]

In essence, an assistive device is an extension of the upper extremity, used to provide support, balance, and weight bearing normally provided by an intact functioning lower extremity.[213] Assistive devices function to reduce GRFs, with the size of the BOS that they provide being proportional to the amount of reduction in these forces.

Assistive devices, in order of the stability they provide, include a walker, crutches, walker cane, quad cane, straight cane, and bent cane, with the walker providing the most stability.

T e indications for using an assistive device include[214]

- decreased ability to bear weight on the lower extremities;
- muscle weakness or paralysis of the trunk or lower extremities;
- decreased balance and proprioception in the upright posture.

Correct fitting of an assistive device is important to ensure the safety of the patient and to allow for minimal energy expenditure. For correct fitting, the patient is positioned in bilateral support stance, wearing the footwear that he or she will typically wear for ambulation, with the toes slightly out, the ankle in neutral, the knee in neutral extension, and the hip in neutral extension. T e upper extremity should be positioned so that the elbows and the shoulders are relaxed and level. Once fitted, the patient should be taught the correct walking technique with the device. T e fitting depends on the device chosen:

- Walkers, hemiwalking canes, and quad canes. T e height of the device handle should be adjusted to the level of the greater trochanter of the patient's hip, or at the ulnar styloid of the upper extremity (Figs. 6-6 and 6-7).
- Standard crutches. A number of methods can be used for determining the correct crutch length for axillary crutches:
  - Ask for a patient's height and then adjust according to the height markings on the crutch.
  - Calculate 77% of the patient's height
  - Subtract 16 in from an adult patient's height
  - Take a measurement from the patient's axillary fold to a point 6–8 in lateral to the bottom of the heel (including footwear).
  - Have the patient sit with both arms abducted to 90 degrees. Ask the patient to flex one of the elbows to 90 degrees. T e measurement is then taken from the olecranon process of the patient's flexed elbow to the tip of the long finger of the opposite hand (Fig. 6-8).

When the crutches are fitted correctly, there is a 5–8-cm (2–3-in) gap between the tops of the axillary pads and the patient's axilla (Fig. 6-9) when the crutch tip is vertical to the

FIGURE 6-6 Measuring for a quad cane.

ground and positioned approximately 5 cm (2 in) lateral and 15 cm (6 in) at a 45-degree angle anterior to the patient's foot. T e handgrips of the crutch are adjusted to the height of the greater trochanter of the hip of the patient, or at the ulnar styloid of the upper extremity with the elbow flexed 20–30 degrees.

FIGURE 6-7 Measuring for a walker.

FIGURE 6-8 A method for measuring for crutches.

- Forearm/lofstrand crutches. T e crutch is adjusted so that the handgrip is level with the greater trochanter of the patient's hip and the top of the forearm cuff just distal to the elbow.

FIGURE 6-9 Checking to see there is a 5–8-cm (2–3-in) gap between the tops of the axillary pads and the patient's axilla.

- Canes. Using a cane to aid walking is perhaps as old as the history of humankind. In ancient times, canes were used for support, defense, and the procurement of food.[215] Later, canes became a symbol of power and aristocracy.[216] Currently, canes are used to provide support and protection, to reduce pain in the lower extremities, and to improve balance during ambulation.[217] It is common practice to instruct patients with lower extremity pain to use the cane in the hand contralateral to the symptomatic side.[218] T e use of a cane in the contralateral hand helps preserve reciprocal motion and a more normal pathway for the COG.[219] Use of a cane in this fashion also helps to decrease forces at the hip, as estimated by external kinematics and kinetics.[220–223] Use of a cane can transmit 20–25% of body weight away from the lower extremities.[224,225] T e cane also allows the subject to increase the effective BOS, thereby decreasing the hip abductor force exerted. If measuring for a standard cane, the cane tip should be approximately 3–4 in anterior to the foot at a 45-degree angle.

GAIT TRAINING WITH ASSISTIVE DEVICES

T e clinician must always provide adequate physical support and instruction while working with a patient using an assistive gait device. When providing gait training, it is important that the patient receive verbal and illustrated instructions. Patient instruction should initially be provided in a safe environment and in an environment free from distraction so that the patient can concentrate. Ideally, the clinician should demonstrate how to use the assistive device before asking the patient to do so. T e patient should be encouraged to look ahead rather than down to help with proprioceptive training. T e training should be initiated on level surfaces and then advanced to include negotiation of curbs, stair negotiation, ambulating in busy corridors, and sit-to-stand/stand-to-sit transfers from different surfaces. T ese instructions should also include any weight-bearing precautions pertinent to the patient, the appropriate gait sequence, and a contact number at which to reach the clinician if questions arise. Finally, the patient should be educated on how to create a safe home environment to prevent any falls, and on care and maintenance of the device (replacing rubber tips as needed, and tightening any loose fasteners, etc.).

T e clinician must always provide adequate physical support and instruction while working with a patient using an assistive gait device. Guarding is the process of protecting a patient from excessive weight bearing, incorrect gait pattern, loss of balance, or falling. Proper guarding requires the use of a gait belt fitted around the patient's waist to enable the clinician to assist the patient. T e key is to minimize the distance between the patient's COG and the clinician's COG. Typically, the clinician positions himself or herself on the involved side of the patient, to be able to assist the patient on the side where the patient will most likely have difficulty. When ambulating with a patient, the clinician should be just behind the patient, standing toward the involved side. Whatever side is chosen, if the patient falls forward, backward, or to either side, the aim is to return the

combined COG of the patient and the clinician within the BOS of the clinician, with only a shift of the clinician's weight, and with no large foot movements by the clinician. T us, the BOS of the clinician must be large enough to support such shifts in the COG should the patient start to fall and the closer the clinician is to the patient, the easier this is to maintain. Although falls typically occur in one direction, the clinician must remember that sometimes the patient's lower extremities can give way resulting in a collapsing fall. In such instances, the clinician should move closer to the patient and lift on the gait belt to provide time for the patient to regain support.

T e selection of the proper gait pattern to instruct the patient is dependent on the patient's balance, strength, cardiovascular status, coordination, functional needs, and weight-bearing status:

- NWB. T e patient is not permitted to bear any weight on the injured limb.
- Partial weight bearing (PWB). T e patient is permitted to bear a portion (25%, 50%, etc.) of his or her weight through the injured limb.
- Touch down weight bearing/toe touch weight bearing. T e patient is permitted minimal contact of the injured limb with the ground for balance. T e expression "as though walking on eggshells" can be used to help the patient understand.
- Weight bearing as tolerated. T e patient is permitted to bear as much weight through the injured limb as is comfortable.
- Full weight bearing. Patient no longer medically requires an assistive device.

Several gait patterns are recognized (Table 6-12), the most common of which will be described here.

Two-Point Pattern

T e two-point gait pattern, which closely approximates the normal gait pattern (VIDEO 15), requires the use of an assistive gait device (canes or crutches) on each side of the body. T is

TABLE 6-12 Gait Patterns when Using Assistive Devices

Pattern	Description
Two-point pattern	Closely approximates the normal gait pattern, but requires the use of an assistive gait device (canes or crutches) on each side of the body The patient moves the assistive gait device and the contralateral lower extremity at the same time Requires some coordination and is used when there are no weight-bearing restrictions in the presence of bilateral weakness or to enhance balance
Two-point modified	Is the same as the two-point except that it requires only one assistive device, positioned on the opposite side of the involved lower extremity This pattern cannot be used if there are any weight-bearing restrictions, i.e., PWB, NWB, but is appropriate for a patient with unilateral weakness or mild balance deficits The patient is instructed to move the cane and the involved leg simultaneously, and then the uninvolved leg
Four-point pattern	Requires the use of an assistive gait device (canes or crutches) on each side of the body, is used when the patient requires maximum assistance with balance and stability The pattern is initiated with the forward movement of one of the assistive gait devices, and then the contralateral lower extremity, the other assistive gait device, and finally the opposite lower extremity (e.g., right crutch, then left foot; left crutch, then right foot)
Four-point modified	Is the same as the four-point except that it requires only one assistive device, positioned on the opposite side of the involved lower extremity This pattern cannot be used if there are any weight-bearing restrictions, i.e., PWB, NWB, but are appropriate for a patient with unilateral weakness or mild balance deficits The patient is instructed to move the cane, then the involved leg, and then the uninvolved leg
Three-point	Used for nonweight bearing—when the patient is permitted to bear weight through only one lower extremity Involves the use of two crutches or a walker (cannot be used with a cane or one crutch) Requires good upper body strength, good balance, and good cardiovascular endurance The pattern is initiated with the forward movement of the assistive gait device(s). Next, the involved lower extremity is advanced, while staying NWB as the patient then presses down on the assistive gait device and advances the uninvolved lower extremity
Three-point modified or 3 point 1	A modification of the three-point gait pattern that requires two crutches or a walker This pattern is used when the patient can bear full weight with one lower extremity but is only allowed to partially bear weight on the involved lower extremity. In partial weight bearing, only part of the patient's weight is allowed to be transferred through the involved lower extremity The pattern is initiated with the forward movement of one of the assistive gait devices, and then the involved lower extremity is advanced forward, allowing only PWB. The patient presses down on the assistive gait device and advances the uninvolved lower extremity, using either a "swing-to" or a "swing-through" pattern

pattern requires the patient to move the assistive gait device and the contralateral lower extremity at the same time. T is pattern requires coordination and balance. T e uninvolved lower extremity can be advanced to a point at which it is parallel to the involved lower extremity (VIDEO 1) or it can be advanced ahead of the uninvolved lower extremity.

Two-Point Modified

T e two-point modified pattern is the same as the two-point except that it requires only one assistive device, positioned on the opposite side of the involved lower extremity (VIDEO 2). T is pattern cannot be used if there are any weight-bearing restrictions, that is, PWB or NWB but are appropriate for a patient with unilateral weakness or mild balance deficits. T e patient is instructed to move the cane and the involved leg simultaneously, and then the uninvolved leg.

Three-Point Gait Pattern

T is pattern is used for nonweight bearing—when the patient is permitted to bear weight on only one lower extremity. T e three-point gait pattern, which demands a high degree of energy from the patient, involves the use of two crutches or a walker. It cannot be used with a cane or one crutch. T e three-point gait pattern requires good upper body strength, good balance, and good cardiovascular endurance. T e pattern is initiated by the forward movement of the assistive gait device. Next, the involved lower extremity is advanced as the patient then presses down on the assistive gait device and advances the uninvolved lower extremity. Two methods of advancing the lower extremity can be used:

- Swing to: the uninvolved lower extremity is advanced to a point at which it is parallel to the involved lower extremity (VIDEO 3).
- Swing through: the involved lower extremity is advanced ahead of the uninvolved lower extremity (VIDEO 4).

Sit-to-Stand Transfers

Before the patient can begin ambulation, he or she must first learn to safely transfer from a sitting position to a standing position. T e wheels of the bed or wheelchair are locked, and the patient is reminded of any weight-bearing restrictions. T e patient is asked to slide to the front edge of the chair or bed, and the weight-bearing foot is placed underneath the body so that the COG is closer to the BOS, which will make it easier for the patient to stand.

T e patient is then instructed to lean forward and push up with the hands from the bed or armrests.

- If the patient is being instructed on the use of a walker, he or she should grasp the handgrips of the walker only after becoming upright and should not be permitted to try to pull up to a standing position using the walker, because this can cause the walker to tip over and increase the potential for falls.
- If the patient is using crutches, he or she is instructed to hold both crutches with the hand on the same side as the involved lower extremity. T e patient then presses down on the handgrips of the crutches, the armrest, or bed and with the uninvolved lower extremity, to stand. Once standing, and with adequate balance, the patient moves the crutches into position and begins to ambulate.
- If the patient is using one or two canes, he or she is instructed to push up with the hands from the bed or armrests. Once standing, the patient should grasp the handgrip(s) of the cane(s) with the appropriate hand and begin to ambulate.

Stand-to-Sit Transfers

T e stand-to-sit transfer is essentially the reverse of the sit-to-stand transfer. In order to sit down using an assistive device, the patient must first back up against the front edge of the bed or chair. If the patient has difficulty bending the knee of the involved lower extremity, he or she is instructed to slowly advance this extremity forward. Once in position:

- the patient using a walker reaches for the bed or armrest with both hands and slowly sits down;
- the patient using crutches moves both crutches to the hand on the side of the involved lower extremity. With that hand holding onto both handgrips of the crutches, the patient reaches back for the bed or armrest with the other hand before slowly sitting down;
- T e patient using one or two canes places the handgrip of the cane(s) against the edge of the chair or bed. Next, the patient reaches back for the bed or armrest and slowly sits down.

Stair Negotiation

Ascending Stairs

To ascend steps, the patient must first move to the front edge of the step. T e walker will have to be turned toward the opposite side of the handrail or wall. Ascending more than two to three stairs with a walker is not recommended.

- To ascend stairs using a walker, the patient is instructed to grasp the stair handrail with one hand and to turn the walker sideways so that the two front legs of the walker are placed on the first step. When ready, the patient pushes down on the walker handgrip and the handrail and advances the uninvolved lower extremity onto the first step. T e patient then advances the involved lower extremity to the first step and moves the legs of the walker to the next step. T is process is repeated as the patient moves up the steps.
- To ascend steps or stairs with crutches, the patient should grasp the stair handrail with one hand and grasp both crutches by the handgrips with the other hand. If the patient is unable to grasp both crutches with one hand, or if the handrail is not stable, then the patient should use both crutches only, although this is not recommended if there are more than two to three steps. When in the correct position at the front edge of the step, the patient pushes down on the crutches and handrail, if applicable, and advances the uninvolved lower extremity to the

first step. The patient then advances the involved lower extremity and finally the crutches. This process is repeated for the remaining steps.

- To ascend steps or stairs with one or two canes, the patient should use the handrail and the cane(s). If the handrail is not stable, then the patient should use the cane(s) only. The patient pushes down on the cane(s) or handrail, if applicable, and advances the uninvolved lower extremity to the first step. The patient then advances the involved lower extremity. This process is repeated for the remaining steps.

Descending Stairs

In order to descend steps, the patient must first move to the front edge of the top step. Descending more than two to three stairs with a walker is not recommended.

- To descend stairs using a walker, the walker is turned sideways so that the two front legs of the walker are placed on the lower step. One hand is placed on the rear handgrip, and the other hand grasps the stair handrail. When ready, the patient lowers the involved lower extremity down to the first step. Then the patient pushes down on the walker and handrail and advances the uninvolved lower extremity down the first step. This process is repeated as the patient moves down the steps.
- To descend steps or stairs with crutches, the patient should use one hand to grasp the stair handrail and the other to grasp both crutches and handrail. If the patient is unable to grasp both crutches with one hand, or if the handrail is not stable, then the patient should use both crutches only, although this is not recommended if there are more than two to three steps. When ready, the patient lowers the involved lower extremity down to the first step. Next, the patient pushes down on the crutches and handrail, if applicable, and advances the uninvolved lower extremity down to the first step. This process is repeated for the remaining steps.
- To descend steps or stairs with one or two canes, the patient should use the cane(s) and handrail. If the handrail is not stable, then the patient should use the cane(s) only. When ready, the patient lowers the involved lower extremity down to the first step. Next, the patient pushes down on the cane(s) and handrail, if applicable, and advances the uninvolved lower extremity down to the first step. This process is repeated for the remaining steps.

GAIT ASSESSMENT SCALES

A number of gait assessment scales have been designed for a variety of settings and patient populations.

- Modified Gait Efficacy Scale (mGES).[226] This is is a 10-item measure that addresses the perception of older adults of their level of confidence in walking during challenging circumstances. The items include walking on a level surface and on grass, stepping over an obstacle, stepping up and down a curb, ascending and descending stairs (with and without the handrail), and walking over a long distance (Fig. 6-10). The mGES has been reported to be a reliable and valid measure of confidence in walking among community dwelling older adults.[226]
- The 40-m Self-Paced Walk Test. Participants are asked to walk as quickly but as safely as possible to a mark 10 m away, return, and repeat for a total distance of 40 m. Subjects are timed for this test, and data are expressed as speed.[227]
- The Timed Up and Go (TUG) Test. Participants are asked to rise from a standard armchair, walk as quickly but as safely as possible to a mark 3 m away, turn around, and return to the seated chair position. Subjects are timed for this test.[228]
- The Figure-of-Eight Walk Test. This test is designed to determine participants' curved path walking ability, which is necessary for daily living in the home and community.[229] The participants walk in a figure-of-eight pattern at their usual pace around two cones that are 1.5 m (5 ft) apart, and the time to complete the figure-of-eight is recorded. This test has demonstrated test-retest reliability (ICC = 0.84) and interrater reliability (ICC = 0.90).[230]
- Six-Minute Walk Test (6MWT). This test measures are walking endurance and exercise capacity by having participants walk as far as possible in 6 minutes. The 6MWT has demonstrated test-retest reliability (Pearson r = 0.95) in community dwelling older adults.[231]
- Gait Speed. This test determines participants' gait speed by walking on a 4-m computerized walkway (Gait Matt II, E.Q. Inc., Chalfont, Pennsylvania) with additional 2-m panels at each end to allow for acceleration and deceleration. The participants' "usual walk" gait speed is averaged over four passes and has demonstrated test-retest reliability (ICC = 0.98).[232]
- Simple and Complex Walking While Talking (WWT) Tests. These tests are designed to provide a cognitive challenge while walking to predict falls by imposing the need to divide attention. During the simple WWT, participants are asked to say the letters of the alphabet out loud while walking down a 6.2-m (20-ft) corridor. The complex WWT is identical except for the fact that individuals are asked to say every other letter of the alphabet out loud while walking down the 6.2-m corridor. The simple WWT test has demonstrated a specificity of 89.4% and sensitivity of 46.1% with a time of 20 seconds or longer (on a 12.2-m [40-ft] corridor) as a predictor of falls in community-dwelling older adults.[233] The complex WWT predicts falls in older adults with a time of 33 seconds or longer (on a 12.2-m corridor) with a specificity of 95.6% and sensitivity of 38.5% in community dwelling older adults.[234]
- Narrow Walk Test. This test requires the participant to walk 4 m at his or her usual pace within a 15-cm corridor marked on the floor using two lines, and the time to complete the walk and the number of deviations from the 15-cm wide path are recorded. Participants who cannot complete the test independently or who step outside of the walkway more than 10 times are classified as unable.
- Obstacle Walk Test. This test determines whether an individual can modify his or her gait kinematics while walking. A small (6-cm-high) obstacle is placed at 2 m,

1. How much confidence do you have that you would be able to safely walk on a level surface such as a hardwood floor?

No Confidence — Complete Confidence

Data from Newell AM, VanSwearingen JM, Hile E, Brach JS. The modified gait efficacy scale: Establishing the psychometric properties in older adults. *Phys Ther*. 2012;92:318–328.

FIGURE 6-10 The modified gait efficacy scale.

and a large (30-cm-high) obstacle is placed at 4 m within a 7-m distance. The participant is asked to step over both obstacles and the time to complete the walk is recorded.

Participants complete two trials of each walk (narrow and obstacle), and the mean time is calculated for each condition. In community dwelling older adults, the narrow and obstacle walk tests have demonstrated test-retest reliability (ICC = 0.76 and 0.89, respectively).[233]

- Dynamic Gait Index (DGI). This test measures the capacity of the participant to adapt gait to complex tasks

commonly encountered in daily life using a combined score of gait pattern and level of assistance. Item 1 of the DGI examines the ability to walk under low-challenge conditions (self-paced, level surface, gait), while the remaining seven items examine the participants ability to adapt gait in four environmental dimensions: temporal (changing speed, postural transition) changing direction using a pivot turn, changing head orientation including horizontal and vertical head turns, terrain (climbing stairs), and density dimension (stepping over and around obstacles for collision avoidance).[235]

POSTURE

As with the so-called good movement, good posture is a subjective term reflecting what the clinician believes to be correct based on ideal models. Various attempts have been made to define and interpret posture.[89,236–240] Good posture may be defined as "the optimal alignment of the patient's body that allows the neuromuscular system to perform actions requiring the least amount of energy to achieve the desired effect."[238] Postural or skeletal alignment has important consequences as each joint has a direct effect on both its neighboring joint and on the joints further away. A syndrome is a characteristic pattern of symptoms or dysfunctions. Abnormal or nonneutral alignment is defined as "positioning that deviates from the midrange position of function."[241] To be classified as abnormal or dysfunctional, the alignment must produce physical functional limitations or impairments. T ese confines can occur anywhere along the kinetic chain, at adjacent or distal joints through compensatory motions or postures.

From the mechanical point of view, the spinal system is highly complex and statically highly indeterminate. T e requirement for muscular control of the spine varies within the ROM. T e neutral zone is a term used by Panjabi[242] to define a region of laxity around the neutral resting position of a spinal segment. T e neutral zone (see Chapter 22) is the position of the segment in which minimal loading is occurring in the passive structures (all of the noncontractile elements of the spine including the ligaments, fascia, joint capsules, intervertebral disks [IVDs], and noncontractile components of muscle), and the contribution of the active system (the muscles and tendons that surround and control spinal motion) is most critical—within its neutral zone of motion, the restraints and control for bending, rotation, and shear force are largely provided by the muscles that surround and act on the spinal segment.[243,244] T e size of the neutral zone is determined by the integrity of the passive restraint and active control systems, which in turn are controlled by the neural system.[242] Studies have demonstrated that a larger than normal neutral zone caused by injury or disease is related to a lack of segmental muscle control and is associated with intersegmental injury and IVD degeneration.[242,245–248] Unfortunately, there is as yet no clinical method to measure the size of the neutral zone.

T e research of Gardner-Morse et al.[249] and O'Sullivan et al.[250] lends support to the hypothesis of a neutral zone. T ey proposed that the passive system alone is incapable of providing sufficient spinal stabilization during most activities and would buckle under its own weight without sufficient muscular tension.[251,252] In addition, activities such as acute repetitive loading have been shown to have a significant effect on reducing the stiffness of the passive system, because of the viscoelastic nature of the structures of the passive system (e.g., ligaments and IVDs).[253,254] T us, in addition to structural integrity, stabilization of the spine must also rely on muscular support.

T e overall contour of the normal vertebral column in the frontal plane is straight. In contrast, the contour of the sagittal plane changes with development. At birth, a series of primary curves give a kyphotic posture to the whole spine. With the development of the erect posture, secondary curves develop. For example, the cervical spine forms a lordotic curve that develops secondary to the response of an upright posture, which initially occurs when the child begins to lift the head at 3–4 months. T e presence of the curve allows the head and eyes to remain oriented forward and provides a shock-absorbing mechanism to counteract the axial compressive force produced by the weight of the head. T us, the curves in the spinal column provide it with increased flexibility and shock-absorbing capabilities.[255] A continual force that impacts posture is gravity. T e muscles and inert structures of the body function to counteract the forces of gravity during both static and dynamic activities. T us, postural alignment is both static and dynamic.

T e postural control system, the mechanism by which the body maintains balance and equilibrium, has been divided into several subsystems, namely, the vestibular, visual, and somatosensory subsystems (see Chapter 3).[256,257] In a multisegmented organism such as the human body, many postures are adopted throughout the course of a day. Nonneutral alignment, whether maintained statically or performed repetitively, appears to be a key precipitating factor in soft tissue and neurologic pain.[258] T is may be the result of an alteration in joint load distribution or in the force transmission of the muscles. T is alteration can result in a muscle imbalance.

T e ability to maintain correct posture appears to be related to a number of factors:[259]

- Energy cost.[259] T e increase in metabolic rate over the basal rate when standing is so small, compared with a metabolic cost of moving, as to be negligible. T e type of posture that involves a minimum of metabolic increase over the basal rate is one in which the knees are hyperextended, the hips are pushed forward to the limit of extension, the thoracic curve is increased, the head is projected forward, and the upper trunk is inclined backward in a posterior lean.
- Strength and f exibility. Pathological changes to the neuromuscular system (e.g., excessive wearing of the articular surfaces of joints, the development of osteophytes and traction spurs, and maladaptive changes in the length-tension development and angle of pull of muscles and tendons) may be the result of the cumulative effect of repeated small stresses (microtrauma) over a long phase of time or of constant abnormal stresses (macrotrauma) over a short phase of time (see Chapter 2). Strong, flexible muscles are able to resist the detrimental effects of faulty postures for longer phases and provide the ability to unload the structures through a change of position. However, control of these changes in position

are not possible if the joints are stiff (hypomobile) or too mobile (hypermobile), or the muscles are weak, shortened, or lengthened.

- Age. As the human body develops from infancy to old age, several physical and neurological factors may affect posture. As discussed, at birth, a series of primary curves cause the entire vertebral column to be concave forward, or flexed, giving a kyphotic posture to the whole spine, although the overall contour in the frontal plane is straight. In contrast, the contour of the sagittal plane changes with development. At the other end of the lifespan, the aging adult tends to alter posture in several ways. A common function of aging, at least in women, is the development of a stooped posture associated with osteoporosis.
- Psychological aspects.[259] Not all posture problems can be explained in terms of physical causes. Atypical postures may be symptoms of personality problems or emotional disturbances.
- Evolutionary and heredity influences.[259] The transformation of the human race from arboreal quadrupeds to upright bipeds is likely related to the need of the male hominid to have the hands and arms available for carrying a wider variety of foods for fairly long distances.[260] This transformation was responsible not only for the changes in the weight-bearing parts of the musculoskeletal structure but also for changes in the upper extremities, which are now free for the development of a greater variety of manipulative skills. In attempting to correct an individual's posture, one must be realistic and accept the limits imposed by possible hereditary factors.
- Structural deformities. The normal frontal and sagittal alignment of the spine can be altered by many conditions, including leg-length inequality (see Chapter 29), congenital anomalies, developmental problems, trauma, or disease (Table 6-13).[261–263]
- Disease. The normal coronal alignment of the spine can be altered by many conditions, including joint degeneration and scoliosis. Scoliosis, which is a descriptive term for lateral curvature, is usually accompanied by a rotational abnormality. Scoliosis can be idiopathic, a result of congenital deformity, pain, or degeneration, or be associated with numerous neuromuscular conditions, such as leg-length inequality (see Chapter 29). Sagittal plane alignment can also be altered by disease and injury. This alteration is manifested clinically with areas of excessive kyphosis or lordosis, or a loss of the normal curves. Respiratory conditions (e.g., emphysema), general weakness, excess weight, loss of proprioception, or muscle spasm (as seen in cerebral palsy or with trauma) may also lead to poor posture.[264]
- Pregnancy. Although never substantiated, postural changes have often been implicated as a major cause of back pain in pregnant women.[265,266] The relationship between posture and the back pain experienced during pregnancy is unclear. This is may be because significant skeletal alignment changes that are related to back pain that are occurring at the pelvis during pregnancy but may not be directly measured by postural assessments, such as lumbar lordosis, sacral base angle, and pelvic tilt. Moore et al.[267] found a significant relationship ($r = 0.49$) between change in lordosis during 16–24 and 34–42 weeks of pregnancy and an increase in low back pain. Ostgaard et al.[268] found that abdominal sagittal diameter ($r = 0.15$), transverse diameter ($r = 0.13$), and depth of the lordosis ($r = 0.11$) were related to the development of back pain during pregnancy. Bullock et al.,[266] in the only study that used a validated and reliable posture assessment instrument, found no relationship between spinal posture (thoracic kyphosis, lumbar lordosis, and pelvic tilt) magnitude or changes during pregnancy, and back pain. The results from a study by Franklin and Conner-Kerr[269] suggest that from the first to the third trimester of pregnancy, lumbar lordosis, posterior head position, lumbar angle, and pelvic tilt increase; however, the magnitudes and the changes of these posture variables are not related to back pain.
- Habit. The most common postural problem is a poor postural habit and its associated adaptive changes. Poor posture, and, in particular, poor sitting posture, is considered to be a major contributing factor in the development and perpetuation of shoulder, neck, and back pain. Muscles maintained in a shortened or lengthened position eventually will adapt to their new positions. Although these muscles initially are incapable of producing a maximal contraction in the newly acquired positions,[270] changes at the sarcomere level eventually allow the muscle to produce maximal tension at the new length.[271] Although this may appear to be a satisfactory adaptation, the changes in length produce changes in tension development, as well as changes in the angle of pull.[272] It is theorized that, if a muscle lengthens as part of a compensation, muscle spindle activity increases within that muscle, producing reciprocal inhibition of that muscle's functional antagonist and resulting in an alteration in the normal force–couple and arthrokinematic relationship, thereby effecting the efficient and ideal operation of the movement system.[271,273–276] For example, a passively insufficient muscle is activated earlier in a movement than normal muscle and has a tendency to be more hypertonic, thereby producing a reflex inhibition of the antagonists.[273,274,277,278] It is difficult to determine why a particular posture becomes dysfunctional in one individual, yet not in another. Differing adaptive potentials of the tissues between individuals may be among the causes in addition to neurologic, neurodevelopmental, and neurophysiologic factors.

CLINICAL PEARL

The pain from any sustained position is thought to result from ischemia of the isometrically contracting muscles, localized fatigue, or excessive mechanical strain on the structures. Intramuscular pressure can compress the blood vessels and prevent the removal of metabolites and the supply of oxygen, either of which can cause temporary pain.[279,280]

TABLE 6-13 Common Structural Deformities

Deformity	Description	Manifestation
Lordosis	An excessive anterior curvature of the spine. Pathologically, it is an exaggeration of the normal curves found in the cervical and lumbar spines The pelvic angle, normally approximately 30 degrees, is increased with lordosis There are two types of exaggerated lordosis: pathological lordosis and swayback deformity Pathological lordosis: Involves scapulae protraction, internally rotated arms, internally rotated legs, and forward head, accompanied by weakness of the deep lumbar extensors and tightness of the hip flexors and tensor fasciae latae, combined with weak abdominals Swayback deformity: Increased pelvic inclination to approximately 40 degrees and kyphosis of the thoracolumbar spine. A swayback deformity results in the spine bending back rather sharply at the lumbosacral angle. With this postural deformity, the entire pelvis shifts anteriorly, causing the hips to move into extension. To maintain the center of gravity in its normal position, the thoracic spine flexes on the lumbar spine. The result is an increase in the lumbar and thoracic curves. Such a deformity may be associated with tightness of the hip extensors, lower lumbar extensors, and upper abdominals, along with weakness of the hip flexors, lower abdominals, and lower thoracic extensors	Causes of increased lordosis include: 1. Postural deformity 2. Lax muscles, especially the abdominal muscles, in combination with tight muscles, especially hip flexors or lumbar extensors 3. A heavy abdomen, resulting from excess weight or pregnancy 4. Hip flexion contractures 5. Spondylolisthesis 6. Congenital problems, such as bilateral congenital dislocation of the hip 7. Failure of segmentation of the neural arch 8. Fashion (e.g., wearing high-heeled shoes)
Kyphosis	Excessive posterior curvature of the spine Pathologically, it is an exaggeration of the normal curve found in the thoracic spine There are four types of kyphosis: 1. Round back—a long, rounded curve with decreased pelvic inclination (<30 degrees) and thoracolumbar kyphosis. The patient often presents with the trunk flexed forward and a decreased lumbar curve. On examination, there are tight hip extensors and trunk flexors, with weak hip flexors and lumbar extensors 2. Humpback or gibbus—a localized, sharp posterior angulation in the thoracic spine 3. Flat back—decreased pelvic inclination to 20 degrees and a mobile lumbar spine 4. Dowager hump—often seen in older patients, especially women. The deformity commonly is caused by osteoporosis, in which the thoracic vertebral bodies begin to degenerate and wedge in an anterior direction, resulting in a kyphosis	There are several causes of kyphosis, including tuberculosis, vertebral compression fractures, Scheuermann disease, ankylosing spondylitis, senile osteoporosis, tumors, compensation in conjunction with lordosis, and congenital anomalies The congenital anomalies include a partial segmental defect, as seen in osseous metaplasia, or centrum hypoplasia and aplasia In addition, paralysis may lead to a kyphosis because of the loss of muscle action needed to maintain the correct posture, combined with the forces of gravity

Data from Magee DJ. Assessment of posture. In: Magee DJ, ed. Orthopaedic Physical Assessment. Philadelphia, PA: WB Saunders; 2002:873–903; Kendall FP, McCreary EK, Provance PG. Muscles: Testing and Function. Baltimore, MD: Williams & Wilkins; 1993.

Postural development begins at a very early age. As the infant starts to activate the postural system, skeletal muscles develop according to their predetermined specific uses in various recurrent functions and movement strategies.[281] Jull and Janda[278,282] developed a system that characterized muscles based on common patterns of kinetic chain dysfunction, into two functional divisions (see Table 1-4):

- Postural muscles. These relatively strong muscles are designed to counter gravitational forces and provide a stable base for other muscles to work from, although they are likely to be poorly recruited, lax in appearance and show an inability to perform inner range contractions over time.
- Phasic muscles. These muscles tend to function in a dynamically antagonistic manner to the postural muscles. Phasic muscles tend to become relatively weak compared to the postural muscles, are more prone to atrophy and adaptive shortening, and show preferential recruitment for synergistic activities. In addition, these muscles will tend to dominate movements and may alter posture by restricting movement.

The work of Jull and Janda[278] also introduced the concept of postural patterns and described a lower quadrant syndrome called the pelvic crossed syndrome. In this syndrome, the erector spinae and iliopsoas are adaptively shortened (tight), and

the abdominals and gluteus maximus are weak. T is syndrome promotes an anterior pelvic tilt, an increased lumbar lordosis, and a slight flexion of the hip. T e hamstrings frequently are adaptively shortened in this syndrome, and this may be a compensatory strategy to lessen the anterior tilt of the pelvis,[275] or because the glutei are weak. In addition to increasing the lumbar lordosis, an increased thoracic kyphosis and a compensatory increase in cervical lordosis to keep the head and eyes level occurs. Janda also described an upper quadrant syndrome called the upper crossed syndrome.[282] T is syndrome involves adaptive shortening of the levator scapulae, upper trapezius, pectoralis major and minor, and sternocleidomastoid (SCM), and weakness of the deep neck flexors and lower scapular stabilizers. T e syndrome produces elevation and protraction of the shoulder and rotation and abduction of the scapula, together with scapular winging. It also theoretically produces a forward head and hypermobility of the C4–C5 and T4 segments.

More recently, Sahrmann[271] has stressed the importance of the relationship of neighboring joints along both directions of the kinetic chain to determine the mechanical cause of the symptoms.

CLINICAL PEARL

Postural imbalances involve the entire body, as should any corrections. It is important to remember that an appropriate examination must take place prior to any intervention.

Many studies have evaluated the effect of injury on the neuromuscular system.[283–289] If muscle control is poor, joint strain and pain may result.[242,290] Trauma to tissues that contain mechanoreceptors may result in partial deafferentation, which can lead to proprioceptive deficits and alter joint function.[291,292] For example, in addition to the mechanical restraint provided by ligaments, it has been observed that ligaments provide neurologic feedback that directly mediates reflex muscle contractions about a joint.[291,293]

As the neuromuscular system begins to decline in function, certain predictable and stereotypical changes tend to occur.[294] T ese include increased lumbar lordosis and thoracic kyphosis, decreased hip extension, decreased medial–lateral stability and increased hip flexed posture due to muscle imbalance and decreased anterior–posterior stability, decreased stride length, greater weight placed on the forefoot, increased double-foot stance time, decreased proprioception, and harder heel strike.[281] As the decline progresses, the locomotor system becomes less able to adapt to its environment, requiring greater attention to recruit more sensory information in order to maintain postural control. Many of the changes that occur in the developing neuromuscular system interestingly recur in some sort of reverse order during the degrading process.[281] T ese changes include a transition from an ankle strategy during gait back to a hip strategy, a broadened stance to combat increased medial–lateral instability, a shortened stride length to better maintain COG, decreased integration of upper body counter rotation, increased visual sensory input, and recruitment of additional afferentation for postural equilibrium, such as the use of a cane, the aid of a more posturally stable person, or both.[281]

Examination

T e assessment of posture primarily involves information gleaned from the history in addition to visual and palpatory observations. A clear understanding of functional anatomy and topographical landmarks is vital.[281] As with gait analysis, various attempts have been made to objectively measure posture, including radiography, goniometry, inclinometry, flexible ruler measurement, photography, the Iowa anatomical position system, and plumb line assessment. Because there is an almost endless variety of activity postures and because these are extremely difficult to assess, a convenient custom has been to accept the standing posture as the individual's basic posture from which all other postures stem.[259] Under this concept, ideal postural alignment for standing (viewed from the side) was defined as a straight line (line of gravity) that passes through the ear lobe, the bodies of the cervical vertebrae, the tip of the shoulder, midway through the thorax, through the bodies of the lumbar vertebrae, slightly posterior to the hip joint, slightly anterior to the axis of the knee joint, and just anterior to the lateral malleolus (Fig. 6-11).

CLINICAL PEARL

A simple and commonly applied parameter of global balance is the plumb line offset taken from a full-length standing radiograph. The center of C2 (or C7) is drawn vertically downward, and the distance from the center of the sacrum is noted on the frontal projection, while the offset from the anterior–superior edge or posterior–superior edge of S1 is noted on the lateral projection.

Although this measurement is simple, it may not accurately reflect the balance of the spine—the plumb line measurement is a radiographic value and not a representation of the applied forces.

T eoretically, this postural alignment results in minimum stress being applied to each joint, with minimal muscle activity being required to maintain the position.

To assess posture accurately, the patient must be adequately undressed. Standard protocols for patient attire vary with respect to, among other factors, regional, societal, religious, legal, healthcare specialty, gender, and age-related issues.[281] Ideally, male patients should be in shorts, and female patients should be in a bra and shorts, and the patient should not wear shoes or stockings. However, if the patient uses walking aids, braces, collars, or orthoses, they should be noted and may be used after the patient has been assessed in the "natural" state to determine the effect of the appliances.[264] In addition, the floor on which the patient stands and is assessed, should be a level, hard surface. A slight degree of padded carpeting is acceptable, although a hard floor is preferable.[281]

T e patient should assume a comfortable and relaxed posture, looking straight ahead, with feet approximately 4–6 in apart. Often, it takes some time for the patient to adopt the usual posture because of tenseness, uneasiness, or uncertainty.[264] For the static examination, the clinician must be oriented to the patient so that the dominant eye (Table 6-14) is located in the midline between the landmarks being compared. T e static assessment of posture is initially performed

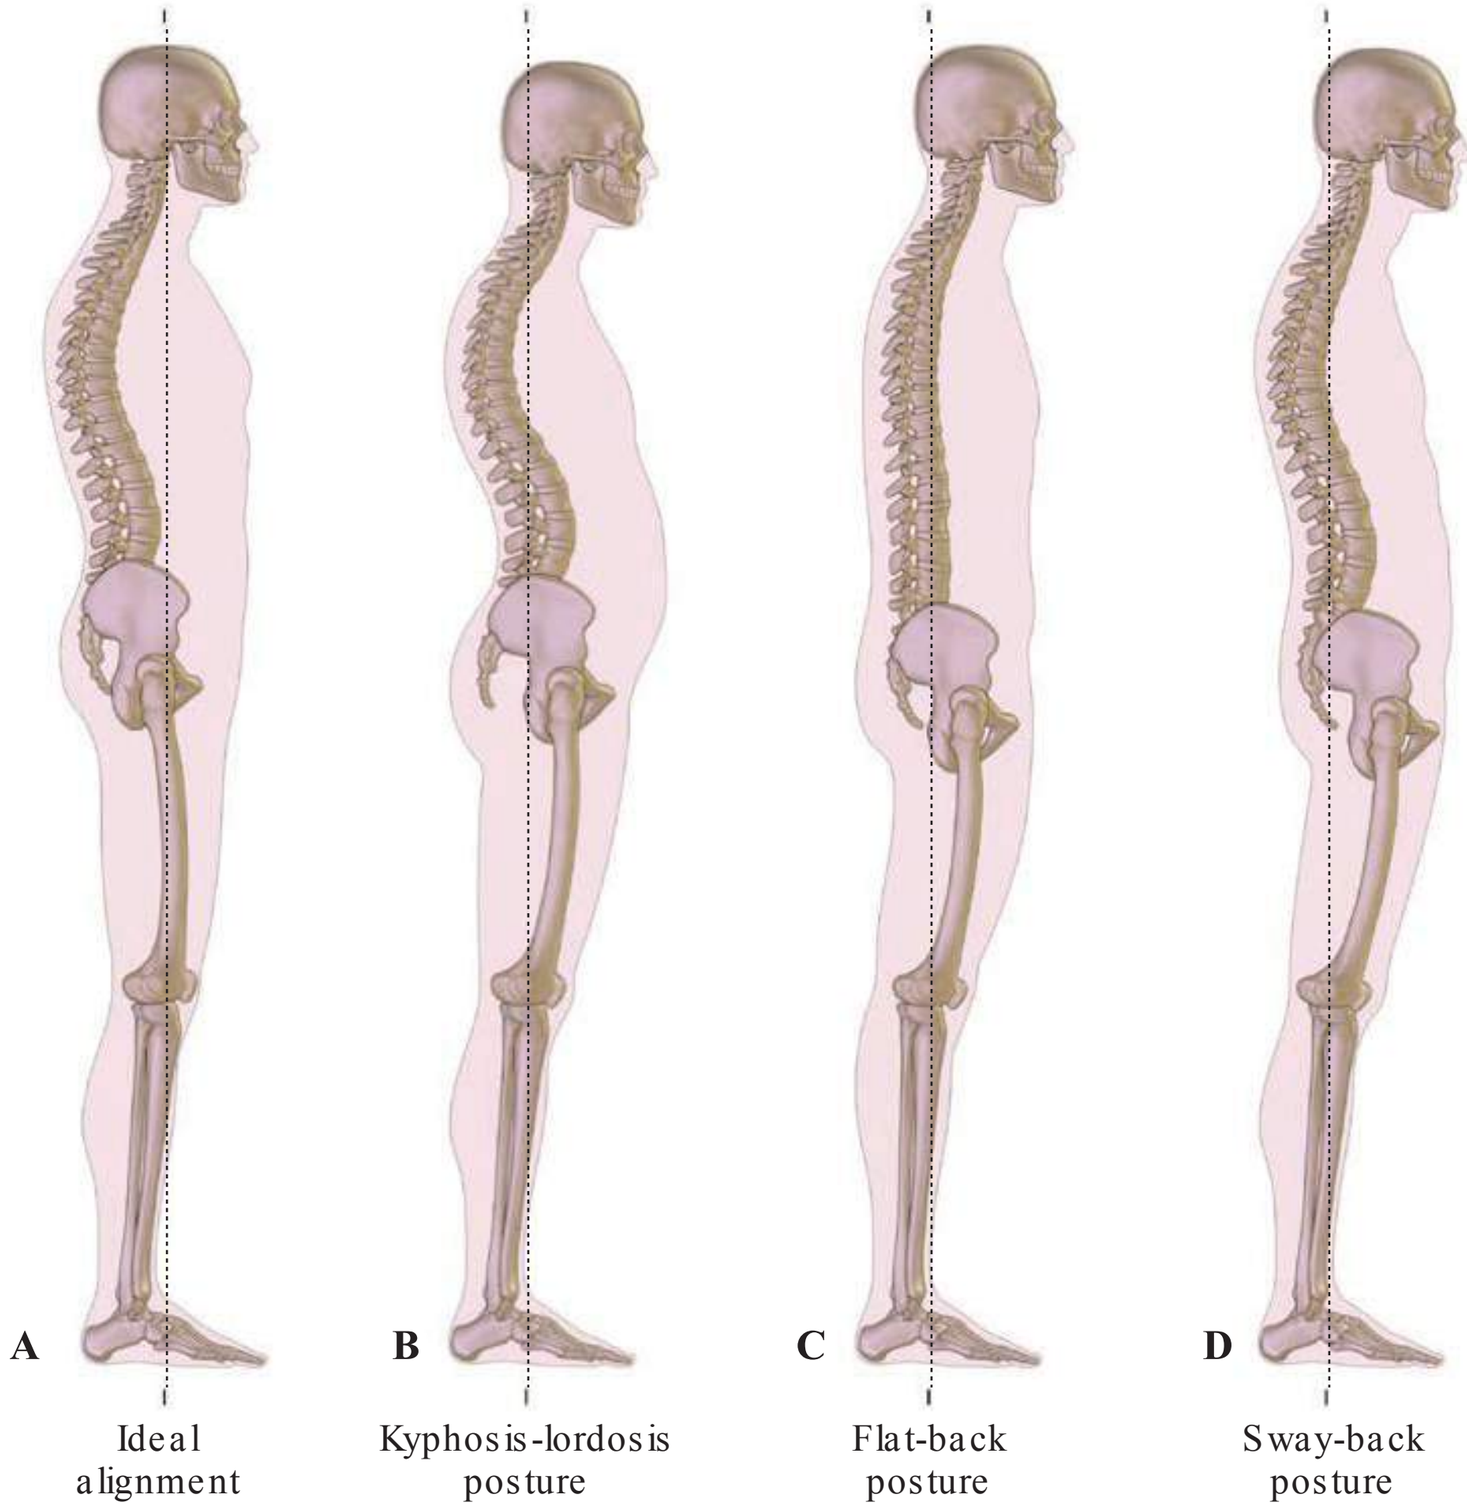

FIGURE 6-11 Common postural dysfunctions.

in a global fashion, with the patient in the standing, sitting, and lying (supine and prone) positions.[264] Although it may seem contrary, unassisted still, upright postural stance requires greater stability than unassisted walking, which is why walking occurs first in the toddler.[281] During mature still, upright stance, the hip joints account for the majority of medial–lateral stability while the ankle joints account for a great deal of anterior–posterior stability.[295]

When observing a patient for abnormalities in posture, the clinician looks for asymmetry.[264] Regional asymmetry should trigger a further evaluation of that area, but asymmetry alone does not confirm or rule out the presence of dysfunction. As some asymmetry between left and right sides is normal, the clinician must make the determination as to whether the apparent deviation is normal or caused by pathology. It must be remembered that postural adaptations can occur in a number of ways, including changes in gait, joint loading, neural function, muscle coordination, respiratory function, endurance, strength, and balance.[281] After the patient has been examined in the aforementioned positions, the examiner may

TABLE 6-14 Identifying the Dominant Eye

- Having made a circle with the first finger and thumb and, holding the arm out in front of the face, observe an object across the room, through that circle, with both eyes open
- Close one eye
- If the object is still in the circle, the dominant eye is open
- If, however, the image shifts out of the circle when only one eye is open, open the closed eye and close the open eye, and the image should shift back into clear view, inside the circle
- The eye that sees the same view when both eyes were open is the one to use in close observation of the body
- When attempting to assess by observation, a position should be adopted that allows the dominant eye to be closest to the center of what is being viewed

decide to include other habitual, sustained, or repetitive postures assumed by the patient to see whether these postures increase or alter symptoms.[264]

Static Examination

The static postural examination, as it relates to each joint and the various postural syndromes that exist, is described in the relevant chapters. A summary of the most common findings and faults are listed in Table 6-13. Common lower limb skeletal malalignments and possible correlated and compensatory motions or postures are compiled in Table 6-15.

Due to the relationships between head, neck, thorax, lumbar spine, and pelvis, any deviation in one region can affect the other areas. A number of common postures are described here.

Pelvic and Lumbar Region

The more common faulty postures of the pelvic and lumbar region include[296]:

- Lordotic posture (Fig. 6-11). It is characterized by an increase in the lumbosacral angle, an increase in lumbar lordosis, and an increase in the anterior pelvic tilt and hip flexion.[297] This posture is commonly seen in pregnancy,

TABLE 6-15 Skeletal Malalignment of the Lower Quarter and Correlated and Compensatory Motions or Postures

Malalignment	Possible Correlated Motions or Postures	Possible Compensatory Motions or Postures
Ankle and foot		
Ankle equinus		Hypermobile first ray Subtalar or midtarsal excessive pronation Hip or knee flexion Genu recurvatum
Rearfoot varus Excessive subtalar supination (calcaneal valgus)	Tibial; tibial and femoral; or tibial, femoral, and pelvic external rotation	Excessive internal rotation along the lower-quarter chain Hallux valgus Plantarflexed first ray Functional forefoot valgus Excessive or prolonged midtarsal pronation Excessive external rotation along the lower-quarter chain Functional forefoot varus
Rearfoot valgus Excessive subtalar pronation (calcaneal valgus) Forefoot varus	Tibial; tibial and femoral; or tibial, femoral, and pelvic internal rotation Hallux valgus Subtalar supination and related rotation along lower quarter	Plantarflexed first ray Hallux valgus Excessive midtarsal or subtalar pronation or prolonged pronation Excessive tibial; tibial and femoral; or tibial, femoral, and pelvic internal rotation; or all with contralateral lumbar spine rotation
Forefoot valgus	Hallux valgus Subtalar pronation and related rotation along lower quarter	Excessive midtarsal or subtalar supination Excessive tibial; tibial and femoral; or tibial, femoral, and pelvic external rotation; or all with ipsilateral lumbar spine rotation
Metatarsus adductus	Hallux valgus Internal tibial torsion Flat foot In-toeing	
Hallux valgus	Forefoot valgus Subtalar pronation and related rotation along the lower quarter [33]	Excessive tibial; tibial and femoral; or tibial, femoral, and pelvic external rotation; or all with ipsilateral lumbar spine rotation
Knee and tibia		
Genu valgus	Pes planus Excessive subtalar pronation External tibial torsion Lateral patellar subluxation Excessive hip adduction Ipsilateral hip excessive internal rotation Lumbar spine contralateral rotation	Forefoot varus Excessive subtalar supination to allow lateral heel to contact ground In-toeing to decrease lateral pelvic sway during gait Ipsilateral pelvic external rotation

TABLE 6-15 Skeletal Malalignment of the Lower Quarter and Correlated and Compensatory Motions or Postures (Continued)

Malalignment	Possible Correlated Motions or Postures	Possible Compensatory Motions or Postures
Genu varus	Excessive lateral angulation of tibia in frontal plane (tibial varum and tibia vara)	Forefoot valgus
		Excessive subtalar pronation to allow medial heel to contact ground
	Internal tibial torsion	
	Ipsilateral hip external rotation	Ipsilateral pelvic internal rotation
	Excessive hip abduction	
Genu recurvatum	Ankle plantarflexion	Posterior pelvic tilt
	Excessive anterior pelvic tilt	Flexed trunk posture
		Excessive thoracic kyphosis
External tibial torsion	Out-toeing	Functional forefoot varus
	Excessive subtalar supination with related rotation along lower quarter	Excessive subtalar pronation with related rotation along lower quarter
Internal tibial torsion	In-toeing	Functional forefoot valgus
	Metatarsus adductus	Excessive subtalar supination with related rotation along lower quarter
	Excessive subtalar pronation with related rotation along lower quarter	
Excessive tibial retroversion (posterior slant of tibial plateaus)	Genu recurvatum	
Inadequate tibial retrotorsion (posterior deflection of proximal tibia due to hamstrings pull)	Flexed knee posture	
Inadequate tibial retroflexion (bowing of the tibia)	Altered alignment of Achilles tendon, causing altered associated joint motion	
Bowleg deformity of tibia (tibia vara and tibial varum)	Internal tibial torsion	Forefoot valgus
		Excessive subtalar pronation
Hip and femur		
Excessive femoral anteversion	In-toeing	Excessive external tibial torsion
	Excessive subtalar pronation	Excessive knee external rotation
	Lateral patellar subluxation	Excessive tibial; tibial and femoral; or tibial, femoral, and pelvic external rotation; or all with ipsilateral lumbar spine rotation
Femoral retrotorsion	Out-toeing	Excessive knee internal rotation
	Excessive subtalar supination	Excessive tibial; tibial and femoral; or tibial, femoral, and pelvic internal rotation; or all with contralateral lumbar spine rotation
Excessive femoral neck to shaft angle (coxa valga)	Long ipsilateral lower limb and correlated motions or postures of a long limb	Excessive ipsilateral subtalar pronation
		Excessive contralateral subtalar supination
		Contralateral plantarflexion
	Posterior pelvic rotation	Ipsilateral genu recurvatum
	Supinated subtalar joint and related external rotation along the lower quarter	Ipsilateral hip or knee flexion
		Ipsilateral forward pelvis with contralateral lumbar spine rotation
Decreased femoral neck to shaft angle (coxa vara)	Pronated subtalar joint and related internal rotation along lower quarter	Excessive ipsilateral subtalar supination
		Excessive contralateral subtalar pronation
	Short ipsilateral lower limb and correlated motions or postures along lower quarter: anterior pelvic rotation	Ipsilateral plantarflexion
		Contralateral genu recurvatum
		Contralateral hip or knee flexion
		Ipsilateral backward pelvic rotation with ipsilateral lumbar spine rotation

Data from Riegger-Krugh C, Keysor JJ. Skeletal malalignments of the lower quarter: Correlated and compensatory motions and postures. J Orthop Sports Phys Ther. 1996;23:164–170.

obesity, and those individuals with weakened abdominal muscles. Potential muscle impairments include

- decreased mobility in the hip flexor muscles (iliopsoas, tensor fascia latae, rectus femoris) and lumbar extensor muscles (erector spinae);
- impaired muscle performance due to stretched and weakened abdominal muscles (rectus abdominis, internal and external obliques, and transversus abdominis).

This posture places stress throughout the lumbar spine on the anterior longitudinal ligament, the zygapophyseal (facet) joints, and narrows the posterior disk space and the intervertebral foramen, all of which are potential sources of symptoms.

- Slouched posture: This posture, also referred to as the swayback,[240] is characterized by a shifting of the entire pelvic segment anteriorly, resulting in relative hip extension, and a shifting of the thoracic segment posteriorly, resulting in a relative flexion of the thorax on the upper lumbar spine (Fig. 6-11). As a result, there is an increased lordosis in the lower lumbar region, increased kyphosis in the thoracic region, and usually a forward (protracted) head. This posture is commonly seen throughout most age groups and is typically the result of fatigue or muscle weakness. Potential muscle impairments include the following:
  - Decreased mobility in the upper abdominal muscles (upper segments of the rectus abdominis and obliques), internal intercostal, hip extensor, and lower lumbar extensor muscles and related fascia.
  - Impaired muscle performance due to stretched and weakened lower abdominal muscles (lower segments of the rectus abdominis and obliques), extensor muscles of the lower thoracic region, and hip flexor muscles.

This posture places stress on the iliofemoral ligaments, the anterior longitudinal ligament of the lower lumbar spine, and the posterior longitudinal ligament of the upper lumbar and thoracic spine. In addition, there is narrowing of the intervertebral foramen in the lower lumbar spine and approximation of the zygapophyseal (facet) joints in the lower lumbar spine.

- Flat low back posture. This posture is characterized by a decreased lumbosacral angle, decreased lumbar lordosis/extension, and posterior tilting of the pelvis (Fig. 6-11). This posture is commonly seen in those individuals who spend long periods slouching or flexing in the sitting or standing positions. The potential muscle impairments include
  - decreased mobility in the trunk flexor (rectus abdominis, intercostals) and hip extensor muscles;
  - impaired muscle performance due to stretched and weak lumbar extensor and possibly hip flexor muscles.

This posture can apply stress on the posterior longitudinal ligament, the posterior disk space, and on the normal physiological lumbar curve, which reduces the shock-absorbing effects of the lumbar region and predisposes the patient to injury.

Cervical and Thoracic Region

The more common faulty postures of the cervical and thoracic region include:[296]

Scoliosis. Two terms, scoliosis, and rotoscoliosis, are used to describe the lateral curvature of the spine, which typically involves the lumbar and thoracic regions. Scoliosis is the older term and refers to an abnormal side bending of the spine but gives no reference to the coupled rotation that also occurs. Rotoscoliosis is a more detailed definition, used to describe the curve of the spine by detailing how each vertebra is rotated and side flexed in relation to the vertebra below. For example, with a left lumbar convexity, the L5 vertebra would be found to be side flexed to the right and rotated to the left in relation to the sacrum. The same would be true with regard to the relation between L4 and L5. This rotation, toward the convexity, continues in small increments until the apex at L3. L2, which is above the apex, is right rotated and right side flexed in relation to L3. The small increments of right rotation continue up until the thoracic spine, where the side bending and rotation return to the neutral position. The currently accepted definition of scoliosis is a 10-degree lateral curvature measured radiographically (see Chapter 7), with the vertebral rotation of the spine taken with the patient standing upright.[298] This definition is based on the fact that a graph of lateral spinal curvature of the general population is a smooth exponential function in which the sharpest change in slope occurs at 10 degrees.[299] Despite this reasonable approach to the definition of the disease state, it results in an extremely high prevalence of the disorder in the general population of 2–3%.[300] Scoliosis can be found in four forms: static, sciatic, idiopathic, and psychogenic. The cause of the latter is self-explanatory. An abnormal lateral thoracic curve is described as being static (structural) or dynamic (nonstructural):

- Static. The term static, or structural, scoliosis is used to describe an irreversible lateral curvature with fixed rotation of the vertebrae. With structural scoliosis, the vertebral bodies rotate toward the convexity of the curve, producing a prominence.[301] The prominence, which occurs posteriorly on the side of the spinal convexity in the thoracic spine is called a rib hump. The rotation of the vertebral bodies causes the spinous processes to deviate toward the concave side, which causes a prominence anteriorly on the side of the concavity. The curvature results in an adaptive shortening of the intrinsic trunk muscles on the concave side and lengthening of the intrinsic muscles on the convex side. Persistent scoliosis during forward bending (Adam's sign) is indicative of a structural curve. Structural curves may be genetic, congenital, or idiopathic, producing a structural change to the bone and a loss of spinal flexibility. For example, structural scoliosis may be caused by a hemivertebra, osteoporosis, osteomalacia, or compression fractures.

Dynamic. The term dynamic, or nonstructural, scoliosis is used to describe a reversible lateral curvature that can be changed with forward or side bending and with positional changes. Causes include poor posture, nerve root irritation (see Sciatic), leg-length discrepancy, atrophy, or hip flexor contracture. In the case of a leg-length discrepancy, if a platform under the heel of the shorter limb eases or even abolishes the symptoms while standing or on lumbar flexion or extension, a shoe lift is advised.[75,302]

Other types of scoliosis to consider include:

- Sciatic. The sight of a patient with a pelvic shift or list is relatively common in patients presenting with LBP. The sciatic, or nonstructural, lumbar scoliosis results from sciatic pain caused by a lumbar disk herniation and unilateral spasm of the back muscles. Sciatic scoliosis usually occurs with convexity to the symptomatic side of the herniated disk.[303] The shift is thought to result from the body finding a position of comfort and protection, as a consequence of an irritation of a spinal nerve or its dural sleeve,[303] although the neuronal mechanisms of sciatic scoliosis have not been well clarified. These postural changes cannot be relieved by voluntary efforts but usually disappear after alleviation of the sciatic pain.[303] The extent of scoliosis should be noted if it is thought to be contributing to the patient's symptoms and is occurring because of pain or dysfunction. An attempt should be made to manually correct the shift (see Chapter 28) to ascertain whether this can be done painlessly. A compensatory shift or scoliosis is often easy and painless to correct.[304,305]
- Idiopathic. Scoliosis is never normal, although most cases are idiopathic, manifesting in the preadolescent years.[306,307] The curve of idiopathic scoliosis differs from the tilt of the spine associated with recent IVD problems in that it is accompanied by a lower thoracic or lumbar rotation deformity.[302] If this deformity is not obvious in the standing posture, it should become obvious during flexion, as it is manifested by the so-called razor back eminence of the thoracic cage.

The curve patterns are named according to the level of the apex of the curve. For example, a right thoracic curve has a convexity toward the right, and the apex of the curve is in the thoracic spine. There may be a number of curves spanning the thoracic and lumbar region, and the clinician should determine if the curvature is contributing to the patient's pain as, frequently, these curves can be asymptomatic. A slight lateral curve in the frontal plane is thought to result from right-hand dominance or the presence of the aorta.[308]

Round Back with Forward Head. This posture is characterized by increased kyphotic thoracic curve, protracted scapulae (round shoulders), and forward head (excessive flexion of the lower cervical spine and hyperextension of the upper cervical spine) (Fig. 6-12). The causes of this posture are similar to those found with the flat low back posture. The potential muscle impairments include the following:

- Decreased mobility in the muscles of the anterior thorax (intercostal muscles), muscles of the upper extremity originating on the thorax (pectoralis major and minor, latissimus dorsi, serratus anterior), muscles of the cervical spine and head that attach to the scapular and upper thorax (levator scapulae, SCM, scalene, upper trapezius), and muscles of the suboccipital region (rectus capitis posterior major and minor, obliquus capitis inferior and superior).
- Impaired muscle performance due to stretched and weak lower cervical and upper thoracic erector spinae and scapular retractor muscles (rhomboids, middle trapezius), anterior throat muscles (suprahyoid and infrahyoid), and capital flexors (rectus capitis anterior and lateralis, superior oblique longus colli, and longus capitis).

FIGURE 6-12 Forward-head posture.

This posture can place excessive stress on any or all of the following structures:

- The anterior longitudinal ligament in the upper cervical spine and posterior longitudinal ligament in the lower cervical and thoracic spine.
- Irritation of the zygapophyseal (facet) joints in the upper cervical spine.
- Impingement on the neurovascular bundle from anterior scalene or pectoralis minor muscle tightness (thoracic outlet syndrome).
- Impingement of the cervical plexus from levator scapulae muscle tightness.
- Temporomandibular joint dysfunction.
- Lower cervical disk lesions.
- Flat upper back and neck posture. This posture is characterized by a decrease in the thoracic curve, depressed scapulae, depressed clavicles, and decreased cervical lordosis with increased flexion of the occiput on the atlas. Although not common, this posture occurs primarily with exaggeration of the military posture (Fig. 6-13). The potential muscle impairments include the following:
  - Decreased mobility in the anterior neck muscles, thoracic erector spinae, and scapular retractors, with potentially restricted scapular movement, which can interfere with shoulder elevation.

FIGURE 6-13 Flat upper back and neck posture.

- Impaired muscle performance in the scapular protractor and intercostal muscles of the anterior thorax.

T is posture can place stress on the neurovascular bundle in the thoracic outlet between the clavicle and ribs and can decrease the shock-absorbing function of the kyphotic curvature, thereby predisposing the neck to injury.

Forward Head. Forward head posture is described (in sitting or standing) as the excessive anterior positioning of the head, in relation to a vertical reference line, increased lower cervical spine lordosis, and rounded shoulders with thoracic kyphosis (Fig. 6-12). Other postural adaptations associated with the forward head posture include protracted scapulae with tight anterior muscles and stretched posterior muscles and the development of a cervicothoracic kyphosis between C4 and T4.[274,309] For each inch that the head is anterior to the COG, the weight of the head is added to the load borne by the cervical structures.[310] For example, the average head weighs 10 lb. If the chin is 2 in anterior to the manubrium, 20 lb is added to the load. If normal motion is undertaken in this poor postural environment, the result may be abnormal strain placed on the joint capsule, ligaments, IVDs, levator scapulae, upper trapezius, SCM, scalene, and suboccipital muscles.

Sustained forward head postures may cause a painful fatigue in the levator scapulae, rhomboids, and lower portion of the trapezius, a condition referred to as tired neck syndrome.[311] T e traumatized muscles may cause pain, which in turn causes the patient to restrict motion. Patients with these postural abnormalities may experience myofascial pain that can cause referral zone pain.[263] T is myofascial pain is thought to be caused by waste products produced by the muscles or from localized ischemia of those structures. An underlying cycle of abnormal relaxation in some muscles, with shortening, stretching, and a loss of tone in others, occurs during this process, with resultant joint strain and dysfunction.

As the head is brought forward by flexing the cervical segments, the scalene muscles are permitted to adaptively shorten, thus lessening the support of the upper ribs. T e cervical flexion is followed by an increase of the thoracic curvature and the tension of the spinal musculature increases.[312,313] In this position, the capital extension must now occur to keep the eyes horizontal and allow the individual to look ahead.[236,314,315] T is occipital hyperextension of the cranium on the cervical spine has been related to head, neck, and temporomandibular joint pain. A postural-pain relationship has been described by Willford et al.[316] in people wearing multifocal corrective lenses.

Under normal circumstances, the COG for the head falls slightly anterior to the ear. T e habitual placement of the head anterior to the COG of the body places undue stress on the temporomandibular joint, the cervical and upper thoracic facet joints (especially at the cervicothoracic junction), and the supporting muscles.[237,238]

T e abduction of the scapulae or protraction of the shoulders causes a lowering of the coracoid process, producing adaptive shortening of the pectoralis minor, which, in turn, may flatten the anterior chest wall and alter the motion of the scapula, producing a mechanical impairment of the shoulder.

Protraction of the shoulder girdles also limits extension of the upper thoracic spine, which, in turn, limits elevation and abduction of the shoulders. T is alteration can lead to a hypermobility or instability of the glenohumeral joint and overuse syndromes of the shoulder elevators or abductors. Shoulder protraction also causes the humerus to rotate internally which stretches the posterior glenohumeral joint capsule; in addition, it increases the anterior force at the joint as a result of gravity. T e former may lead to posterior instability and rotatory hypermobility, and the latter to anterior instability and a biceps tendonitis, as this muscle becomes overused in its attempt to stabilize the glenohumeral joint.

T e anteriorly displaced line of gravity induced by the forward head posture has an effect on respiration. T is change in posture is postulated to have the following consequences:[317]

1. Open-mouth breathing.[318] Open-mouth breathing is the normal pattern of breathing for a newborn. T is pattern of breathing becomes abnormal if it persists into the 5–7 years. A child with a long bout of sinus infections and blockages is forced to use mouth breathing as the primary method of breathing. With the development of the teeth and tongue, the oral passageway for air is gradually reduced, forcing the child to open the mouth further in order to breathe. It is postulated that this can result in[243–245]:
   - a failure to filter the inspired air of pathogens and particles. T ese particles go directly into the alveoli, producing an inflammatory reaction in the lungs that results in bronchospasm or asthma and stimulates a future hypersensitivity to any new particles;
   - a failure to humidify the inspired air, so that the air entering the lungs is dry;
   - a failure to warm the inspired air. Cold or cool air entering the lungs stimulates an increased presence of white blood cells, increasing the hypersensitivity

of the lungs. Early intervention with mouth breathers is essential, and it is recommended that the child be encouraged to keep the tongue against the roof of the mouth while breathing.

2. Thoracic hyperflexion. Although only theoretical, the thoracic compensation is necessary to counteract the backward tilting of the head and to return the eyes to a horizontal position. This compensation produces the following:
   - A reduction in thoracic extension.
   - A reduced ability of the ribs to elevate during inspiration, resulting from a reduced ability of the thoracic cavity to expand during inspiration.[319–321]
   - An increase in the respiratory rate.[319–321]
   - A shortening of the scalene muscles. Because of their newly acquired shortened position, the muscles have a reduced ability to contract, resulting in a reduced ability to elevate the first rib; a reduced ability to increase the vertical dimension of the thoracic cavity during inspiration; an increase in apical breathing.[319–321]

The forces from the cervical and thoracic regions of the spine can be transmitted to the lumbar spine, increasing the lordotic curve.[322,323] The exaggeration of the lumbar curve is accompanied by a shift of the weight to the posterior part of the vertebral bodies and to the articular processes, producing maximum joint strain of the lumbosacral junction and a forward inclination of the pelvis.

The increased forward inclination of the pelvis may produce a shortening of the erector spinae group and flexors of the hip, accompanied by a lengthening of the abdominal and hamstring muscles. These muscle imbalances serve to maintain the deformity.[324]

The intervention for the forward head is outlined in Chapter 25.

DYNAMIC EXAMINATION

It should be apparent that any postural examination should include a dynamic assessment, as a static examination alone cannot demonstrate the effect of a particular posture on function. A dynamic examination that assesses functional movement patterns, such as the Selective Functional Movement Assessment (SFMA),[325,326] helps the clinician to ascertain whether the apparent postural abnormality is dysfunctional. The SEMA assesses functional movement using four categories:

- Functional and nonpainful
- Functional and painful
- Dysfunctional and nonpainful
- Dysfunctional and painful

Within these categories, the term *functional* describes any unlimited or unrestricted movement, whereas the term *dysfunctional* is used to describe movements that are limited or restricted and which reproduce pain and/or demonstrate a lack of mobility, stability, or symmetry within a given functional movement. Although most clinicians can appreciate that repeated movement patterns performed in a therapeutic manner may be beneficial, it must also be remembered that repeated motions performed erroneously can produce changes in muscle tension, muscle strength, length, and stiffness.[271] It is quite normal for muscles to frequently change their lengths during movements. However, this change in resting length may become pathologic, when it is sustained through incorrect habituation or as a response to pain.

The dynamic postural examination can also be designed to assess each joint to its extremes of motion. The following should serve as a guideline:

- Joints of the extremities: active movements through the full range of each direction for each joint, with passive overpressure and a maximum isometric contraction, applied at the end range. Combined motions should also be assessed, for example, elbow flexion and supination.
- Joints of the spine: flexion, extension, side bending, and rotation of the cervical, thoracic, and lumbar spine in sitting, standing, and lying as appropriate. Combined motion should also be assessed, for example, cervical flexion with rotation superimposed on the flexion.
- Functional movements: deep squatting (heels flat and shoulders flexed), Apley scratch test (fingertips touching behind the back).

During these various movements, the clinician is looking for symmetry, ease of movement, and the provocation of any symptoms.

Special Tests

The special tests used in the assessment of posture include all those that are related to the assessment of muscle length and strength. Examples include manual muscle testing, the Thomas test, and the Ober test. These tests are described in the relevant chapters. In addition, the clinician should examine neurodynamic mobility for the presence of adverse neural tension (see Chapter 11).

Intervention

The focus of therapeutic intervention for posture and movement impairment syndromes is to alleviate symptoms and to play a significant role in educating the patient against habitual abuse. Interestingly, despite the widespread inclusion of postural correction in therapeutic interventions, there is limited experimental data to support its effectiveness. Therapeutic exercise programs for the correction of muscle imbalances traditionally focus on regaining the normal length of a muscle so that good movement patterns can be achieved. The intervention of any muscle imbalance is divided into three stages:

1. Restoration of the normal length of the muscles. If the muscle activity is inhibited, the muscle should be stretched in the inhibitory phase. If the muscle is hypertonic, muscle energy techniques may be used to produce minimal facilitation and a minimal stretch. With true adaptive shortening of the muscle, stronger resistance is used to activate the maximum number of motor units, followed by vigorous stretching of the muscle.

2. Strengthening of the muscles that have become inhibited and weak. Vigorous strengthening should be initially avoided to prevent substitutions and the reinforcement of poor patterns of movement.
3. Establishing optimal motor patterns to secure the best possible protection to the joints and the surrounding soft tissues.

In addition to using specific techniques to stretch and strengthen muscles, muscle energy (see Chapter 10), proprioceptive neuromuscular facilitation, and the incorporation of a more "wholistic" approach can often have a beneficial effect on postural dysfunction and movement impairment. T ere is a growing interest in the field of integrative care—the blending of complementary or wholistic therapies with conventional medical practice. Wholistic approaches provide whole-person care—addressing people rather than diseases, caring rather than curing, using all possible therapeutic modalities rather than a limited few, and empowering patients wherever possible to use self-care approaches and to be active participants in decisions regarding their health.

Examples of these "wholistic" approaches, currently used in association with physical therapy, include the Alexander technique, Feldenkrais method, Trager psychophysical integration (TPI), Pilates, Tai Chi Chuan (TCC), and yoga.

Alexander Technique

T e Alexander technique[327] is commonly viewed as a series of breathing and posture techniques. However, the purpose of the technique is to make patients more aware of structural imbalances, different ways of moving, and the excessive tensions that can be produced in activities of daily living. Although it is not within the scope of this chapter to fully describe the Alexander technique, some of its principles are outlined here, and the reader is encouraged to learn more about this technique through further reading.

T e Alexander technique uses reeducation to change the thought processes, as well as the postural and movement habits, that are theorized to provoke pain. According to this theory, the main reflex in the body termed the primary control, which is situated in the area of the neck, controls all of the other reflexes of the body. Dysfunction of this main reflex, resulting from increased tension in the neck, causes a pulling back of the head and changes the relationship of the neck and back, eventually causing tensions in other parts of the body.

Based on these assumptions, Alexander devised three directions:[327]

1. Allow the neck to be *f*ree. T e purpose of this direction is to eliminate any excess tension in the muscles of the neck.
2. Allow the head to go *f*orward and upward. When the neck muscles are released, the head goes slightly forward and upward.
3. Allow the back to lengthen and widen. As the head moves slightly forward and upward, the spine lengthens. Because an increase in the spine length can also narrow the spine, widening of the back, through a retraction of the shoulders and broadening of the rib cage, is encouraged.

Feldenkrais Method

T e Feldenkrais method of somatic education is a self-discovery process using movement. It was developed by Dr. Moshe Feldenkrais, a physicist and electronics engineer. T e aim of the Feldenkrais method is for an individual to move through relaxation and self-awareness, with minimum effort and maximum efficiency. T e method teaches that many pains and movement restrictions are the results not of an actual physical defect or the inevitable deteriorations of age, but of habitual poor use.[328] Over time, this causes fatigue, disability, and pain.

T e antidote, according to Feldenkrais, is to relearn certain functional movements and postures using the so-called organic learning style, based on the way humans learn to perform, as they develop during early childhood. During this growth phase, some of the movements are learned correctly, others are not. Incorrect movement patterns may result in inefficient movements or restrictions to movements. In humans, the premotor cortex relates to posture stability and the act of reaching. It is also the supplementary motor area for planning, programming, and initiating movement.[329] T ese latter components require correct sequencing and organization. T e Feldenkrais method is seen as a way of reprogramming the nervous system and re-teaching the body how to perform the functional movement patterns correctly.

Functional movement patterns involve the integration and sequencing of movement patterns while maintaining neuromuscular control. T ese patterns and postures are developed using the two aspects of the Feldenkrais method: awareness through movement (ATM) and functional integration (FI). Although closely related, ATM and FI have fundamental differences:

- ATM is usually done in a group, whereas FI involves one-on-one learning.
- ATM involves the performance of gentle exploratory movements using verbal guidance. In contrast, FI uses guidance into nonhabitual movements, with tactile cueing by a trained practitioner.

Both of the aspects work toward changing old movement patterns or creating new movement patterns. Individuals are led through a series of movement sequences. All movements are performed slowly, without pause and short of the range of discomfort and pain. T e proponents of the Feldenkrais method claim that these movements promote improved attention and awareness.[330] It is also claimed that these movements refine the ability to detect information and make perceptual discriminations.[330] Regular use of such attentive explorations and integration of the skills lead to an automatic use of these motor abilities. An example of a Feldenkrais exercise is to move one's head in one direction and one's shoulder and eyes in the other.[331] T ese movement sequences are usually repeated a number of times.

Five key principles are involved in the development of the Feldenkrais method:[330,332]

1. Self-organization: Dynamic systems theorists believe that behaviors are assembled in the moment and context of the current movement task.
2. Behavior is dynamic and plastic.

3. Perturbation is the instrument of change.
4. T e choice is necessary.
5. T e human development follows a logical sequence.

T e Feldenkrais method is both educational and experimental. It is process-, not goal-, oriented and is entirely pragmatic.[333] With acute conditions, the patient starts in the position of maximum comfort. T e lesson then uses any movement, however small, within the limit of comfort. T e patient is encouraged to become aware of the smoothness and clarity of the movement. T e movement is repeated and practiced. Further movements within this framework are investigated and practiced. T ese movements are simple initially, becoming more complex as the patient gains confidence.[333]

Trager Psychophysical Integration

TPI is a multifaceted intervention, consisting of light, gentle, and painless movements to facilitate the release of deep-seated physical (and mental) patterns.[334] TPI was designed at the beginning of the 20th century by Dr. Milton Trager and has been shown to be effective in promoting mobility and decreasing pain for patients with a wide variety of diagnoses, including cerebral palsy,[335] chronic spinal pain and dysfunction,[336] and arthritis.[334,337]

According to TPI philosophy, detrimental physical patterns are those developed by poor posture, trauma, stress, and poor movement habits.[338] Trager techniques serve to produce overall relaxation on the part of the patient, developing a sense of integration and effortless movement through a series of guided movements and mental gymnastics.[339,340]

T e Trager approach is broken down into two components: tablework and mentastics.

Tablework

Tablework consists of a series of gentle and painless movements that resemble general mobilization techniques. T e body of the patient is passively moved by the clinician who looks and feels for involvement of the tissue. T e aim is to provoke a feeling of softness and freedom to motion throughout the body.[336] Using these movements, the entire body is mobilized. Rhythmic rocking motions are initiated during these movements to stimulate the vestibular and reticular activating systems of the patient. T is is theorized to produce an overall sense of relaxation and well-being through an inhibition of the sympathetic system and the facilitation of the parasympathetic system.[341]

Mentastics

Mentastics is a system of active movements, designed to enhance the feeling of well-being provided by the tablework exercises. Mentastics encourage the patient not to control the movement, as in traditional exercise, but to let go of the control.[336] T e patient is taught to listen to signals of pain and fatigue and to change the symptoms by altering the movement. Over time, the patient learns how to move comfortably and to release tension.[340]

Pilates

T e Pilates method (Pilates Inc.) is a technique and apparatus developed in the 1940s by Joseph Pilates, who was prone to chronic illness as a child. Described as a unique mind–body exercise program, it was originally called Contrology[342] and its original goal was to fuse the mind and body so that without thinking, the body chooses the greatest mechanical advantage to achieve optimal balance, strength, and health.[342] T is is achieved by developing the body uniformly and correcting postures.

CLINICAL PEARL

The Pilates method incorporates movement principles that include both physical and cognitive elements: whole body movement, attention to breath, balance muscle development, concentration, control, centering, precision, and rhythm.[343]

Joseph Pilates is credited for labeling the core, or center, as "the powerhouse," and centering, where all energy begins and then radiates outward to the extremities, which is the focal point of the Pilates method. According to Pilates, he described the core as a box delineated by two horizontal lines: one line running from shoulder to shoulder, and the second line running from hip joint to hip joint.[344] T us, according to Pilates, core strengthening included strengthening of the shoulder and hip girdles.

Although, the Pilates method is not yoga or dance, it was first embraced by the dance community and dance medicine. Its inherent concept of core stabilization, mind–body awareness, and control of movement and posture has since been used successfully in rehabilitation, for the development of overall strength and fitness in patients with back pain, balance deficits, and urinary incontinence due to pelvic floor muscle weakness.

Part of the appeal of the Pilates method is that it incorporates many of the concepts and techniques that physical therapists commonly employ, with an increased emphasis on neuromuscular control. As such, the Pilates method focuses on motor training, rather than on motor strength, using precise and controlled exercises. T e Pilates method stresses the importance of the so-called powerhouse muscles of the body; deep, coordinated breathing; postural symmetry; and controlled movement. According to the Pilates method, the powerhouse muscles include the transversus abdominis, the lumbar multifidus, the pelvic floor muscles, and the diaphragm muscle. Approximately 10 repetitions are needed for each exercise.

T e Pilates exercises emphasize the maintenance of a neutral pelvis, spine, and scapulae throughout machine and mat exercises. T e joints are always stacked: shoulders over the hips, hips over the knees, and knees over the ankles.[344] Pilates-based exercise is progressed from basic gravity eliminated movements to complex and functional movements requiring coordination and balance against gravity.[345] Many of the Pilates exercises involve squeezing the inner thighs together in the Pilates stance, while simultaneously engaging the pelvic floor muscles, in an effort to increase trunk stability. Unlike specific stabilization exercise therapy, Pilates does not attempt

to facilitate conscious activation of any isolated muscle or muscle group. However, some have incorporated conscious muscle activation techniques into a Pilates-based exercise program for a combined therapeutic intervention.[346] For example, the Pilates stance involves slight external rotation in both hips and lower extremities, while maintaining the thighs in firm contact. Other Pilates exercises include instructions on how to isolate a transversus abdominis contraction from the rest of the abdominal muscles. T is is commonly achieved using the verbal cueing of "pull your belly button toward your spine." T is contraction is then practiced in a variety of positions and techniques, in order to enhance spinal, or core, stability. Pelvic stability is encouraged with such verbal cueing as "pull your sitting bones together," thereby producing a contraction of the ischiococcygeal muscle that provides support for the pelvic contents, in addition to contributing to sacroiliac joint stability.

Although many of the Pilates exercises can be performed on mats, 12 specially designed pieces of equipment may also be used. Four basic machines comprise the Pilates equipment line:

1. Reformer. T is is the basic machine of the Pilates method. It resembles a twin bed in size and frame and is equipped with handholds, pulleys, and cables that exercisers push or pull with their hands or feet. T e reformer is an apparatus for providing an assisted environment through its pulley system and springs, graded movement from assisted to resistive, and allowing nonpainful movement to begin early in the rehabilitation phase.[345] Graded movement may be helpful in the treatment of fear-avoidance, which can cause faulty motor patterns and has been linked to a number of conditions including low back injuries.[345,347] T e reformer can also be used in the rehabilitation of hamstring tears, and stress fractures.
2. Cadillac or trapeze table. T is piece of equipment is equipped with multiple bars and straps and features a pull-down bar. It is used for overall conditioning.
3. Pedi-pull. T e pedi-pull is the equipment of choice for footwork and for ankle rehabilitation. It can be adapted for such activities as one-arm pushes, lunges, and dips.
4. Ladder-barrel. T is piece of equipment consists of a sliding base and five rungs and is used for a variety of strengthening and flexibility exercises.

T e use of Pilates apparatus to train stabilization strategies during movement may enhance the effect of the more relatively static mat exercises.

Tai Chi Chuan

TCC is a Chinese low-speed and low-impact conditioning exercise and is well known for its slow and graceful movements. During the practice, diaphragmatic breathing is coordinated with graceful motions to achieve mind tranquility.

Classical Yang TCC includes 108 postures, with some repeated sequences. Each training session includes 20 minutes of warm-up, 24 minutes of TCC practice, and 10 minutes of cool down.[348] Warm-up exercise is very important because it may enhance TCC performance and prevent injury. It usually includes 10 movements (ROM exercises, stretching, and balance training), with 10–20 repetitions.

T e exercise intensity of TCC depends on training style, posture, and duration.[349,350] A high-squat posture and short training duration are suited to those with low levels of fitness or elderly participants; a low-squat posture and longer durations are suited to healthy or younger participants.[348]

Recent investigations have found that TCC is beneficial to cardiorespiratory function,[351] strength,[352] balance,[352,353] flexibility,[353] microcirculation,[354] and psychological profile.[349] Hartman et al.[355] also reported that TCC could control fatigue and regulate pain during activities and could improve walking speed and self-care activities in patients with osteoarthritis.

Yoga

Yoga, a literal translation from the Sanskrit word for "union," is a 5,000-year-old Indian practice. T ere are 40 main schools of yoga philosophy, of which Hatha (pronounced haht-ha) yoga is the most popular in the United States. According to Indian tradition, Hatha yoga is one of the four main traditions of Tantra yoga, a holistic approach to the study of the universe from the point of the individual. Hatha yoga is based on the practice of physical postures (asanas), breath control (pranayama), and meditation in order to energize subtle channels of the mind called nadis.

- Asanas. Physical postures that are performed using isometric contractions and held firmly from a time that ranges from seconds to minutes. T ere are 84 basic asanas in Hatha yoga, which are categorized in accordance with the movement they create in the body.
- Pranayama. Yoga breathing is performed slowly and without strain throughout the routine, with a brief pause of 1–2 seconds after each inhalation and exhalation.

T e theoretical benefits associated with yoga encompass physiological, psychological, psychomotor, cognitive, and biochemical aspects. T e physiological, psychological, psychomotor, and cognitive benefits include reduced stress; improved attention, memory, and learning efficiency; decreased pulse rate, respiratory rate, and blood pressure; and increased muscular strength and aerobic and muscular endurance.[356–363] T e biochemical benefits include an increase in high-density lipoprotein cholesterol, a decrease in low-density lipoprotein cholesterol, and an increase in hematocrit levels.[356]

Imaging Studies in Orthopaedics

CHAPTER 7

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. List the various imaging studies available and give a brief discussion of each.
2. Describe how the various musculoskeletal tissues are depicted in imaging studies.
3. Understand the strengths and weaknesses of each of the imaging studies.
4. Outline the rationale for the choice of one imaging technique versus another.
5. Describe how the results of imaging studies may help in the clinical decision-making process.

OVERVIEW

For healthcare professionals involved in the primary management of neuromusculoskeletal disorders, diagnostic imaging is an essential tool. T e availability of diagnostic images to physical therapists greatly depends on the practice setting. For example, physical therapists in the United States army have had privileges for ordering diagnostic imaging procedures since the early 1970s.[1] Outside of the United States military health system, few published examples describe civilian-sector practice models that include physical therapists referring patients directly for imaging tests.[2] T e role of imaging based on the Physical T erapy Practice Act language for the 50 states and the District of Columbia reveals tremendous variability, ranging from "prohibiting the use of roentgen rays for any purpose" to the prohibition of physical therapists from referring patients for diagnostic imaging, to being "silent" on the issue.[2] T is is somewhat surprising given the drive to pass patient direct access to physical therapy services, as the ability to directly refer patients to other providers, including a radiologist, would seem paramount.[3] At the heart of the issue is whether physical therapists are adequately educated regarding appropriate imaging referral. Although Springer et al.[4] demonstrated that military physical therapists were as competent as orthopedists in the utilization of the modified Ottawa ankle rules (determining whether ankle-foot radiographs are indicated for patients post ankle injury), the participating physical therapists had completed an advanced training program.[3] With regard to those physical therapists trained in the civilian sector, the advent of Doctor of Physical T erapy (DPT) degree programs has resulted in increased emphasis on imaging as a content area in these degree programs, although it is difficult to find publications that describe current imaging curricular within these programs.[3] Boissonnault et al.[3] performed a descriptive survey to describe the status of diagnostic and procedural imaging curricula within the United States physical therapist professional degree programs and found that, while the majority of programs reported including imaging curricula, variability was noted in all curricular aspects.

Although the ordering of imaging studies is not currently within the scope of many physical therapy practices, clinicians frequently request or receive imaging study reports. Although the interpretation of diagnostic images is always the responsibility of the radiologist, it is important for the clinician to know what importance to attach to these reports, and the strengths and weaknesses of the various techniques that image bone and soft tissues, such as muscle, fat, tendon, cartilage, and ligament. In general, imaging tests have a high sensitivity (few false negatives) but low specificity (high false-positive rate), so are thus used in the clinical decision-making process to test a hypothesis but should not be used in isolation. In addition, imaging studies are expensive and somewhat more invasive compared to a physical examination, so the clinician must weigh the relative value of recommending an imaging study in relation to the working hypothesis. For example, when there is little likelihood that imaging will reveal anything that will change the course of treatment, the tests should be considered unnecessary.[1] In addition, the clinician needs to understand that the results of an imaging study may not correlate with the results of the physical examination. Although imaging may provide evidence of pathology, the mere presence of the abnormality may or may not be relevant to the presenting signs and symptoms. In such situations, the clinician should place no more or less weight on the imaging results than on other aspects of the decision-making process.

Radiography

In 1895, Wilhelm Conrad Röntgen was experimenting with a type of electrical tube that produced an electrical discharge when a high voltage current was passed through it.[5] When Röntgen shielded the tube with heavy black cardboard, he noticed that a fluorescent screen a few feet away lit up and glowed indicating that some form of energy was passing through the tube. Further experiments led Röntgen to discover that these energy waves could reliably reproduce images of the human skeleton on a glass photographic plate.[5] Röntgen named these energy waves x-rays because "x" was the unknown quantity in a mathematical equation, and he was unsure of what the rays were composed of.[5] In 1896, Henri Becquerel discovered the basic nature of radiation and almost immediately an article appeared in the Journal of the American Medical Association theorizing on the possible diagnostic and therapeutic uses of this new discovery.[5] X-rays were soon determined to be part of the electromagnetic spectrum with the ability to penetrate through body tissues of varying densities. It was also discovered that the amount of beam absorbed as it passed through the body depended on the density of the tissue. T is allowed physicians to use the images to view a number of anatomical structures. Initially, only small segments of the body could be radiographed in a single exposure—studies of large, thick body parts such as the abdomen, and hip could not be adequately covered. T en, in 1912, Dr. Gustav Bucky published his findings describing a stationary, cross-hatched or "honeycombed" lead grid, which helped absorb scatter radiation and thus enhanced image quality. T e grid consisted of wide strips of lead arranged in two parallel series that intersected at right angles. One disadvantage of the stationary grid is that the lead strips left "blank" or white lines on the film ("grid lines"). A few years later, Dr. Hollis Potter introduced a multi-leafed focused grid, which moved the grid sideways across the film during the exposure, thereby blurring out the shadows of the grid strips, and further enhancing the image quality. Over the years, various mechanisms have been utilized to achieve this movement. Two physical factors responsible for grid efficiency are the grid ratio and the grid frequency.

- Grid ratio: T e height of the lead strip in relationship to the distance between them. Example: A 10:1 grid has lead strips 10 mm high, and these strips are 1 mm apart. T e strips are ten times as tall as the distance between them.
- Grid frequency: Defined as the number of lead strips per centimeter (or per inch). T e greater the frequency, the thinner the strips, and the greater the likelihood of scattered photons passing through.

Grid selection involves a compromise between film quality and patient exposure. High-ratio grids produce films with better contrast at the cost of increased patient exposure; however, proper alignment is more critical.

CLINICAL PEARL

A number of pieces of radiology equipment are named after Doctor Gustav Bucky:

- Bucky factor: sometimes referred to as grid factor or grid conversion factor (GCF)—a ratio of patient dose with and without a grid. It measures the penetration of primary and secondary radiation with and without a grid.
- Bucky tray: houses the image receptor.
- Bucky slot cover: a cover that shields the opening under the radiology examination table that houses the Bucky tray. This cover is engaged when the Bucky tray is moved to the foot of the examination table and is used during fluoroscopy.

Conventional (plain film) radiography is generally considered to be the first-order diagnostic imaging modality.[6] T e basic process is fairly simple. T e patient's body part of interest is oriented in a prescribed position and the film plate, receptor or, detector is positioned to capture the particles of the x-ray beam that are not absorbed by the tissues of the body. Both sides of the film are thinly coated with a fluorescent gel, and then the film is placed within a two-layered hard plastic shell, which protects the film and allows easy portability. An x-ray machine then directs electromagnetic radiation upon the specified region of the body.

CLINICAL PEARL

The term radiograph refers to the image produced on the radiographic film. X-ray film, like any photographic film, initially produces a negative image. Once the brief exposure of the patient to x-rays has occurred, the x-ray film is placed into a mechanical or electronic film developer and the final image is produced.

Exposure to the x-ray particles causes the film to darken, whereas areas of absorption appear lighter on the film.

Tissues of greater density allow less penetration of the x-rays and, therefore, appear lighter on the film. A difference in radio density is necessary for two structures to appear different on resultant radiographs. T e following structures are listed in order of descending density: metal, bone, soft tissue, water or body fluid, fat, and air. Because air is the least dense material in the body, it absorbs the least amount of x-ray particles, resulting in the darkest portion of the film. Bones can have varying densities within the body. For example, cancellous bone is less dense than cortical bone and thus appears lighter than the cortical bone on the radiograph. Soft tissues often cannot be separated because they have similar radio densities.

CLINICAL PEARL

An infection of the lung tissues, like pneumonia, has a great deal of water and cellular matter in it. This material absorbs a great deal of radiation, and thus little of the film is exposed. Therefore, if pneumonia is present, it is easily diagnosed by the appearance of a large white shadow (or "infiltrate") in the middle of the normally homogeneous black lung.

Numerous technical factors are manipulated and equilibrated in order to produce a high-quality diagnostic image while keeping the radiation dose as low as possible. Long focal

film distances, short object film distances, small focal spots, short exposure time, tight collimation (the process of restricting and confining an x-ray beam to a given area), and optimal film/screen combinations can all be used to enhance the image.[7] Reducing radiation exposure to the lowest levels may be addressed by attention to details of patient centering, shielding, and collimation, reducing repeat films, and the timely calibration of x-ray equipment.[7]

Digital radiography exists in the form of computed radiography or direct radiography. Image processing and distribution is achieved through a picture archiving and communication system. However, the spatial resolution of digital radiography systems is not yet as great as that with film screen radiography.[8]

Plain-film, or conventional, radiographs are relatively inexpensive and give an excellent view of cortical bone (Figs. 7-1 to 7-7). Radiographs may be more specific than MRI in differentiating potential causes of bony lesions because of the proven ability to characterize specific calcification patterns and periosteal reactions.[1] Plain radiographs are not considered sensitive to the early changes associated with tumors, infections, and some fractures.[9] However, they can be very helpful in detecting fractures and subluxations in patients with a history of trauma.[10] Radiographs may also be used to highlight the presence of degenerative joint disease, which is characterized by an approximation of the joint surfaces on the radiograph. However, radiographs do not provide the most accurate image of soft tissue structures, such as muscles, tendons, ligaments, and intervertebral disks (IVDs).

Radiographs are a 2D representation of a 3D structure. During the initial exposure to reading radiographs, it is important that the clinician examines as many "normal" radiographs as possible. T ere is a great deal of variations in the human body and a great deal of variations in what is considered to be normal. When evaluating radiographs, a systematic approach such as the mnemonic ABCS is recommended[11]:

FIGURE 7-2 Radiograph showing an extensive history of ACL reconstructions.

FIGURE 7-1 Radiograph showing abnormal bone growth of femur.

FIGURE 7-3 Radiograph showing grade I Salter–Harris fracture of the fibula.

FIGURE 7-4 Radiograph following medial wedge osteotomy of the right knee.

- A: Architecture or alignment. The entire radiograph is scanned from top to bottom, side to side, and in each corner to check for the normal shape and alignment of each bone. The outline of each bone should be smooth and continuous. Breaks in continuity usually represent fractures. Malalignments may indicate subluxations or dislocations, or in the case of the spine, scoliosis. Malalignment in a setting of trauma must be considered traumatic rather than degenerative until proven otherwise.[7]

FIGURE 7-5 Radiograph following ACL reconstruction (allograft) of the right knee.

FIGURE 7-6 Radiograph showing end-stage medial compartment degeneration (Varus malalignment) of the right knee.

- B: Bone density. The clinician should assess both general bone density and local bone density. The cortex of the bone should appear denser than the remainder of

FIGURE 7-7 Radiograph showing right ankle avulsion fracture/ deltoid sprain.

the bone. Subchondral bone becomes sclerosed in the presence of stress in accordance with Wolff's law[12] and increases its density. T is is a radiographic hallmark of osteoarthritis.

- C: Cartilage spaces. Each joint should have a well-preserved joint space between the articulating surfaces. A decreased joint space typically indicates that the articular cartilage is thinned from a traumatic process or a degenerative process such as osteoarthritis.
- S: Sof tissue evaluation. Trauma to soft tissues produces abnormal images resulting from effusion, bleeding, and distension.

For all joints and regions, there are a number of standard, or routine, radiographic series that are typically obtained.[13] A radiographic series is a group of x-rays films, taken from one area of the body, from different angles. T ese groups of films have been standardized by long years of experience and standards of care to provide all the needed information about an area of interest. For example, a standard chest x-ray uses certain established angles and amounts of radiation to enhance the view of the soft tissues of the heart and lungs, whereas a rib series uses an entirely different set of angles and radiation to bring out the bony detail with more clarity. In addition to the standard series, there are also additional or special views that can be ordered to visualize a particular structure more effectively (Table 7-1).[13] For example, a patient presenting with pain in the "anatomic snuf ox" area of the wrist may have a fracture of the scaphoid bone, requiring a special view of the area rather than a standard wrist series. It is important that the clinician has an appreciation of various views and what each represents.

Radiographs, like all medical procedures, have risks and benefits. Ionizing radiation can increase the risk of cancer, and in sufficient doses can cause death.[14] In addition to the health risks, the overutilization of radiologic studies has become a significant economic problem in the United States.[15] For these reasons, there has been an increased need for clinical prediction or decision rules indicating a need for radiography for specific types of injury in certain areas of the body. A clinical decision rule (CDR) is a tool that can quantify individual contributions from the components of the examination to determine the diagnosis, prognosis, or treatment for a given patient.[1]

Clinical Applications

Cervical Spine

CDRs for reevaluation of cervical spine injuries remain controversial, although consensus exists that cervical radiographic studies are over-utilized in the emergency department (ED).[16] In addition to the routine projections of the cervical spine, the anteroposterior (A-P) and lateral views, a number of other views can be used to aid in the evaluation of trauma and arthritis (Table 7-1). T e A-P view provides information about the shape of the vertebra, the presence of any lateral wedging or osteophytes, and the disk space. In the lower cervical spine, the A-P view can also provide information about the presence of a cervical rib. T e lateral view provides information about the lordosis and general shape of the cervical curve and cervical vertebrae. T is view also provides information about any anterior or posterior displacement of the vertebrae, the size of the disk space, the integrity of the vertebral edges (lipping), facet subluxation, soft tissue abnormalities, and the presence of any osteophytes. By measuring the prevertebral soft tissue width at the anteroinferior border of the C-3 vertebra, a determination is made as to the existence of edema or hemorrhage if the width is wider than the normal 7 mm.[17]

CLINICAL PEARL

The normal ratio of spinal canal diameter to vertebral body diameter (Torg ratio) is 1. A Torg ratio that is less than 0.8 indicates possible cervical stenosis.[18]

Radiographic images are limited in their ability to detect instability of the craniovertebral region because of an incomplete image definition of soft tissues, but the disruption of normal skeletal relationships may indicate a loss of integrity of the interposed tissues. To measure the degree of atlantoaxial subluxation, the anterior atlantodens interval (AADI), which measures the spatial relationship between the odontoid process and the anterior arch of the atlas has been used. Before skeletal maturity occurs, this value may be up to 4–5 mm. In adults and older children, a value of 3 mm is generally considered to be the upper limit of normal.[19] Roche et al.[20] have proposed that 3–6 mm suggests transverse ligament damage and greater than 6 mm implies alar ligament injury. However, AADI interpretations must be used with caution. T e posterior atlantodens interval (PADI), which is the distance between the anterior margin of the posterior ring of the atlas and the posterior surface of the odontoid, may be a more valuable measurement, as it results in a more accurate reflection of canal size and potential for neurologic compromise. A PADI of 40 mm is considered the lower limit to avoid encroachment onto the spinal cord.[20]

Thoracic Spine

Standard views of the thoracic spine include the A-P view and lateral view (Table 7-1).

A-P view. T is view is used to help the clinician determine if there is any wedging of the vertebrae (suggestive of structural kyphosis resulting from conditions such as Scheuermann's disease or a wedge fracture), whether the disk spaces appear normal, whether there is normal symmetry of the ribs, whether there is any malposition of the heart and lungs, whether any scoliosis is present, and whether the ring epiphysis, if present, is normal. From a disease perspective, in patients with suspected ankylosing spondylitis, the clinician is observing for a bamboo spine. T e Cobb method is a technique used to measure spinal curvature in cases of suspected scoliosis. A line is drawn parallel to the superior cortical plate of the proximal end vertebra and to the inferior cortical plate of the distal end vertebra. A perpendicular line is then used to join each of these lines, and the angle of intersection of the perpendicular lines is the angle of spinal curvature resulting from scoliosis.

Lateral view. T is view is to help the clinician determine if there is a normal kyphosis, whether the disk spaces appear

TABLE 7-1 Standard and Special Radiographic Views

Region	Common Views/ Special Views	Patient Position	Purpose and Structures Imaged
Shoulder complex	A-P, external rotation	The patient is supine or erect, preferably erect, and slightly oblique, so the scapula is near parallel to the film. The forearm is supinated with a slight abduction of the shoulder for external rotation, and the elbow is slightly flexed. Central ray perpendicular to the coracoid process	Anatomic position of the shoulder girdle with the greater tuberosity seen in profile, laterally. The glenohumeral and acromioclavicular joints, proximal humerus, clavicle, and portions of scapula can all be viewed in this position
	A-P, internal rotation	The patient is positioned as for external rotation except that the back of the hand rests on the hip. Central ray is perpendicular to the coracoid process	Provides approximately 90-degree opposing view to anteroposterior, external rotation including a true lateral of the humerus with the lesser tuberosity seen in profile, medially
	Axillary	Has many variations but essentially consists of the x-ray beam passing through the axilla from inferior to superior. The West Point axillary view is obtained with the patient prone and the tube angled 25 degrees cranially and medial to the midline of the glenohumeral joint. The Stryker notch view is taken with the patient supine and the arm flexed (without abduction), and the cassette beneath the shoulder. The central ray is directed 10 degrees cranially	The glenohumeral joint, coracoid process, and the acromion process can be seen in addition to the humeral head position with respect to glenoid fossa West Point view maximizes visualization of the anterior inferior glenoid rim, enhancing the detection of bony Bankart lesions Stryker notch view: maximizes the visualization of the humeral head and Hill–Sachs lesions
	A-P, lateral scapula		Useful in identifying fractures of scapula
	Transscapular or Y view		Entire scapula; best view for comminuted and displaced fractures of the scapula
Acromioclavicular joints	A-P	The patient is erect with the arms hanging at the sides. The central ray is 15 degrees cranially at the level of the coracoid process.	A bilateral frontal projection of the AC joint
	Stress	As above except with 10–20 lb weight strapped (if the patient holds the weight, the resulting muscle contraction may produce a false-negative) to the patient's wrist	Helps dif erentiate incomplete from complete injuries
Sternoclavicular	P-A	The patient is positioned in prone. The central ray is perpendicular to the midpoint of the body at the level of the sternoclavicular joints	A frontal view of the sternoclavicular joints and medial aspects of the clavicles.
	Serendipity	The patient is supine or erect, facing the tube. A 40-degree cranial tilt of the central ray	Allows for evaluation of anterior and posterior dislocation
Elbow	A-P	The elbow is extended with the forearm supinated and the patient leaning laterally until the anterior surface of the elbow is parallel with the plain x-ray cassette of the film. Central ray is perpendicular to the elbow joint	An A-P projection of the elbow joint including the distal end of the humerus, the humeroulnar and humeroradial joints, and the proximal end of the forearm
	Lateral	The elbow is flexed 90 degrees and the hand is in a lateral position. Central ray is perpendicular to the elbow joint	Integrity of olecranon articulation with olecranon fossa; look for fat pad signs

(Continued)

TABLE 7-1 Standard and Special Radiographic Views (Continued)

Region	Common Views/ Special Views	Patient Position	Purpose and Structures Imaged
	Epicondylar groove (cubital tunnel)	This view is an axial view, modified by 15 degrees of external rotation	Used to determine whether there is bony encroachment on the cubital tunnel, contributing to ulnar nerve entrapment
	Radial head-capitellum	Obtained in the same position as a lateral view with the primary beam angled 45 degrees toward the shoulder and centered on the radial head	Best view of radial head, capitellum, and coronoid process
Forearm	A-P, lateral	Both views include the elbow and the wrist, and both views are centered on the midshaft of the forearm bones	Entire radius and ulna, wrist, elbow
Wrist	P-A	Forearm and hand on x-ray cassette with palmar surface down; the hand is slightly arched, placing the wrist in close contact with the film. Central ray perpendicular to the midcarpus	P-A projection of all carpals, the distal end of the radius and ulna, and the proximal ends of the metacarpals, carpal alignment
	Lateral	Elbow flexed 90 degrees, the forearm and arm on the x-ray cassette are ulnar side down. Central ray perpendicular to the carpus	Lateral view of the carpus, the proximal end of the metacarpals and the distal end of the radius and ulna highlighting posterior (dorsal)/volar relationships
	Posterior oblique	From the lateral position, the forearm is pronated until the wrist forms an angle of approximately 45 degrees with the plane of the film. The central ray is perpendicular to the scaphoid	Demonstrates the carpal bones on the lateral side of the wrist, in particular the scaphoid. In addition the first metacarpal, thumb carpometacarpal joint, and trapezium can be viewed
Hand	P-A	Forearm and hand on x-ray cassette with palmar surface down. Central ray perpendicular to the third metacarpophalangeal joint	P-A view of the carpals, metacarpals and phalanges (except the thumb), and the distal ends of the radius and ulna. This position yields an oblique view of the thumb. A true anterior–posterior projection of the thumb is obtained by turning the hand into a position of extreme internal rotation and holding the extended fingers back with the opposite hand, with the posterior (dorsal) surface of the thumb resting on the x-ray cassette
	Lateral	Forearm and hand on x-ray cassette, ulnar side down with fingers superimposed. Central ray perpendicular to the MCP joints	Lateral view of the bony and soft tissue structures highlighting the posterior (dorsal)/volar relationships so that anterior and posterior displacement of fracture fragments can be seen
	Posterior oblique	Forearm and hand on x-ray cassette, ulnar side down with the forearm pronated so that the fingers, which are slightly flexed, touch the cassette and the MCP joints form an angle of approximately 45 degrees. Central ray perpendicular to the third MCP joint	Oblique view of the bone and soft tissue of the hand. With a slight adjustment of this position, a true lateral of the thumb can be obtained
Hip	A-P pelvis	Patient supine with the feet internally rotated 15 degrees (to eliminate overlay of the greater trochanter). Central ray perpendicular to the midpoint of the film	Frontal projection of the entire pelvis, both hips and proximal femurs

TABLE 7-1 Standard and Special Radiographic Views (Continued)

Region	Common Views/ Special Views	Patient Position	Purpose and Structures Imaged
	Lateral-oblique (frog-leg)	The patient is turned to a near lateral position and toward the af ected side with the hip and knee flexed. A straight tube is centered on the femoral head	Extremely valuable for examining the femoral head and neck, especially to exclude fractures and to assess the apophysis and femoral capital epiphysis in the immature patient
Knee	A-P	Patient supine with the knee extended. Central ray 5–7 degrees cranial to the knee joint	Frontal view of the tibiofemoral joint space and articular surfaces; distal femur; proximal tibia
	Lateral	Lateral with the af ected side down and the knee flexed approximately 30 degrees. The central ray is 5 degrees cranial	Lateral view of the patellar position, distal femur; proximal tibia and fibula
	Sunrise axial	The patient is positioned in prone and the knee is flexed more than 90 degrees. The beam is angled perpendicular to the x-ray cassette	Patellofemoral joint and medial/lateral positioning of patellar; intercondylar groove
	Intercondylar	The patient is positioned kneeling on the table with the knee flexed to 70 degrees and the beam centered on the inferior pole of the patella	Intercondylar fossa, notch of popliteal tendon, tibial spines, intercondylar eminence, posterior aspects of the distal femur and proximal tibia, intercondylar eminence of tibia
	Merchant	The patient is supine and the knees are flexed over the end of the x-ray cassette. The beam is directed toward the feet and the film cassette is held on the shins	Patellar, femoral condyles. Preferred view of articular surface of the patellar, subtle dissertations
Ankle	A-P	The patient is positioned in supine with the foot vertical. The central ray perpendicular to a point midway between the malleoli	Frontal projection of the ankle joint, the distal end of the tibia and fibula, and the proximal portion of the talus. Neither the syndesmosis nor the inferior portion of the lateral malleoli is well demonstrated in this projection
	Mortise	Supine with the leg and foot rotated internally approximately 15 degrees. The central ray perpendicular to the ankle joint	The syndesmosis is well seen without overlap of the anterior process of the distal tibia; best view of mortise and distal aspect of the lateral malleolus
	Lateral	Lateral side of the ankle down; the patient is supine and turned toward the af ected side. The central ray is perpendicular to the lateral malleolus	A lateral view of the distal third of the tibia and fibula, the ankle joint, talus, calcaneus, and the hind foot
	Impingement	The ankle is positioned in extreme plantar flexion to detect posterior impingement, and weight bearing and maximum dorsiflexion to detect anterior impingement	To assess bony contribution to posterior or anterior impingement
	Oblique tarsal	The ankle is positioned to provide an oblique view of the foot	Best view to detect a fracture of the anterior process of the calcaneus, but can also demonstrate fractures of the base of the fifth metatarsal
	Inversion stress	Best performed with a calibrated standardized device needed to position and stress the ankle	Check for lateral instability
	Eversion stress	Best performed with a calibrated standardized device needed to position and stress the ankle	Check for medial instability

(Continued)

TABLE 7-1 Standard and Special Radiographic Views (Continued)

Region	Common Views/ Special Views	Patient Position	Purpose and Structures Imaged
Foot	Dorsoplantar	Patient supine with the knee flexed and the sole of the foot resting on the x-ray cassette. Central ray is perpendicular to the base of the third metatarsal	A frontal projection of the tarsals, metatarsals, and phalanges; tarsometatarsal, metatarsophalangeal, and interphalangeal joints
	Lateral	Lateral side down with the patient supine. The central ray is perpendicular to the midfoot	A true lateral projection of the talocrural, subtalar, transverse, and tarsometatarsal joint; hind foot, midfoot, and forefoot relationships
	Medial oblique	Supine with the knee flexed and the leg rotated medially until the sole of the foot forms an angle of 30 degrees to the plane of the film. The central ray is perpendicular to the midfoot	The calcaneocuboid, cuboid-fourth and fifth metatarsal, cuboid cuneiform, and talonavicular articulations Less overlap of tarsals than anteroposterior Good view of sinus tarsi
	Harris Beath (axial) view of the hind foot	The patient is positioned in sitting on the x-ray table, leg extended, and the heel resting on the cassette. The ankle is extended and held in this position by the patient applying traction to the forefoot with a bandage or strap. A 45-degree cranial tube angle is used with the primary beam entering the sole of the foot at the level of the base of the fifth metatarsal	Best shows the articular surfaces of both the posterior and medial subtalar joints, coalition at the medial facet, and avulsions fractures at the medial or lateral aspects of the calcaneal tuberosity
Cervical spine	A-P	The patient is placed either supine or erect. The central ray is 15–20 degrees cranial at the most prominent point of the thyroid cartilage	A frontal view of the C3–C7 vertebral bodies, and the upper two or three thoracic bodies, the interpedicular spaces, the superimposed transverse and articular processes, the uncinate processes, and the intervertebral disk spaces
	Lateral	The patient is lateral to the x-ray cassette, either seated or standing. The central ray is perpendicular to the midneck	A lateral view of the C1–C7 vertebral bodies, disk spaces, the articular pillars, spinous processes, and the lower five facet joints. Depending on how well the shoulders can be depressed, the seven cervical vertebrae and sometimes the upper one or two thoracic vertebrae can be seen; all seven cervical vertebrae, particularly in trauma cases, must be seen
	A-P obliques	Obtained by rotating the entire patient 45 degrees one way and then the other, obtaining images in each position	Provides information on the neural foramen and posterior elements of the cervical spine. Best view for detecting osteoarthritic encroachment of the intervertebral foramina
	A-P open mouth	The patient's head is positioned in slight extension to prevent the front teeth from being superimposed over the odontoid	Anteroposterior view of C1–C2 articulation. Fractures of C1 and arthritic changes at the C1–C2 facets may also be identified
	Flexion/extension laterals	Obtained by asking the patient to flex and then extend the neck, obtaining images in each position	Stress films to check for instability that may not be detected on routine neutral views

TABLE 7-1 Standard and Special Radiographic Views (Continued)

Region	Common Views/ Special Views	Patient Position	Purpose and Structures Imaged
	Pillar	An A-P view taken with 20–30 degrees of caudal tube angulation, with a pad under the upper thoracic spine to elevate the shoulders and to allow extension of the cervical spine	Shows the articular pillars or lateral masses to advantage as the central beam is angulated parallel to their sloping course, caudad in the A-P projection, and cranial in the P-A projection. Occult fractures may be detected with this view
	Swimmers view	Obtained by positioning the patient so that one arm is raised above their head and the other is by their side like a freestyle swimmer	Best view of C7–T2, prevents obstruction by shoulders. Proximal humerus, lateral clavicle, AC joint, superior lateral aspect of the scapula
Thoracic spine	A-P	Obtained with the patient in the supine position, arms by the side and shoulders at the same level. The knees are slightly flexed to reduce the dorsal kyphosis and the beam is sent to 10 cm below the sternal notch	T1–T12 vertebral end plates, pedicles, and spinous processes; intervertebral disk spaces; costovertebral joints; medial aspect posterior ribs
	Lateral	The patient is positioned standing side-on, with the shoulder just touching the Bucky for support. The arms are extended and the patient's balance is stabilized. The film is centered on T7	T1–T12 vertebral end plates, pedicles, spinous processes; intervertebral disk spaces and foramina
	Posterior oblique	The patient is positioned with their back against the bucky, and then rotated posteriorly so they are angled 45 degrees with the affected side touching the bucky. The arm on the affected side is positioned so that it is away from the area of interest (either out to the side, or over the patient's head)	Facet joints, pedicles, and the pars interarticularis
	Anterior oblique	The patient is positioned with their back against the bucky, and then rotated anteriorly so they are angled 45 degrees with the affected side touching the bucky. The arm on the affected side is positioned so that it is away from the area of interest (either out to the side, or over the patient's head)	Sternum, axillary portion of the ribs
Lumbar spine	A-P or posteroanterior	Either frontal projection is adequate and can be taken with the patient supine or erect with patient comfort dictating the position. If the patient is supine, the knees and hips should be flexed. The central ray is perpendicular to L3	A frontal view of the L1–L5 vertebral bodies, pedicles, disk spaces, the lamina, and the spinous and transverse processes. The Ferguson view is an A-P view with a cranial angulation, which essentially compensates for the normal lordosis of the lumbosacral region, and allows one to see the junction clearly
	Lateral	Supine or erect. If supine, the left side is down with the hips and knees flexed to a comfortable position. The central ray is perpendicular to L3	A lateral view of the lumbar vertebral bodies and their disk spaces, the spinous processes, the lumbosacral junction, sacrum and coccyx, the intervertebral foramina, and the pedicles

(Continued)

TABLE 7-1 Standard and Special Radiographic Views (Continued)

Region	Common Views/ Special Views	Patient Position	Purpose and Structures Imaged
	Obliques	The patient is positioned in supine with their body angled 30–45 degrees	Not only shows the neural foramina but also demonstrates the pars interarticularis to aid in the detection of spondylolysis; best view of facet joints
	L5–S1 (coned down lateral) spot view	The patient is positioned standing in a lateral position with the arms across the chest	Lateral of L4–S1 vertebral bodies and disk spaces
	Flexion–extension	The patient is positioned standing side-on and is asked to flex and extend the lumbar spine. An image is taken at each position	May enhance spondylolisthesis or retrolisthesis or demonstrate pivotal motion at a given disk
Sacroiliac joint	A-P axial, obliques	The patient is positioned in standing, with the af ected side rotated 20–30 degrees away from the film.	A-P images bilateral sacroiliac joints; obliques image unilateral sacroiliac joint
Pelvis	A-P	Supine with the feet internally rotated approximately 15 degrees. Central ray perpendicular to the midpoint of the pubic symphysis	A frontal view of the pelvic girdle and proximal third of both femora
	Oblique	Also called the bilateral "frog-leg" position, and the patient is positioned accordingly for a bilateral view	Detection of acetabular and pubic rami fractures
	Inlet	Patient supine and the beam angled 10 degrees cranially	
	Outlet	Patient supine and the beam angled 15 degrees caudad	
	Judet	Patient positioned so that the injured side is rotated 45 degrees internally and externally	Internally rotated: an anterior oblique view or obturator oblique view is obtained which demonstrates the iliopubic (anterior) column and the posterior lip of the acetabulum Externally rotated: a posterior oblique view or iliac oblique view is obtained which shows the ilioischial (posterior) and the anterior acetabular rim

A-P, anteroposterior; P-A, posteroanterior.

Data from Shankman S. Conventional radiography and tomography. In: Spivak JM, Di Cesare PE, Feldman DS, et al., eds. Orthopaedics: A Study Guide. New York, NY: McGraw-Hill, 1999:173–178; Barr JB. normal, the angle of the ribs, the presence of any osteophytes, whether there is any wedging of the vertebrae, and whether there are any Schmorl's nodes indicating herniation of the IVD into the vertebral body.

Lumbar Spine

Routine projections for the lumbar spine are the posteroanterior (P-A) or A-P, and lateral views (Table 7-1). Lower back radiographs have been described as the single most overprescribed diagnostic imaging procedure.[21,22] Specific guidelines have been developed by the Agency for Health Care Policy and Research to help reduce the ordering of lumbar plain films that are of minimal diagnostic value.[21] Imaging in the event of spinal trauma must be fully evaluated regarding the forces involved as well as the metabolic bone health of the patient.[1] Symptoms that are not relieved by rest or changes in position, symptoms that sharply increase with movement, unremitting paraspinal musculature spasm, and an unwillingness to move the spine all suggest a spinal fracture.[1]

Pelvis

Routine projections for the pelvis are outlined in Table 7-1. Additional views include the following:

Prone view of the symphysis pubis. T is view improves the detail of the symphysis in patients with a groin strain, as well as demonstrating the pubic rami. T e view is taken with the patient lying prone to bring the symphysis close to the film and with 20–30 degrees of cranial tube angulation.

Obturator view. T is view, which can be obtained supine or prone, provides the clinician with more detail of the pubic rami and ischial tuberosities. In the supine position, the cranial angulation of the tube is 25–30 degrees and, if the prone

position is used, the angulation is caudal. The primary beam is centered just below the inferior margin of the symphysis.

Flamingo views. These views of the symphysis are used in the diagnosis of pelvic instability by demonstrating movement of the symphysis under weight-bearing stress. Two P-A views of the symphysis are obtained with weight bearing on each leg in turn. Any movement at the symphysis in excess of 2 mm is considered abnormal.

Cone P-A/A-P view. These views of the sacroiliac joints (SIJs) are used when an abnormality of the SIJ is suspected on a routine view of the pelvis. A tube angulation of about 30 degrees is used although this will vary depending upon the lumbar curve.

Shoulder

Radiographic examination of the shoulder girdle may be tailored to any given clinical situation. A trauma series consists of an A-P, axillary, and scapular lateral views (Table 7-1).

A-P view. A true A-P of the shoulder girdle is one in which the x-ray beam is perpendicular to the scapula. This requires obliquing the patient 45 degrees such that the scapula itself is parallel to the x-ray cassette. In this way, the glenohumeral (GH) joint is seen without overlap of the humeral head and glenoid fossa. One view that is helpful in the evaluation of impingement syndrome is the outlet view, which centers the beam at the coracoacromial arch. A standing bilateral A-P image is used to assess the clavicle and acromioclavicular (AC) joint.

Axillary. This view shows the relation of the humeral head to the glenoid and is used to diagnose anterior and posterior dislocations at the GH joint, AC joint dysfunctions, and to look for avulsion fractures of the glenoid or a Hill–Sachs lesion (see Chapter 16). The technique requires that the patient be able to abduct the arm 70–90 degrees.

Scapular-Y. The "scapular-Y" view, obtained by tilting the x-ray beam approximately 60 degrees relative to the A-P view, provides good visualization of the humerus relative to the glenoid and the acromion and coracoid process.[23]

Stryker notch view. The patient is positioned in supine with the arm forward flexed and the hand on top of the head. The beam is centered on the coracoid process. This view is used to assess a Hill–Sachs lesion or a Bankart lesion (see Chapter 16).

West point view. The patient is positioned in prone. This projection gives a good view of the glenoid to delineate glenoid fractures.

Arch view. The arch view is used to determine the width and height of the subacromial arch and helps to determine the type of acromial arch (see Chapter 16).

Elbow

The standard x-ray series of the elbow includes A-P and lateral views (Table 7-1).[24]

- A-P view. The A-P view is taken with the elbow extended, and the forearm supinated, with the x-ray beam directed perpendicular to the anterior aspect of the elbow. The A-P view demonstrates the humeroradial and humeroulnar joints, as well as the medial and lateral epicondyles. The carrying angle of the elbow can also be measured from the A-P view.
- Lateral view. The lateral view is taken with the elbow flexed at 90 degrees and forearm in a neutral position, with the x-ray beam directed perpendicular to the lateral aspect of the elbow. The lateral view best demonstrates the coronoid process of the ulna and the tip of the olecranon. Fat pads are also best identified on the lateral view.

Special views can be ordered to help define specific symptomatic areas and include oblique, axial, radial head, and stress views.

Medial oblique views. This view is taken with the arm internally rotated, the elbow extended, and the forearm pronated. This view allows better visualization of the trochlea, olecranon, and coronoid process of the ulna.

Lateral oblique views. This view is taken with the arm externally rotated, the elbow extended, and the forearm supinated. The lateral oblique view provides good visualization of the radiocapitellar joint, proximal radioulnar joint, and medial epicondyle. Often nondisplaced or minimally displaced fractures and loose bodies not seen on the A-P or lateral views will be demonstrated on the oblique views.

Axial view. The axial view is obtained with the arm on the cassette; the elbow flexed to 110 degrees, and the x-ray beam directed perpendicular to the arm. The reverse axial view is obtained with the forearm on the cassette, the elbow completely flexed, and the beam projected perpendicular to the forearm. The axial and reverse axial views best demonstrate the olecranon fossa and the olecranon, respectively.

Radial head view. The radial head view will help identify occult radial head fractures. This view is obtained with the elbow flexed to 90 degrees and the beam angled at 45 degrees to the lateral elbow. A-P stress views demonstrate subtle changes in joint space and congruency with varus or valgus stress on the elbow. These changes are then compared to the nonstressed A-P view, or to a stress view of the opposite side. Widening of the radiocapitellar joint with varus stress reflects injury to the lateral ligaments. Widening of the humeroulnar joint with valgus stress reflects injury to the medial ligaments.

The radiocapitellar view is especially helpful in demonstrating radial head and capitellum fractures. On the lateral view of the elbow, a line is drawn through the mid portion of the radius that normally passes through the center of the capitellum. The lateral projection angles the central beam cranially, projecting the radiocapitellar joint free of the ulnar trochlear articulation. Views of the cubital tunnel can be obtained with the elbow flexed approximately 45 degrees, and the forearm supinated with its posterior (dorsal) surface against the x-ray cassette. The central ray is angled approximately 20 degrees with respect to the olecranon process. This is mostly useful for inspecting the bony aspect of the cubital tunnel where the ulnar nerve lies and can show osteophytes and loose bodies.

Wrist

In addition to the standard and special radiographic views depicted in Table 7-1, an anterior oblique position or semi-supinated oblique view may be obtained for the evaluation of arthritis. From the lateral position, the forearm is supinated until the wrist forms an angle of approximately 45 degrees with the plane of the film. The pisiform-triquetral joint compartment

is only seen with such a view. Early erosions that are associated with inflammatory arthritis, especially rheumatoid arthritis, may occur at this joint. Stress views of the first carpometacarpal joints can be obtained by asking the patient to press the tips of the thumb together with the hands in a nearly lateral position. Radial subluxation of the first carpometacarpal joint is most commonly seen in basal joint osteoarthritis.

The carpal tunnel view is taken with the wrist hyperextended. The x-ray beam is angled along (parallel to) the anterior aspect of the wrist showing the bony anatomy of the carpal tunnel. This view is helpful in detecting erosions in the carpal tunnel and may detect occult fractures of the hook of the hamate, which may be difficult to see on routine radiographs.

Motion series of the wrist may aid in the detection of ligamentous injuries that result in instability. This includes P-A radial and ulnar deviation views and lateral anterior and dorsiflexion views. Such static views may be normal in the setting of ligamentous injury, and dynamic video fluoroscopy of the wrist may be required. The clenched fist anterior–posterior view may demonstrate a scapholunate dissociation by driving the capitate proximally between the lunate and scaphoid. Specialized views of the scaphoid itself have been designed for the detection of occult fractures.

Hand

All significant hand injuries, including those with any degree of swelling, should be evaluated radiographically even if the likelihood of a fracture seems remote.[25] Chip or avulsion fractures cannot be suspected based on the clinical examination alone and yet if undetected, and untreated may result in a significant disability.[25] Rotational deformity involving the metacarpal or proximal phalanx can result in a poorly functioning partially disabled hand. With a rotational alignment of the distal interphalangeal joint, the planes of the fingernails are not parallel when one compares the planes of the injured nail to the normal fingernail of the opposite hand.

In addition to the standard and special radiographic views depicted in Table 7-1, stress views of the first metacarpophalangeal joint may be required for evaluation of the ligamentous injuries. Specifically, abduction stress views of the injured and normal form may demonstrate widening of the ulnar aspect of the joint with radial subluxation of the proximal phalanx when the ulnar collateral ligament is disrupted, as with the "game-keeper thumb" (see Chapter 18). Fractures of the fourth and fifth metacarpals are frequently undetected until a lateral view with 10 degrees of supination is obtained.[25] Second and third metacarpal injuries are often detected on a lateral view with 10 degrees of pronation.[25] Finger injuries require a true lateral view without superimposition of the other digits.[25]

Hip

There are two projections in the routine hip series (Table 7-1):

- A-P view. This view allows the clinician to
  - compare the two hips for symmetry.
  - note the neck shaft angle (coxa vara or coxa valga), and the shape of the femoral head.
  - view the joint spaces (presence of osteophytes or arthritis), pelvic lines, and other landmarks.
  - note the presence of any bone disease (e.g., Legg–Calve–Perthes disease).
  - note any evidence of fracture, dislocation, or pelvic distortion.
- Lateral-oblique view. This view allows the clinician to look for any pelvic distortion or any slipping of the femoral head.

In addition to the standard and special radiographic views, cross-table lateral filming is the best approximation of a true lateral film of the hip and is particularly useful in assessing subtle subcapital fractures and as a postoperative evaluation of hip arthroplasty. The patient is positioned in supine with the film cassette centered at the greater trochanter. The knee and hip of the unaffected side are flexed. The central ray is perpendicular to the long axis of the femoral neck and the film cassette. The Judet view is used if there is a suspicion of a fracture in the region of the acetabulum. This view is taken by rolling the patient 40 degrees one way and then the other, acquiring images in both positions by using a straight tube centered on the femoral head.

CLINICAL PEARL

- Pistol grip deformity: abnormal head-neck offset (i.e., flattening of the superior femoral head).
- Sagging rope sign: occurs with Legg–Calve–Perthes disease as a result of osteonecrosis of a developing femoral head, and indicates damage to the growth plate.
- Teardrop sign: results from superior migration of the femoral head in relation to the pelvis due to joint degeneration. The teardrop sign is visible at the base of the pubic bone, extending vertically inferiorly to terminate in a round teardrop or head.

Tibiofemoral Joint

In addition to the standard and special radiographic views depicted in Table 7-1, weight-bearing views of the knees with and without flexion are particularly helpful in the evaluation of arthritis and the detection of joint space narrowing which may not be as obvious with nonweight-bearing or nonstanding views. Weight bearing with flexion is particularly helpful in the detection of osteoarthritis when focal cartilage loss can be seen posteriorly. The Ottawa knee CDRs and the Pittsburgh CDRs are guidelines for the selective use of radiographs in knee trauma. Application of these rules may lead to a more efficient evaluation of knee injuries and a reduction in health costs without an increase in adverse outcomes.[15] The Ottawa knee CDRs, which have been demonstrated to have near 100% sensitivity for knee fractures and reduce the need for knee radiographs by 20% when used by emergency physicians,[6] is summarized in Table 7-2. The Pittsburgh CDR of the knee indicating the need for radiographic studies is summarized in Table 7-3.

Patellofemoral Joint. Standard workup for patellar instability include anteroposterior (A-P), lateral, and one of several patellofemoral views (sunrise/skyline view at 20 degrees of knee flexion, or a Merchant view at a 30-degree downward

TABLE 7-2 Ottawa Knee Rules for Radiography	
Indications for Radiography, if Any	**Exclusion Criteria**
Patients older than 55 years	Age younger than 18 years
Tenderness at the head of the fibula	Isolated superficial skin injuries
Isolated tenderness of the patella	Injuries more than 7 days old
Inability to flex to 90 degrees	Recent injuries being reevaluated
Inability to weight bear four steps both immediately after the injury and in the emergency department	Patients with altered levels of consciousness Paraplegia or multiple injuries

Data from Seaberg DC, Yealy DM, Lukens T, et al. Multicenter comparison of two clinical decision rules for the use of radiography in acute, high-risk knee injuries. Ann Emerg Med. 1998;32:8–13.

angle on a knee flexed at 45 degrees).[26] For patella height the Insall–Salvati ratio is the vertical length of the patella over the length of the patella tendon (from the inferior pole of the patella to the tendon's corresponding insertion on the top of the tibial tubercle).[27] Alternatively, the Blackburn–Peel ratio is the length of a patellar articular surface divided by the distance from the distal patella to a line crossing through the lowest pole of the tibial plateau.[27] Trochlea dysplasia is evaluated on lateral radiographs by the crossing sign—the intersection of the trochlea floor and the most anterior edge of the lateral femoral condyle.[28]

- Lateral radiographs.[29] Radiographs should include a lateral view with posterior condyles approximated as closely as possible. The distance between the lateral femoral condyles and the trochlea is a measure of trochlear depth. The absence of the groove at any point along the trochlear arc is pathologic.
- Axial radiographs.[29] The axial view should be obtained in the manner described by Merchant et al.,[26] but with the knee flexed 50 degrees rather than 45 degrees to better detect abnormal tilt and lateral displacement. Lateral displacement, in particular, is most pronounced in the early degrees of flexion, before the patella engages the trochlear groove.

Ankle

The Ottawa ankle CDR was developed to help predict fractures in patients with ankle injuries and has been shown to be 100% sensitive and 40% specific and to reduce the need for ED ankle radiographs by 36%.[6,30] Using this CDR, radiography is indicated if any of the following are present:

- Bone tenderness at the posterior edge or tip of the lateral malleolus.
- Bone tenderness at the posterior edge or tip of the medial malleolus.
- Inability to bear weight both immediately and in the ED.

Standard views of the ankle include the A-P, mortise, and lateral views (Table 7-1):

A-P view. This view provides the clinician with information about the shape, position, and texture of the bones, and helps determine whether there is any fractured or new subperiosteal bone.

Mortise view. This view provides information about the ankle mortise and the distal tibiofibular joint.

Lateral view. This view provides the clinician with information about the shape, position, and texture of bones, including the tibial tubercle, talus, and calcaneus.

Other nonroutine views include the following:

- Dorsoplantar view of the foot. This view provides information with regard to the forefoot.
- Medial oblique view of the foot. This view provides information about the tarsal bones and joints and the metatarsal shafts and bases. In addition, this view can highlight any pathology in the calcaneocuboid joint.

Stress views of the ankles are routinely utilized for assessment of instability and injury to the lateral collateral ligament of structures (Table 7-1). Both the affected and normal sides are examined for comparison. Complete tears of the deltoid ligament may be demonstrated with eversion stress. However, the value of stress roentgenograms of the ankle is a controversial topic.[31,32]

TABLE 7-3 Pittsburgh Decision Rules for Radiography	
Indications for Radiography if the Mechanism of Injury is Blunt Trauma or Fall and Either	**Exclusion Criteria**
The patient is younger than 12 or older than 50 years	Knee injuries sustained more than 6 days before presentation
The injury causes an inability to walk more than four weight-bearing steps in the emergency department	Patients with only superficial lacerations and abrasions History of previous surgeries or fractures on the affected knee Patients being reassessed for the same injury

Data from Seaberg DC, Yealy DM, Lukens T, et al. Multicenter comparison of two clinical decision rules for the use of radiography in acute, high-risk knee injuries. Ann Emerg Med. 1998;32:8–13.

The stress views include inversion to assess talar tilt and the anterior drawer stress. The accuracy of these tests increases with the use of local anesthesia and a comparison with the uninvolved ankle.

The anterior drawer test is performed with a lateral view of the ankle in a neutral position while attempting to manually translate the foot anteriorly with respect to the leg.[31,32] The sagittal plane translation of the talus with respect to the tibia is measured. When compared with the same foot unstressed, anterior subluxation of more than 3 mm is considered to indicate an anterior talofibular ligament (ATFL) injury.[33]

The talar tilt test is used more often and is felt to be more reliable. In this examination, a mortise or A-P view of the ankle held in neutral position to slight plantar flexion with an inversion stress applied to the foot is obtained.[31,32] The angle to be measured is that formed by a line parallel to subchondral bone of the distal tibia and proximal talus. It is the consensus that a talar tilt test is positive when the injured ankle has a stressed tibiotalar angle of 5–15 degrees[34,35] greater than the uninjured side. However, the absolute number of degrees is not as important as the functional instability of the patient, as laxity does not always mean instability.[31,32]

Stress Radiograph

A stress radiograph is a procedure using radiographs taken while a stress is applied to a joint. An unstable joint demonstrates widening of the joint space when the stress is applied. For example, spine flexion and extension views can be helpful in assessing spinal mobility and stability and are typically ordered in the acutely injured athlete when there is a high degree of suspicion of spine injury. Greater than 2 mm of motion beyond normal at any segmental level in the spine would suggest instability and warrant further examination.

Video Fluoroscopy

Fluoroscopic procedures involve the use of x-rays to evaluate the quality and quantity of joint motion. Because of the relatively high exposure to radiation with this technique, it is used mainly in the detection of joint instability.

Contrast-Enhanced Radiography

Contrast-enhanced radiography procedures involve the use of a contrasting agent to highlight different structures. These agents may be administered orally, rectally, or by injection. Different contrast media may be used and include radiopaque organic iodides and radiotranslucent gases. Contrast-enhanced radiography procedures include the following:

- Arthrography. Arthrography is the study of structures within an encapsulated joint using a contrast medium with or without air that is injected into the joint space. The contrast medium distends the joint capsule. This type of radiograph is called an arthrogram. An arthrogram outlines the soft tissue structures of a joint that would otherwise not be visible with a plain-film radiograph. This procedure is commonly performed on patients with injuries involving the shoulder or the knee. The primary general indications for performing a conventional arthrogram are[36]
  - to confirm intracapsular positioning of a needle or catheter following a joint aspiration or prior to an anesthetic joint injection
  - in place of an MR scan (see later) if it is not available, contraindicated, or if the patient is too obese for the gantry or is claustrophobic
  - for the diagnosis and treatment of adhesive capsulitis

  Arthrography can also be performed in conjunction with magnetic resonance imaging (MRI) or computed tomography (CT) (see later).
- Myelography. Myelography is the radiographic study of the spinal cord, nerve roots, dura mater, and spinal canal. The contrast medium is injected into the subarachnoid space, and a radiograph is taken. This type of radiograph is called a myelogram. Myelography is used frequently to diagnose IVD herniations, spinal cord compression, stenosis, nerve root injury, or tumors. The nerve root and its sleeve can be observed clearly on direct myelograms. When myelography is enhanced with CT scanning, the image is called a CT myelogram (CTM) (see later).
- Diskography. Diskography is the radiographic study of the IVD. A radiopaque dye is injected into the disk space between two vertebrae. A radiograph is then taken. This type of radiograph is called a diskogram. An abnormal dye pattern between the IVDs indicates a rupture of the disk. The indications for lumbar or cervical diskogram are[36]
  - severe or unremitting low back or neck pain with or without radicular symptoms in a patient with negative standard imaging studies or degenerative disk disease
  - for use in preoperative planning prior to spinal fusion to include only those painful disk levels
  - in the evaluation of neural foramina masses, which may represent an extruded disk herniation or nerve sheath tumor
  - to determine accurate needle placement prior to chymopapain injection
  - persistent pain in the postoperative period
- Angiography. Angiography is the radiographic study of the vascular system. A water-soluble radiopaque dye is injected either intra-arterially (arteriogram) or intravenously (venogram). A rapid series of radiographs is then taken to follow the course of the contrast medium as it travels through the blood vessels. Angiography is used to help detect injury to or partial blockage of blood vessels. The indications for angiography are[36]
  - as a diagnostic study, following possible vascular injury from trauma
  - embolization of active bleeding sites not amenable to surgical control, such as within the pelvis
  - evaluation of bone and soft tissue tumors (the findings will assess neovascularity of the lesion, the extent of the tumor, and invasion or impingement of major vessels)
  - preoperative or palliative intra-arterial embolization or chemotherapy
  - diagnosis and treatment of arteriovenous malformations

- evaluation of the arterial anatomy prior to bone or soft tissue grafts
- diagnosis of arteritis that is further complicating collagen vascular disease

Computed Tomography

T e word "tomography" is derived from the Greek tomos (slice) and graphia (to write). CT images are useful to evaluate injured areas where the 3D configuration of the structure makes the plain radiographs difficult to interpret.[25] T e CT image is not recorded in a conventional radiographic manner. A CT scanner system, also known as computerized axial tomography (CAT) and computerized transaxial tomography (CTI), consists of a scanning gantry, which holds the x-ray tube and detectors (moving parts), a moving table or couch for the patient, an x-ray generator, a computer processing unit, and a display console or workstation.[37] Images are obtained in the transverse (axial) plane of the patient's body by rotating the x-ray tube 360 degrees.

T e images are produced by rotating a thin collimated x-ray beam through a 180-degree arc around the patient such that structures of a certain depth will be stationary in the beam and appear with enhanced clarity, whereas tissues superficial and deep to this level will be relatively obscured by motion. T e basic principle of any tomographic system is that all parts of the object that are perpendicular to the direction of the tube motion are maximally blurred, whereas those parts that are parallel to the direction of motion are not blurred but merely elongated.

Like conventional radiography, CT also uses radiation, but instead of a unidirectional beam, both the radiation source and detector systematically encircle the body. T e x-rays are absorbed in part by the patient's body. T e number of x-rays transmitted through the body is detected on the opposite side of the gantry by an array of detectors. Each array detector responds to the amount of rays detected by downloading data to the system's computer, which assigns a numeric value based on the attenuation property of the various tissues of the body, and then forms an image based on the differential absorption of the x-rays. T ese attenuation values, or relative attenuation coefficient (μ), are expressed in Hounsfield units (HU) and are normalized to water.[7] Hence, water measures 0 HU, bone (the highest absorption values) measures >400 HU, muscle measures 40 HU, fat measures −120 HU, and air (the lowest absorption values) measures −1,000 HU.[37] In essence, the CT image is a map of the linear attenuation value of the tissue. By adjusting the level and the width of the displayed ranges of HU (window), the operator can study different tissues optimally. Software has been introduced over the years to allow for fast image reconstruction in any desired plane (2D) or surface reconstruction (3D).[37] CT depends upon multiple thin slices of radiation that are "backplotted" through Fourier transformers. T e continuous movement offered by spiral CT, referred to as multislice or multidetector CT scanners, greatly reduce scan time. T ese newer multislice CT scanners represent a major improvement in helical CT scan technology, wherein simultaneous activation of multiple detector rows positioned along the longitudinal or z-axis (direction of table or gantry) allows acquisition of interweaving helical sections.[38] With this design, section thickness is determined by detector size and not by the collimator (a device that filters rays so that only those moving parallel to a specified direction are allowed to pass) itself.[38]

Image quality in CT imaging depends on a variety of factors, which are mostly selected by the operator. Two parameters are used to define the image quality of a given system: spatial resolution and contrast resolution:[37]

- Spatial resolution: Spatial resolution is defined as the ability of the system to distinguish between two closely spaced objects. For improvement of spatial resolution, the operator selects a small matrix size (256 × 256), small field of view, and thin slices. Special reconstruction algorithms can also be chosen to improve spatial resolutions.
- Contrast resolution: Contrast resolution is defined as the ability of the system to discriminate between two adjacent areas with different attenuation values. T e operator has several choices to improve contrast resolution: appropriate selection of reconstruction algorithm, tube current (measured in milliamperes), scanning time (measured in seconds), pixel size (matrix), and slice thickness. It must be remembered that increasing tube current or scanning time increases the radiation dose. Another strategy to increase contrast resolution is to use contrast material, either intra-articular or intravenous. T e contrast resolution of CT is dramatically better than conventional radiography (approximately 100 times), and the images provide greater soft tissue detail than do plain films.[7]

Provided the patient remains motionless for the study, the CT scan provides good visualization of the shape, symmetry, and position of structures by delineating specific areas (Fig. 7-8). T is information can be helpful in the examination of acute trauma, aneurysms, infections, hematomas, cysts, and tumors.

FIGURE 7-8 CT image of a lumbar spine showing bilateral spondylolysis at the L5–S1 level.

Clinical Applications

Cervical Spine

CT is most often utilized in the cervical spine examination in the assessment of potential fractures, but may not be the modality of choice when used in isolation for soft tissue imaging. For example, the accuracy of CT imaging ranges from 72% to 91% in the diagnosis of disk herniation, but approaches 96% when combining CT with myelography.[39,40] A CTM is a diagnostic tool that uses radiographic contrast media (dye) that is injected into the subarachnoid space (cerebrospinal fluid [CSF]). After the dye is injected, the contrast medium serves to illuminate the spinal canal, cord, and nerve roots during imaging. T e low viscosity of the water-soluble contrast permits filling of the nerve roots and better visualization.[7]

CLINICAL PEARL

Multiple studies have indicated CT to be superior to radiography in detecting fractures of the cervical spine, even small fractures.[41]

Shoulder

CT is typically used for suspected fractures, particularly of the glenoid rim.

Elbow, Forearm, Wrist, and Hand

CT is preferred over radiography in cases of suspected ligamentous instability. In addition, fracture lines and fragment locations can best be delineated with the help of CT. CT has also been used to provide accurate assessment of the reorientation of the distal radius articular surface following fracture, which is critical in determining whether closed or open reduction is the preferred course of action.[42]

Pelvis and Hip

CT of the hip and pelvis is helpful with identifying the spatial relationships of fractures of the femoral head and acetabulum and any associated fragments, particularly in cases of complicated fractures.[43] CT is also recommended when considering congenital hip dysplasia, preoperative prosthesis planning, and the detection of neoplasms.[44]

Knee

CT scans are often used to view soft tissues as well as the bones of the knee joint complex.

Ankle and Foot

CT often enables delineation of cortical and trabecular orientations of bone, and the articular surfaces of the joints better than plain films. T is is particularly true in cases such as a talar dome injury.

MAGNETIC RESONANCE IMAGING

Unlike an x-ray, or CT, MRI does not use ionizing radiation but, rather, utilizes an apparently safe interaction between static magnetic fields, radiofrequency (RF) waves, atomic nuclei, and complex image reconstruction techniques.[45] T e ability to manipulate these interactions allows for different tissue contrast from the same anatomy, and the delineation of pathology.[46] An MRI can also aid in diagnosis, staging, and treatment monitoring. MRI has been a viable imaging technique since the early 1980s, and has now become the standard modality for differentiating among soft tissues in the neuromusculoskeletal system.[37] Certain nuclei (the most common being hydrogen, carbon 13, fluorine, sodium, and phosphorus) generate their own magnetic moment and so have an inherent interaction with external magnetic fields, which means they are able to abandon their normal random spatial orientations and align parallel or antiparallel when exposed to a large magnetic field.[46] Clinical MRI primarily utilizes the abundant hydrogen nuclei, which are present as bound or free water in the body.[46] Protons also have a natural spinning motion at a specific frequency (Lamor frequency). When an RF pulse of the same frequency as that of the spinning protons within the magnetic field is applied, the protons are deflected from their newly aligned axis by a specific angle, with the degree of deflection being dependent on the strength of the applied RF wave pulse. T e angle by which the magnetization is tipped (also known as the flip angle) is also dependent on the length of time the RF pulse is applied.[46] T e protons, now spinning synchronously, or coherently, at an angle with the magnetic field, induce a current in a nearby transmitter–receiver coil or antenna. A range of receiver coils is available to suit different anatomical areas of interest, and provide the best signal-to-noise ratio. T is small nuclear signal is then recorded, amplified, measured, and localized (linked to the exact location in the body where the MRI signal is coming from), producing a high contrast, clinically useful MR image. T e signal starts to decay or relax, as soon as the RF pulse is discontinued, and the protons begin to return back to a state of equilibrium. T e decaying of the signal is intimately related to two relaxation processes:

- T e realignment of the protons within the magnetic field (longitudinal relaxation). T is is an exponential process that depends on the interaction of the nucleus with its surroundings.
- T e time constant that describes the process whereby the nucleus spins go out of phase with each other (dephasing), losing their initial coherence and synchronization as they continue spinning at an angle to the magnetic field (transverse relaxation).

T ese two phenomena, called T1 (longitudinal) and T2 (transverse) relaxation times, are biological parameters with tissue-specific relaxation constants for different types of tissue and their molecular composition. Both of these processes occur together and cannot be separated; but pulse sequences (see later) can be chosen to increase the contribution of either T1 or T2, to optimize the required contrast.[45] T1 refers to the time it takes for the tissue to recover 63% of its original longitudinal magnetization, whereas T2 refers to the time it takes for 63% of the original excited transverse magnetization to remain.[46] Each biological tissue type has different characteristic T1 and T2 rates, which are affected by the nature of the tissue.[46] For example, tissues such as water have very mobile

protons that return very quickly to alignment in the magnetic field, whereas bone protons are largely immobile. A change in relaxation times may indicate pathology.[46] For example, an increase in fat associated with muscle atrophy will shorten T1 and T2 times; whereas the elevated water associated with muscle edema, and muscle denervation, will both lengthen relaxation times.[46] T1 and T2 can be measured independently to create images that are dependent on different T1 values of the tissues (T1-weighted images [T1WI]) or on different T2 values (T2-weighted images [T2WI]). Images containing T1 and T2 information are called balanced images or proton density-weighted images (PDWI). Tissue contrast develops as a result of the rates at which nuclei realign with the main magnetic field and is dependent on the differences between T1, T2, and the proton density values on T1WI, T2WI, or PDWI. For example, fat (including marrow fat) is bright on T1WI, while CSF is dark, and structures with high fibrous tissue content such as tendons, ligaments, and cortical bone are also dark. With T2WI, fluids including CSF, synovial fluid, and edema are bright, while the fat signal varies, and fibrous structures such as tendons, ligaments, and cortical bone are again dark.

CLINICAL PEARL

Contrast agents can be used in MRI to change the T1 and T2 relaxation properties. For example, a gadolinium-based contrast agent is used to shorten both T1 and T2 relaxation times.[46]

T e specific techniques for obtaining the MRI are called pulsed sequences. Most MRI uses a spin echo (SE) technique to produce high-quality images, but at the cost of long scan times and high-energy deposition in tissue.[45] Gradient recalled echo (GRE) sequences reduce the scan time and energy deposition at the cost of some quality, particularly where tissues of different types interface.[45] Another echo type is the stimulated echo, which requires three 90-degree RF pulses in a row, which has half the signal-to-noise ratio of an equivalent SE sequence. Image contrast can be enhanced by manipulating two sequence factors: the repetition time (TR), echo time (TE):

- Repetition time. T is is the amount of time between successive RF pulses applied to the same slice.
- Echo time. T is represents the time in milliseconds between the application of the 90-degree pulse and the peak of the echo signal. By changing these parameters, the operator can control the rate of repetition of the RF pulses (TR), the time elapsed between an RF pulse and the production of the signal or echo (TE), and the intensity of the applied RF pulse which determines the FA.
- Images obtained using short TR and short TE will produce T1-weighted contrast.
- Images obtained with long TR and long TE will produce T2-weighted contrast
- Images obtained with long TR and short TE will produce PD-weighted contrast.

Table 7-4 itemizes the differences in signal intensities on T1-weighted and T2-weighted MR images.

Because of the unique properties of magnetic imaging, MRI is subject to a number of artifacts. T e most important of these are metallic artifacts, specifically those produced by ferromagnetic objects, which distort the alignment of protons in the scanner's main magnetic field.[7] Such spatial distortion may produce grossly erroneous measurements. Somewhat less common artifacts include banding artifacts, "wrap-around" (an adjacent area wrapping into the area of interest, seen on very small fields of view) and chemical shift artifact

TABLE 7-4 Differences in Signal Intensity on T1-Weighted (T1W) Versus T2-Weighted (T2W) Images

Tissue	T1W	T2W
Cortical bone	Low	Low
Tendons and ligaments	Low	Low
Fibrocartilage	Low	Low
Muscle	Intermediate	Intermediate
Nonneoplastic tumor	Low intermediate	Low/intermediate/possible high
Neoplastic tumor	Low intermediate	Intermediate-high/possible low
Water, CSF	Low	High
Inflammation	Low	High
Proteinaceous fluid, abscess	Intermediate	High
Fat	High	High (slightly lower than on T1W)
Hemorrhage, acute	High	High
Hemorrhage, chronic	Low	High

Data from Morris C, ed. Low Back Syndromes: Integrated Clinical Management. New York, NY: McGraw-Hill, 2006:495.

(seen when tissues and markedly different chemical structures lie directly adjacent to one another, for instance, at the discovertebral interface).[7]

Magnetic Resonance Spectroscopy

Magnetic resonance (MR) spectroscopy is an advanced MRI technique involving the addition of a series of tests to a traditional MRI scan that compare the chemical composition of normal tissue with abnormal tissue, and makes an assessment of the chemical metabolism of the tissues. MR spectroscopy can analyze molecules such as amino acids, lipids, creatine, and hydrogen ions or protons. T us, MR spectroscopy can provide detailed information about the structure, dynamics, reaction state, and chemical environment of a variety of tissues. For example, MR spectroscopy has been used to explore and quantify the metabolic environment of the spinal cord and brain in patients with varying spinal conditions with neurological compromise, such as myelopathy, chronic whiplash–related pain and disability, and fibromyalgia.[47]

Clinical Applications

T e advantages of MRI include its excellent tissue contrast, ability to provide cross-sectional images, noninvasive nature, and complete lack of ionizing radiation. MRI provides an excellent view of anatomic and physiologic tissues (Figs. 7-9 and 7-10). It is commonly used to assess the CNS and soft tissue injuries. For example, it is ideal for examining striatal muscle volume, shape, and architecture. In addition, MRI has been shown to be sensitive in the detection of occult bone lesions, and it can also detect and help assess both occult and traumatic bone lesions, especially occult stress and posttraumatic fracture.[25] General contraindications for MRI include:[7]

- intracranial aneurysm clips
- cardiac pacemakers
- some prosthetic heart valves
- implanted cardiac defibrillators
- carotid artery vascular clamp
- spinal cord stimulators (neuro stimulators)
- insulin infusion pump (implanted drug infusion device)
- bone growth stimulator
- metallic hardware, devices, fragments
- hearing aids and dentures (must be removed)
- cochlear implants, ocular implants, penile implants
- some shrapnel and bullets
- intraocular foreign bodies
- tattooed eyeliner
- some types of makeup

FIGURE 7-9 MRI showing ACL-deficient left knee.

FIGURE 7-10 MRI showing ACL-deficient left knee—different view.

Spine

T e combination of multiplanar capabilities and high-contrast resolution that MR images provide are ideal for spinal imaging. Compared to CT and radiography, MRI provides for the best assessment of soft tissue pathology while also providing the only direct evaluation of the spinal cord.[47] MRI has demonstrated excellent sensitivity in the diagnosis of lumbar disk herniation, and is considered the imaging study of choice for detection and staging of demyelinating disorders involving the spine (e.g., multiple sclerosis), syringomyelia, and for detecting nerve root impingement, although the latter use is tempered by the prevalence of abnormal findings in asymptomatic subjects.[48] It can, however, detect ligament and disk disruption, which cannot be demonstrated by other imaging studies.[49,50]

Shoulder

It is important to image the GH joint with a dedicated shoulder coil.[47] Challenges that affect shoulder MRI include inherent off-center magnet placement of this joint, with reduction of the signal-to-noise ratio and less homogeneous fat suppression.[47] T e main indications for MRI of the shoulder

include rotator cuff pathology, proximal humerus fracture, biceps tendinopathy, GH joint instability, and shoulder pain of unknown etiology. The patient is positioned in supine with the arm in a neutral position as internal rotation of the shoulder creates structure overlapping. The shoulder joint is typically imaged in three planes:[51]

- Axial. These can be used to assess the subscapularis tendon, the extra-articular portion of the long head of the biceps tendon, the articular cartilage, the labrum (particular the anterior and posterior labrum); the joint capsule (including the superior, middle, and inferior GH ligaments), the A-C joint, and all the osseous structures, particularly the humeral head.
- Oblique coronal. These can be used to assess the supraspinatus and infraspinatus tendons, the biceps tendon anchor, the superior and inferior labrum, the articular cartilage, the axillary recess of the inferior GH ligament, the A-C joint, the osseous structures, and the deltoid muscle.[51]
- Oblique sagittal. These can be used to assess the rotator cuff interval with the coracohumeral ligament and the joint capsule, the intra-articular course of the long head of the biceps tendon, glenoid morphology, the A-C joint, and the morphology of the acromion.

Elbow

The main indications for MRI at the elbow joint are to differentiate bone and soft tissues, study mass lesions, tendon and ligamentous lesions, osteochondral lesions (including loose bodies), pediatric elbow fractures, compressive neuropathies, rheumatoid arthritis, biceps tendon injury, and miscellaneous conditions.[37] It is important to position the joint as close as possible to the center of the magnet, which usually involves placing the patient in a prone position.[45] Axial scans are best for evaluating the neurovascular structures, whereas sagittal scans best demonstrate the articular anatomy of the elbow joint.[45]

Hand and Wrist

The most frequent indications for MRI of the hand and wrist include: the evaluation of palpable mass lesions, ligamentous tears, triangular fibrocartilage complex tears, posttraumatic avascular necrosis of the scaphoid, Kienböck's disease (avascular necrosis of the lunate), tendon tears, and compressive neuropathies.[37]

Hip

MRI is most commonly used in the hip to evaluate for the presence of avascular necrosis or osteonecrosis of the femoral head.[37] Other indications for MRI of the hip include transient osteoporosis of the hip, osteochondral lesions, tumors, synovial chondromatosis, and pigmented villonodular synovitis (PVNS).[37]

Knee

The knee is one of the most commonly imaged areas of the musculoskeletal system by MRI.[52] Ligaments, tendons, and menisci all have highly ordered collagen ultrastructure, interfering with the movement of hydrogen molecules by magnetization by conventional sequences so that they are uniformly low in signal on traditional MRI pulse sequences.[53] Meniscal and ligamentous injuries (Figs. 7-9 and 7-10) can be diagnosed with an accuracy of almost 95%.[37]

Ankle and Foot

The most common indications for MRI of the ankle include tendon lesions, osteochondritis dissecans, chronic ankle instability, and pain of unknown etiology.[37]

DIAGNOSTIC ULTRASOUND (ULTRASONOGRAPHY)

Ultrasonography evolved with the development of military sonar, the sending and recording of a certain frequency of a sound wave as it is transmitted and then reflected off various objects. Although initially used primarily for abdominal imaging, ultrasound imaging is rapidly becoming appreciated for its musculoskeletal applications. Continuous or pulsed therapeutic ultrasound produces 1 MHz or 3 MHz thermal and nonthermal energy, whereas diagnostic ultrasound produces pulsed waves at 7.5–20 MHz that are processed to produce pulsed echo images. A diagnostic ultrasound system is composed of a set of transducers, a power system, and a computer unit with a display screen. The transducer, which is the device that sends and receives the ultrasound waves, is composed of an array of quartz crystals that generate these waves. As ultrasound waves are transmitted through the body, they are reflected at tissue interfaces, and the time it takes for the waves to be reflected back to the transducing probe allows the computer to produce an image. The reflectivity of the sound wave is influenced by two factors as follows:[54]

- The acoustic impedance of the two tissues composing the interface. Acoustic impedance is the product of the speed of sound transmission within the substance and the density of the material. The reflectivity is greatest at the interfaces between tissues of dissimilar acoustic impedance.
- The angle of incidence of the sound beam. When the angle of incidence of the sound beam is at 90 degrees or perpendicular to the tissue interface, the reflectivity is highest and decreases with increasing angle.

At highly reflective interfaces, almost all of the energy of the sound beam is reflected, producing a sound void area beneath the interface. This is occurs between soft tissues and air or calcium. The sound beam appears to be enhanced when it passes through tissue such as water or other fluids that do not absorb ultrasound, therefore, showing as sound void areas. Thus, different tissues transmit sound waves at different velocities and, therefore, create different images. More dense tissue such as bone and collagen reflects more waves than less dense tissue such as water or fat.

Ultrasonography is perhaps more operator dependent than any other imaging modality.[54] The ultrasound transducer must be held at a 90-degree angle to the scanning target tissue to prevent artifacts so that the maximal number of waves will be processed into an accurate image. Technical considerations

are also important because it is necessary to operate with high-resolution transducers to obtain images with sufficient diagnostic information. Despite its disadvantages, ultrasonography is a readily available technique, is less expensive than most other imaging modalities (with the exception of plain films), does not involve ionizing radiation, and is noninvasive.[54] In addition, it allows real-time imaging, a feature that is very useful for some conditions, such as snapping tendon syndrome or developmental dysplastic hip, where dynamic imaging provides additional information.[54] Some of the disadvantages of ultrasonography, including those already mentioned, are a small field of view and the presence of artifacts. Comet fail artifact is caused by deep echogenicity bands that cross tissue boundaries and is usually associated with metal or glass foreign bodies. Other artifacts are refraction and reverberation. Refraction occurs when the ultrasonography probe is not maintained at a 90-degree angle (perpendicular) to the examined tissues which can cause an incorrect depiction of structure or lesion. Reverberation occurs at highly reflective interfaces causing the appearance of phantom structures.

Ultrasonography can be used to diagnose any pathological condition that is located superficially enough to be detected by the transducer, and is currently used in orthopaedics to help detect soft tissue injuries, tumors, bone infections, and arthropathy and to evaluate bone mineral density. Tendons are well suited because of the parallel fascicles of collagen and the ground substance which provide different receptivity, attenuation, and backscatter. Ultrasonography is particularly useful in staging muscle injuries, allowing for a more accurate estimate of when an athlete can return to sport. Ultrasound imaging may also be used to assess the degree and quality of fracture healing and in the detection of synovitis and wood and plastic foreign bodies. Finally, ultrasonography can be used to confirm proper placement of an injection and provide diagnostic information as well as to provide treatment for inflammatory conditions such as bursitis, intra-articular loose bodies, cysts, and nerve thickening. Future uses for ultrasound imaging will likely include the placement of tissue grafts (stem cells, platelets, matrixes) to aid in the healing of injuries because of its real-time imaging capabilities.

RADIONUCLEOTIDE BONE SCANNING

Radionucleotide scanning studies involve the introduction of bone seeking isotopes, which are administered to the patient orally or intravenously and allowed to localize to the skeleton. T e photon energy emitted by the isotopes is then recorded using a gamma camera 2–4 hours later. T e pathophysiologic basis of the technique is complex but depends on localized differences in blood flow, capillary permeability, and metabolic activity that accompany any injury, infection, repair process, or growth of bone tissue.[25] T e most common radionuclide scanning test is the bone scan (Fig. 7-11). T is test is used to detect particular areas of abnormal metabolic activity within a bone. T e abnormality shows up as a so-called hot spot, which is darker in appearance than normal tissue. T e bone scan is an extremely sensitive but fairly nonspecific tool for detecting a broad range of skeletal and soft tissue abnormalities.

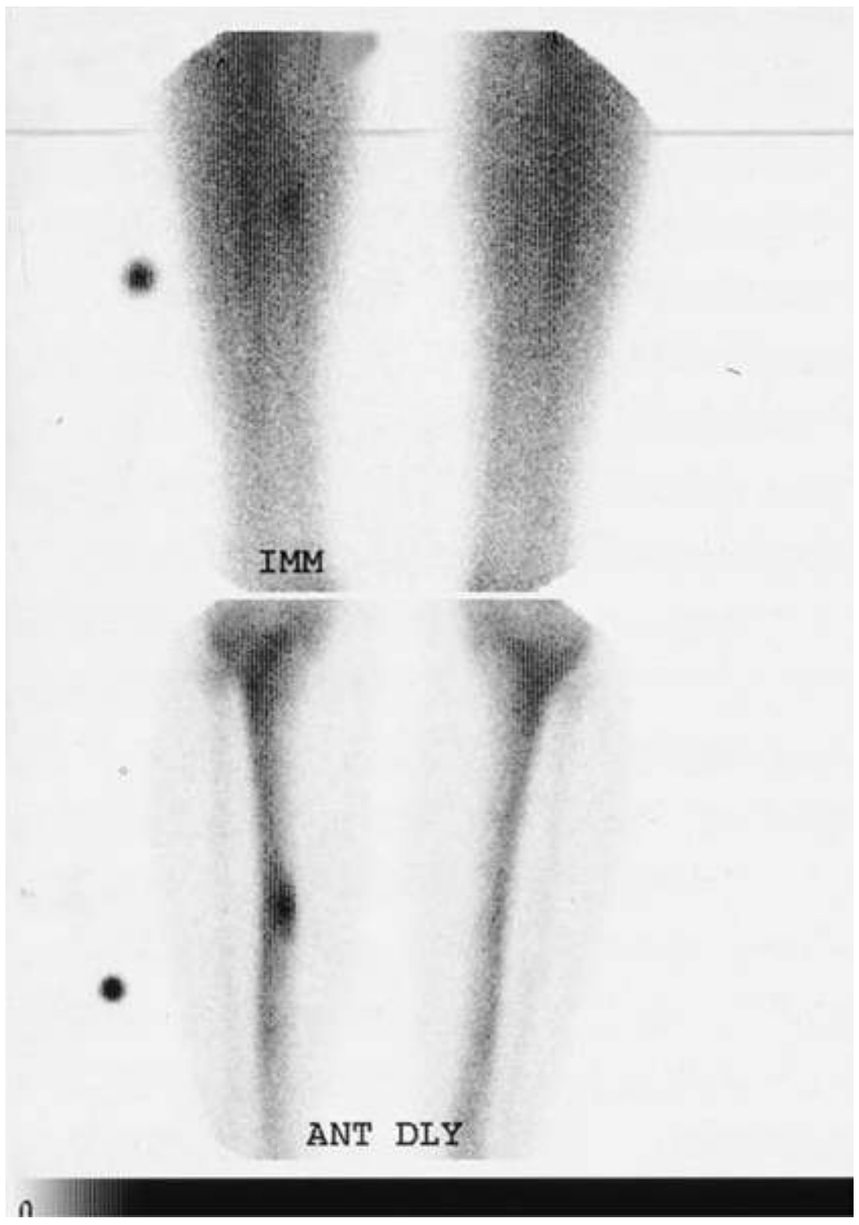

FIGURE 7-11 Bone scan showing stress fracture of the right tibia.

An abnormal bone scan may indicate tumor, osteonecrosis, a bone infection (osteomyelitis), Paget's disease, or recent fracture. Comparison of the affected and unaffected side is generally used to detect differences in uptake. Whole body or spot views, patient positioning, and the number of views employed depend on the indication for the examination.

Three Phase Bone Scan

T e three phase bone scan consists of the following image phases:[55]

1. Flow study. T e injection is the same as for a routine bone scan, but imaging is begun immediately after the injection. Sequential images are obtained every 2–3 seconds for 60 seconds.
2. Blood pool. Immediately following the flow study, a blood pool image is obtained over the area of interest. T is image serves as a marker of extravascular tissue activity.
3. Delayed static images. After a minimum of 2 hours, images are obtained over the area of interest. T ese images demonstrate radioisotope uptake in the osseous structures.

SPECT Scan

Single photon emission computed tomography (SPECT) scanning improves both the detection and localization of an abnormality by permitting spatial separation of bone structures that overlap on standard planar images.[55] After the acquisition of the study, a computer is used to reconstruct images in axial, sagittal, and coronal planes. To date, bone SPECT has been found to be of particular clinical value in studies of the vertebral column and has been shown to be more sensitive than

plain film radiology, with the majority of SPECT lesions corresponding to identifiable disease on CT.[55] SPECT scanning is a highly sensitive means of detecting spondylolysis, a fracture of the pars interarticularis.[55]

Clinical Applications

Radionucleotide bone scans are used throughout the body. Applications of the radionuclide bone scan can be divided into traumatic and nontraumatic categories as follows:[25]

- Traumatic.
  - Fractures.
  - Anatomically difficult locations. T ese include the scapula, sternum, sacrum, and portions of the pelvis.
  - Occult fractures (nondisplaced or stress fractures). Bone scans can reveal metabolic disturbance at a fracture site within 24 hours of the injury, long before a conventional radiograph shows any abnormality and often before they are symptomatic.[25] Such fractures include the tibia (Fig. 7-11), scaphoid, radial head, and the femoral neck. Stress fractures of the metatarsals and other bones are seen on bone scan up to 2 weeks before becoming visible on plain radiographs.
  - Traumatic osteonecrosis without fracture.
- Nontraumatic
  - Osteomyelitis. T is condition causes localized increased uptake of the isotope which is visible on bone scan within 48 hours of the beginning of infection.
  - A tumor, primary or metastatic. T ese are usually detectable by bone scan by the time they cause symptoms. T e ability of the scan to cover the whole skeleton is particularly useful for determining the presence and extent of metastatic disease.
  - Occult fractures.
  - Tendinopathy and tenosynovitis.
  - Hip pain.
    - Adults: aseptic necrosis, arthritis, transient osteoporosis, occult femoral neck fracture. Aseptic necrosis appears either as a hotspot overlying the femoral head or as a cold central area surrounded by a ring of increased uptake. Transient osteoporosis, an entity mainly affecting young men, also demonstrates increased uptake of the femoral head when viewed under a bone scan. However, transient osteoporosis displays a decreased bone density when viewed on plain films. Arthritis causes increased uptake of isotope in the periarticular bone on both sides of the joint. Occult femoral neck fractures resulting from the normal stress placed on bones weakened by osteoporosis are seen on the bone scan as bands of increased uptake localized to the neck of the femur.
    - Children: arthritis, Legg–Perthes disease. T e bone scan in Legg–Perthes disease reveals decreased uptake at the femoral head early in the disease. Later, a ring of increased uptake may surround the cold spot.

SECTION III

INTERVENTION

CHAPTER 8 The Intervention

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Understand and describe the principles of a comprehensive rehabilitation program during the various phases of healing.
2. Discuss the various components of the intervention and their respective importance.
3. List the clinical tools that can be used to decrease pain and inflammation and promote healing.
4. Discuss the intrinsic and extrinsic stimuli that can be used to promote and progress healing.
5. Describe the benefits of each of the electrotherapeutic modalities.
6. Describe the benefits of each of the physical agents and mechanical modalities.
7. Understand the rationale for the therapeutic techniques used in each of the three stages of healing.
8. Understand the importance of patient education.

OVERVIEW

Intervention is organized into three categories[1]:

1. Remediation. Consists of enhancing skills and resources or reversing impairments and assumes that the potential for change exists in the system and the person.
2. Compensation or adaptation. Refers to the alteration of the environment or the task and is the approach taken when it is determined that remediation is not possible.
3. Prevention. Refers to the management of anticipated problems.

The purpose of the physical therapy intervention is to prevent any anticipated problems whenever possible, and to safely return a patient to his or her preinjury state, with as little risk of reinjury as possible and with the minimum amount of patient inconvenience. The latter is normally achieved by reducing inflammation followed by a gradual progression of strengthening and flexibility exercises while avoiding damage to an already compromised structure.[2] For muscles and tendons, this is generally accomplished through measured rest, physical therapy procedures and techniques including, manual therapy, high-voltage electrical stimulation, central (cardiovascular) aerobics, resistance exercises and general conditioning, while avoiding compromise to the healing structures. For the inert structures, such as ligaments and menisci, more emphasis is placed on controlling the level of tension and force placed on them to stimulate the fibroblasts to produce fiber and glycosaminoglycans.[3] Beyond the healing phase, the progression may include advancing to high-functional demands or sports-specific exercises, depending on the patient's requirements. For the athlete, the criteria for return to play should include no pain, full pain-free range of motion (ROM), normal flexibility/strength/balance, good general fitness, normal sports mechanics, and demonstration of sports-specific skills.[4]

According to the "Guide to Physical Therapist Practice,"[5] an intervention is "the purposeful and skilled interaction of the physical therapist and the patient/client and, when appropriate, with other individuals involved in the patient/client care, using various physical therapy procedures and techniques to produce changes in the condition consistent with the diagnosis and prognosis."

Three components comprise the physical therapy intervention: coordination, communication, and documentation; patient/client-related instruction; and direct interventions (Box 8-1).[5]

An intervention is most effectively addressed through a problem-oriented approach and is based on the patient's functional needs and on mutually agreed-upon goals.[5] Decisions about the intervention are made to improve the patient's ability to perform basic tasks and to restore functional homeostasis. The most successful intervention programs are those that are custom designed from a blend of clinical experience and scientific data, with the level of improvement achieved being related to goal setting and the attainment of those goals (Table 8-1). The necessary knowledge to perform an intervention includes:[6]

- the temporal phases of tissue healing (see Chapter 2), common problems associated with each phase, and stresses that tissues can safely tolerate during each phase;

Box 8-1 Components of an Intervention

Coordination, Communication, and Documentation

These interventions may include case management, communication with other healthcare providers or insurers, and the coordination of care with the patient/client or significant others involved in the care of the patient/client. This is to ensure a continuum of care among healthcare providers. Other interventions may include documentation of care, discharge planning, education plans, patient-care conferences, record reviews, and referrals to other professionals or resources.

Patient-Related Instruction

Patient education can include, but is not limited to, verbal, written, or pictorial instructions, which may be part of a home program. Computer-assisted instruction and demonstrations by the patient/client or caregivers are also examples of instructions that may be given. Audiovisual aides and demonstrations of exercises or functional activities may be used. This enables the patient/client to continue with the program when out of the clinic, either independently or with assistance.

Direct Interventions

Direct interventions are selected on the basis of the findings in the evaluation and examination of the patient/client, diagnosis, prognosis, and anticipated outcomes and goals for the individual. The direct interventions are performed with or on the patient. This section encompasses the largest component of patient care. Examples of direct interventions include, but are not limited to, therapeutic exercise, aerobic exercise, functional training, manual therapy, and use of assistive devices and modalities.

- movement characteristics including the amount of range, control, and capacity required for various functional activities;
- the range of available intervention strategies and procedures to promote healing and corresponding outcomes in varied patient populations;
- sequencing of various interventions to challenge appropriately involved tissues and the whole patient.

TABLE 8-1 Key Questions for Intervention Planning

What is the stage of healing: acute, subacute, or chronic?
How long do you have to treat the patient?
What does the patient do for activities?
How compliant is the patient?
How much skilled physical therapy is needed?
What needs to be taught to prevent recurrence?
Are any referrals needed?
What has worked for other patients with similar problems?
Are there any precautions?
What is your skill level?

Data from Guide to physical therapist practice. Phys Ther. 2001;81:S13–S95.

For example, being able to recognize the underlying tissue healing and balance disorders in a patient status post-hip fracture with diabetes mellitus, the need for aerobic conditioning in assessing patients with low back dysfunction, and the importance of body mechanics education in prenatal and postnatal exercise classes; and

- intervention strategies to promote overall health and well-being, and to prevent secondary dysfunction.

CLINICAL PEARL

The goal of the intervention process is to achieve the desired functional outcomes by reducing existing impairments, preventing secondary impairments, enhancing functional ability, promoting optimal health, and reducing environmental challenges.[6,7]

Whether the identification of the specific structure or structures causing the dysfunction is necessary in order to proceed with an intervention, remains controversial. Cyriax[8] designed his examination process to selectively stress specific tissues in order to identify the structure involved and its stage of pathology. In contrast, McKenzie[9] and Maitland[10,11] seldom identified the involved structure, believing that it is not always possible, or even necessary, for the prescription of appropriate therapeutic interventions. Indeed, based on the Maitland and McKenzie philosophy, the therapeutic strategy is determined solely from the responses obtained from tissue loading and the effect that loading has on symptoms.[9] Once these responses have been determined, the focus of the intervention is to provide sound and effective self-management strategies for patients, which avoid harmful tissue loading.[9] However, although self-management must be encouraged whenever feasible, these strategies have their limitations. One cannot realistically expect the majority of patients to fully rehabilitate themselves with a condition that requires the integration of a multitude of decision-making processes such as occurs with a joint replacement, or an anterior cruciate ligament reconstruction.

T e focus of the rehabilitation should be to improve an individual's ROM, flexibility, strength, and coordination to a level that approximates the demands of the desired activity (speed, agility, strength, power, endurance, etc.). T us, in general, the rehabilitation program should follow the following 10 basic principles:[12]

- respect the tissue injury cycle regarding the involved structure(s);
- minimize swelling, pain, and address muscular inhibition and atrophy;
- maintain and restore normal ROM;
- establish a normalized gait pattern within weight-bearing limitations (lower extremity);
- restore neuromuscular control;
- restore cervicothoracic and/or lumbopelvic stability, as appropriate;
- develop upper and/or lower extremity strength, as appropriate;

- improve balance and proprioception;
- increase cardiovascular condition; and
- integrate sports-specific/functional training.

CLINICAL PREDICTION RULES

Many interventions for musculoskeletal disorders have shown small effects when tested in randomized controlled trials. Identifying patients who respond best to certain treatments has received increased interest in research activity. With a clinical prediction rule (CPR), a combination or cluster of patient characteristics is used to determine the diagnosis, prognosis, or likely response to a specific treatment of that individual.[13] The development of a CPR involves the following stages: derivation (analyzing a data set to establish a rule with predictive power), narrow validation (evaluating the rule in a similar clinical setting and population), broad validation (evaluating the rule in multiple clinical settings), and impact analysis (determining whether the rule changes clinicians' behavior, improves patient outcomes, or reduces costs).[13] Thus far, however, the vast majority of the CPRs have been derived using single-arm study designs and, therefore, the results of these studies must be interpreted with caution, as these CPRs run a greater risk of identifying prognostic factors rather than factors that modify the effect of a treatment.[14] Other important limitations of many of the current CPRs are the use of short-term outcomes only, arguably trivial findings, and limited rule application potential. To date, only one CPR on spinal manipulation for low back pain[15] underwent validation in a controlled trial and can be considered for clinical application (and only in a population similar to that tested).[14]

INTERVENTION BASED ON STAGE OF HEALING

The intervention is typically guided by short- and long-term goals, which are dynamic in nature, being altered as the patient's condition changes, and strategies with which to achieve those goals based on the stages of healing (Table 8-1). Intervention strategies can be subdivided into active (direct) or passive (indirect), with the goal being to make the intervention as active as possible at the earliest opportunity. The only intervention that consistently appears beneficial across a wide spectrum of spinal and nonspinal musculoskeletal problems is the continued application of controlled stresses.

Many factors can contribute to the patient's resistance to improvement. In some cases, it may be an individual factor that, when eliminated, will allow the patient to respond well. In the majority of cases, the resistance to improvement is based on the interaction of multiple factors, which must be recognized and corrected.

Misjudgments are sometimes made with the intervention. In general, the patient's pain should not last more than a couple of hours after an intervention. Pain that lasts longer than 2 hours is usually an indication that the intensity of the intervention, rather than the intervention itself, has been inappropriate. The clinician has to remove the notion that all pain is bad. In many respects, a slight increase in pain following an intervention is a more desirable finding than no change in pain, because it indicates that the correct structure is being stressed, albeit too aggressively.

Acute Phase

The acute phase correlates with the hemostasis, inflammatory, and coagulation phases of healing (see Chapter 2). Clinical findings during the acute stage are associated with inflammation and include pain, edema, redness, heat, and impairment or loss of function. Although the redness and heat are not necessarily problems that require a specific treatment goal, pain, edema, and loss of function certainly are. Given the number of pathologic entities that can be evoked by the repair process, such as complex regional pain syndrome (CRPS, previously referred to as reflex sympathetic dystrophy) and myositis ossificans, it is clear that neurophysiologic processes are at work. Usually, during the acute phase, there is a pain at rest or with active motion, or when specific stress is applied to the injured structure. The pain, if severe enough, can result in muscle guarding and loss of function. With passive mobility testing, pain is reported before tissue resistance is felt by the clinician. The goals of the intervention during this phase are to control inflammation, avoid painful positions, minimize pain and edema, restore full, passive ROM, maintain soft-tissue joint integrity, reduce muscle atrophy through gentle isometric muscle setting, maintain aerobic fitness and to enhance function. During the inflammatory stage, it is also important for the patient to function as independently as possible.

Pain

A major focus of physical therapy in the acute phase is the control of pain. At the simplest level, the transmission of information relating to pain from the periphery to the cortex is critically dependent on integration at three levels within the central nervous system: the spinal cord, brain stem, and forebrain (see Chapter 3). Although pain serves as a protective mechanism, allowing an individual to be aware of a situation's potential for producing tissue damage and to minimize further damage, it can persist beyond its usefulness. In addition, the presence of pain can stimulate muscle spasm, which in turn can lead to circulatory deficiency, muscle atrophy, and loss of function. The challenge for the clinician during the various phases of healing is to control the pain while simultaneously progressing the patient. Several different approaches can be used to provide pain relief as follows:[16]

- Encourage the body's central biasing mechanisms (see Chapter 3) through the use of cognitive processes (motivation, relaxation techniques, positive thinking, and mental focus).
- Minimize further tissue damage. Therapeutic modalities are probably the most frequently used tool in all of musculoskeletal rehabilitation. Physical agents, including therapeutic cold, electrical current, and compression can be used throughout the acute phase. Clearly, an understanding of the physiological basis for using these

agents is critical if clinicians are to use these agents effectively.

- Educate the patient as to the rationale of the treatment, and what he or she can expect.
- Recognize that all pain, even psychosomatic pain, feels very real to the patient.

Inflammation and Edema

Inflammation and edema occur as part of the healing process (see Chapter 2). In addition to controlling pain, the goals during the initial phase of intervention for an acute lesion are to control the inflammation and edema, and to protect the damaged structures from further damage, while attempting to promote and progress tissue healing and increase function.

CLINICAL PEARL

Several tools are at the clinician's disposal to help control inflammation, and edema. These include elevation of the injured part as appropriate, compression, the application of electrotherapeutic and physical modalities (cryotherapy, and high-voltage electrical stimulation), gentle (ROM) exercises and graded manual techniques.

Loss of Function

Neuromuscular inhibition can result from pain and joint effusion and should be addressed as early as possible. T e function can be enhanced through the use of assistive and supportive devices (crutches, cane, sling, immobilizer, etc.).

Two acronyms have been used for years to help remember the protocols during the acute stage of healing:

1. R.I.C.E.—Rest, ice, compression, and elevation. T ese should be used.
2. H.A.R.M.—Heat, alcohol, running, and massage. T ese should be avoided, largely due to the fact that they create heat/blood flow or, in the case of running (for lower extremity injuries), heat and physical stress.

More recently, RICE has been expanded to PRICEMEM:

- Protection. Excessive tissue loading must be avoided. For example, in the lower extremity when ambulation is painful, crutches or other assistive devices are advocated until the patient can bear weight painlessly, or within a reasonable tolerance.
- Rest. Rest is generally considered to be absence from abuse, rather than a complete absence from activity as prolonged immobilization can have a detrimental effect on muscles, ligaments, bones, collagen, and joint surfaces. In response to the training stimulus, the healing tissues may undergo some breakdown at the subcellular, cellular, or tissue level, which will temporarily lower the functional ability of each. A rest period allows the body to adapt by resynthesizing the protein in these structures to a higher level than before the overload.[17–19] T is process of synthesizing takes between 12 and 48 hours depending on the intensity (quality) of the exercise and the volume (total amount) of the load.[20] However, it is important to remember that if the training stimulus is stopped, reduced, or altered too much, the training effect will decline.
- Ice. T e therapeutic application of cold or cryotherapy (see "Physical Agents") has been used as a healing modality since the days of the ancient Greeks. In most cases, ice should be used until the swelling has ceased. Limiting the effusion serves to hasten the healing process by minimizing the amount of extracellular fluid and hematoma to be reabsorbed.[21]
- Compression. T e most common method of applying compression is via an elastic bandage.[21] T e compression provided by a pneumatic device,[22,23] or by a felt pad incorporated into an elastic wrap or taping,[24] has also been demonstrated to be effective in decreasing effusion.
- Elevation. Elevation of an extremity aids in venous return and helps minimize swelling. In general, elevation and compression should be continued until the swelling has completely dissipated.[25]
- Manual T erapy. T e controlled application of various manual techniques can have several therapeutic benefits (see Chapter 10). T ese benefits are theoretically achieved through[26,27]
  - stimulation of the large-fiber joint afferents of the joint capsule, soft tissue, and joint cartilage, which aids in pain reduction;
  - stimulation of endorphins, which aids in pain reduction;
  - the decrease of intraarticular pressure, which aids in pain reduction;
  - the mechanical effect, which increases joint mobility;
  - remodeling of local connective tissue;
  - the increase of the gliding of tendons within their sheaths; and
  - an increase in joint lubrication.

Manual techniques, which are discussed in Chapter 10, allow the clinician to choose the degree of specificity of an intervention. Manual therapy techniques including low dosage joint mobilization (grade I or grade II) can be used to improve fluid dynamics and to reflexively inhibit the perception of pain (see Chapter 10). Although the goal is to be as specific as possible, there are many times when a general technique is appropriate. General techniques are typically less aggressive, are applied to the larger muscle groups or regions, and often can be performed by the patient as part of the home exercise program. General manual therapy techniques that can be used during this stage include gentle massage to increase blood flow. Specific manual techniques that can be used during this stage include passive joint distractions and glides (grade I or II).

- Early Motion. Early motion is advocated to[28]
  - reduce the muscle atrophy that occurs primarily in type I fibers;[29–31]
  - maintain joint function;
  - prevent ligamentous "creeping;"
  - reduce the chance of arthrofibrosis or excessive scarring;[32–36] and

- enhance cartilage nutrition and vascularization, thereby permitting an early recovery and enhanced comfort.[31,37,38]

CLINICAL PEARL

The benefits of early mobilization are to prevent the detrimental physiologic effects of immobilization, including loss of muscle, ligament, and bone strength[39,40]; formation of adhesions [41]; and loss of proprioception.[42]

Therapeutic exercise is the foundation of physical therapy and a fundamental component of the vast majority of interventions. Prescribed accurately, therapeutic exercise can be used to restore, maintain, and improve a patient's functional status by increasing strength, endurance, and flexibility. Tissue-specific movement should be directed to the structure involved to prevent abnormal adherence of the healing fibrils and future disruption of the scar. Initially, if the motion is contraindicated, gentle muscle setting exercises can be prescribed. These are performed in the shortened or relaxed position to prevent new scar formation being pulled from the healing site before progressing to a variety of joint angles. Passive ROM within the limits of pain is introduced as early as feasible while being very careful not to impart any significant stretch to the healing tissues. Research has demonstrated that joint motion stimulates the healing of torn ligaments around a joint[43,44] and that early joint motion stimulates collagen bundle orientation along the lines of force, a kind of Wolff's law of ligaments.[43,45] When designing an exercise program, the clinician should create exercises that are safe yet challenging, progressive, systematic, proprioceptively enriched, activity-specific, and based on evidence-based science.[46] A typical exercise continuum includes a number of progressions, which includes the following:[46]

- Activities initially performed slowly before being progressed to a faster pace.
- The performance of familiar activities and then unfamiliar activities.
- Activities are initially performed on a stable base of support and are then made progressively more challenging by increasing the amount of control required, and with the introduction of activities that require dynamic control.
- The introduction of resistance during the movements. The initial resistance used is of low force and then incrementally increased.
- Correct performance of the activity with increasing levels of complexity.

CLINICAL PEARL

The goal of the functional exercise progression is to identify the motion, or motions, that the patient is able to exercise into, without eliciting symptoms other than post-exercise soreness.[47]

- Medications. Pharmacologic intervention, which can play an important role in the management of the pain and inflammation associated with orthopaedic conditions is described in Chapter 9.

Tissue repair can be viewed as an adaptive life process in response to both intrinsic and extrinsic stimuli.[48] Physical therapy cannot accelerate the healing process, but with correct education and supervision, it can ensure that the healing process is not delayed or disrupted and that it occurs in an optimal environment.[9]

CLINICAL PEARL

The promotion and progression of tissue repair involves a delicate balance between protection and application of controlled functional stresses to the damaged structure.

The rehabilitation procedures used to assist with this repair process differ, depending on the type of tissue involved, the extent of the damage, and the stage of healing. Healing is related to the signs and symptoms present rather than the actual diagnosis. These signs and symptoms inform the clinician as to the stage of repair that the tissue is undergoing. Awareness of the various stages of healing is essential for determining the intensity of a particular intervention if the clinician is to avoid doing any harm. Decisions to advance or change the rehabilitative process need to be based on the recognition of these signs and symptoms, and on an awareness of the time frames associated with each of the phases.[49,50]

Janda[51] introduced the concept of the direct and indirect effects of neural input on muscle activation and noted the influence that pain and swelling can have on direct muscle inhibition.

CLINICAL PEARL

According to Janda,[51] muscular development cannot proceed in the presence of pain, because pain has the potential to create a high degree of muscle inhibition that can alter muscle-firing patterns.

During this stage, using the principles of PRICEMEM, results in decreased early bleeding and facilitation of the removal of the inflammatory exudates, which can prevent further damage and inflammation to the area. Limiting the effusion serves to hasten the healing process by minimizing the amount of extracellular fluid and hematoma to be reabsorbed.[52,53]

The criteria for advancement from this phase include adequate pain control and tissue healing, near-normal ROM, and tolerance for strengthening.[4]

Subacute or Intermediate Phase

The various ways in which the musculoskeletal tissues heal at the cellular level during this phase are described in Chapter 2. Clinically, this stage is characterized by a decrease in pain and swelling and an increase in pain-free active and passive ROM (see Chapter 2). During passive ROM, the occurrence of pain is synchronous with tissue resistance.

Although the amount of pain-free ROM may be increased in this phase, it is still not within normal limits, and stress applied to the injured structures still produces pain, although the pain experienced is lessened.[54,55] It is critical during this phase that

the patient be educated to recognize the signs and symptoms of overstressed healing tissues. During this phase, there is less emphasis on the use of passive techniques and modalities and more emphasis on progressively stressing the healing structures. T e treatment goals for this phase are to modify faulty joint mechanics, to protect the forming collagen and direct its orientation to be parallel to the lines of force it must withstand, and prevent cross-linking and scar contracture. If these goals are achieved, the scar will be strong and extensible.

Therapeutic Exercise

T e various types of therapeutic exercise are described in Chapters 12–15. T e role of exercise during the healing phases is discussed in this chapter. As outlined in Chapter 12, the various characteristics of an exercise load include:[20]

- Intensity (i.e., speed, resistance).
- Duration (amount of time of the exercise session).
- Frequency (number of sessions per week).
- Volume of training.
- Length (number of weeks or months).
- Pattern (continuous versus interval).
- Mode (e.g., running, cycling, swimming).

Progressions in the total load of exercise can be achieved by increasing the intensity, duration, or frequency, or a combination of the three (see Chapters 12–15).[20] During recovery from injury, it seems that the fibroblasts need to be guided so that the replaced collagen fibers are laid along the lines of stress.

Gentle movements to the area provide natural tensions for the healing tissues and help produce a stronger repair,[56] so a progressive increase in movement should be encouraged. Each individual responds uniquely to exercise depending on a number of variables, including:[20]

- Genetic endowment. Each individual has a given genetic potential that will limit the extent to which the effects of physical training can be manifested. T e farther an individual is from the genetic limit, the larger will be the improvement, but as the individual gets closer to the limit, less improvement will be elicited. Gender also plays an important role, as women tend to have less muscle mass and more body fat at a given training level.[20]
- Biological age. An individual's biological age has a greater impact than chronological age. Younger adults have a greater response to training than do older adults.[57]
- Training state. Individuals at lower levels of fitness will respond with a higher rate and magnitude of adaptation than when they possess higher levels of fitness.[58]
- Health status. During either sickness or injury, the amount of adaptive energy is reduced, along with the ability to perform at optimal intensities and volumes of work. T is necessitates a reduction (or elimination) in the prescription of exercise during such times.
- Fatigue state. Fatigue limits one's ability to work at optimal intensities or durations.

Early motion exercises follow a predictable path: the passive ROM used in the acute phase is progressed to active assistive and then to active ROM, based on tissue and patient responses. If signs of inflammation increase or the ROM progressively decreases, the intensity of the exercise and activity must decrease. Exercise or activity soreness should decrease after 2–4 hours. Strengthening exercises during this stage are initially restricted to submaximal isometrics (see Chapter 12) and protected weight-bearing exercises. T e submaximal isometrics are initially performed in the early part of the range, before being performed at multiple angles of the pain-free ROM. As ROM and joint play improve, concentric exercises (see Chapter 12) are initiated, with the resistance being increased as tolerated.

Manual Therapy

As with therapeutic exercise, manual therapy (see Chapter 10) plays an integral role in the healing process by providing controlled stresses to the healing tissues. Manual therapies during this stage include joint mobilizations (grade II) to help restore normal joint play, transverse friction massage, and gentle contract–relax techniques. It is important to emphasize to the patient that an overly aggressive approach during this stage can result in a delay or disruption in the repair process through an increase in the stimulation of the inflammatory chemical irritants and exudates.

T e criteria for advancement to the chronic or advanced stage of rehabilitation includes no complaints of pain; full, pain-free ROM; good flexibility and balance; and strength of 75–80%, or greater, compared with the uninvolved side.[4]

Chronic or Return to Function Phase

T e various ways in which the musculoskeletal tissues heal at the cellular level during this phase are described in Chapter 2. During this stage, pain typically is felt at the end of the range with passive ROM, after the tissue resistance has been encountered. T e goals during the early part of this phase include a gradual return to a full and pain-free ROM, to progressively increase movement speed, and continue to develop neuromuscular control. By the end of this phase, a full and unrestricted ROM should be present, and more aggressive work-related and sports-specific movements and activities are incorporated as appropriate.

Manual Therapy

Manual techniques may be required at this stage to emphasize the restoration of accessory joint motion and to increase the extensibility of soft tissues. Techniques to increase accessory joint motion (see Chapter 1) may include joint mobilizations (grades III–V). Techniques to increase soft-tissue extensibility include a variety of techniques including passive stretching and myofascial release (see Chapter 10).

Taping

Similar to manual therapy, taping techniques can be an integral part of a comprehensive intervention to improve the quality of movement. Taping may attempt to reinforce the normal protective-support structures, improve proprioception, enhance

neuromuscular activation, and/or altered biomechanics.[59] The inherent properties of the different types of tape available vary significantly such that the differing characteristics of each can be used for different purposes:[59]

- Zonas (Johnson & Johnson, Skillman, NJ) and Leukotape (BSN, JOBST, Toledo, OH) have approximately the same number of primary fibers that are parallel to the directional loading. However, Leukotape has secondary fibers oriented at 45 degrees to the loading direction, which can help dissipate multidirectional loading, increase the tensile strength, and increase the stiffness of the tape.
- Jaylastic (Jaybird & Mais, Westboro, MA) has considerably fewer fibers in the directional loading and subsequently lower tensile strength but greater extensibility.
- Occlusive taping has less adhesive force than permeable tape (Coban) due to fluid accumulation under the tape.

Therapeutic Exercise

The musculoskeletal tissues respond to the controlled stresses applied to them by adaptation. This response has been described as a specific adaptation to imposed demand (SAID) (see Chapter 12).[60]

CLINICAL PEARL

The SAID principle acknowledges that the human body responds to explicit demands placed upon it with a specific and predictable adaptation. Since each load demands a specific adaptation, a variety of loads (cross training) will stimulate a variety of adaptations.[20]

The application of inappropriate stresses can lead to various forms of tissue dysfunction, such as contracture, laxity, fibrosis, adhesion, diminished function, repeated structural failure, and an alteration in neurophysiologic feedback.[61,62]

CLINICAL PEARL

If the ROM and joint play are restricted, the patient continues with isometrics at various angles in the range. Otherwise, the patient is progressed through a continuum of resistive exercises.

The hierarchy of the resistive exercise progression is based on patient tolerance and response to ensure that any progress made is done in a safe and controlled fashion. The typical sequence occurs in the following order:[63]

- Small arc submaximal concentric/eccentric
- Full ROM submaximal concentric/eccentric
- Full ROM submaximal eccentric
- Functional/activity-specific plane submaximal concentric
- Functional ROM submaximal eccentric
- Open- and closed-kinetic chain exercises performed concentrically and then eccentrically
- Full ROM submaximal concentric isokinetic
- Full ROM submaximal eccentric isokinetic
- Functional ROM submaximal eccentric isokinetic

In the instance of chronic conditions, a slight increase or worsening of symptoms is sometimes permissible with exercise, because the desensitization of some of the structures may require a mechanical input via stimulation of the large A fibers (see Chapter 3). However, the increase in symptoms may also signal a retriggering of the inflammatory process.[64] To help prevent these pathologic changes, Liebenson[65] recommends the following:

- Patient education about how to identify and control external sources of biomechanical overload.
- Early identification of psychosocial factors of abnormal illness behavior.
- Identification and rehabilitation of the functional pathology.

What is considered to be "normal" flexibility, strength, speed, and aerobic or anaerobic endurance for most patients in rehabilitation is inadequate for those patients returning to sport.[66] As skill is associated with enhanced mechanical efficiency and reduced risk of injury, skill in exercise-specific action should be established before the training load is increased.[20]

In the modern, cost-conscious healthcare environment, the stage at which the patient is ready to return to full function is not often played out in the clinic. Although patient education emphasizing a slow and gradual return to activity can, to some extent, prepare the subject for this phase, reinjury, or insufficient recovery, is a real possibility.

The terms *function* and *functional* have been used extensively within the field of rehabilitation. In the context of physical therapy, function has been defined as "those activities identified by an individual as essential to support physical, social, and psychological well-being and to create a personal sense of meaningful living."[67] Functional limitations have been described as the "limitation of performance at the level of the whole organism or person…and should not be confused with diseases, disorders, conditions, or impairments involving specific tissue, organ, or system abnormalities that result in signs or symptoms."[67]

Therefore, in order to restore function, the clinician must think beyond the level of impairments of specific tissues and structures resulting from injury, but instead focus on the functional limitations of the patient. Such focus requires knowledge of functional testing rather than the traditional clinical testing (e.g., ROM, strength). Functional tasks can be designed to assess the balance, balance reach, excursion, speed and agility, endurance, strength, and power of the patient, which can then be equated with function.[68] Similarly, functional progression training should involve not merely the reproduction of an activity or task by an exercise. Instead, the ultimate goal of functional training is the restoration of the patient's confidence, which implies a return to normal of the neurovascular, neurosensory, and kinesthetic systems of the body, so that the reflex performance of a movement is not deliberate, hesitant, or dyskinetic.[69–71]

It should be obvious that the speed and extent by which the injured tissues heal determines both the speed and the extent of the progression toward an optimum functional outcome.

While it is virtually impossible to hasten the healing process, it is possible to prescribe a controlled and safe continuum, in which the patient can improve his or her functional status, without harming the healing structures.

Functional progression training, as with exercise progressions, must be designed in a sequential, step-by-step manner, beginning with simple tasks and progressing to highly coordinated tasks, with each step in the process requiring greater skill than the last. The overriding principle of functional rehabilitation is to return patients to the functional level they desire, or at which they were previously functioning.[70]

A task-oriented approach requires the clinician to understand the specific requirements of an occupation, activity, or sport. The clinician should assume that the tasks involve motions or stresses in all three planes; multiple joints, segments, or limbs; contributions from uniarticular and multiarticular muscles; and the simultaneous need for the body to move and be stable.[72] Important specific considerations include the:[72]

- common postures and movement patterns;
- the amount of motion;
- the speed of movement;
- nature and magnitude of forces/resistances;
- dominant directions/planes of motion;
- muscular activation patterns;
- joint-specific demands;
- symmetry or asymmetry of motion;
- unilateral or bilateral limb demands; and
- environmental demands.

Functional progressions that are specific to the lower or upper extremity are included in various chapters of this book. Functional progressions and their grading for the nonathlete are also included. A number of functional progressions for athletes have been devised to guide the clinician. Most of these progressions originated from postsurgical protocols, in particular, from anterior cruciate ligament reconstructions and rotator cuff surgery, which deal with various functional levels.

Chronic Inflammation

Most injuries, when treated appropriately, resolve on their own, provided that the injured tissue is allowed to progress through the natural stages of healing. If this natural progression does not occur, chronic inflammation can result (Table 8-2) (see Chapter 2). While similar intervention principles can be applied in the presence of chronic inflammation such as cryotherapy, controlled rest, therapeutic exercise, and manual therapy, additional focus must be placed on determining the cause of the chronic irritation. For example, an assessment of flexibility and strength, posture, footwear, technique, running style, repetitive activities, or motions must be performed. A more subtle cause of chronic inflammation can be the presence of a hypermobile joint, which allows the excessive motion to occur that must be

TABLE 8-2 Causes and Contributing Factors of Chronic Inflammation

Causes and Contributing Factors	Description
Overuse, repetitive strain, and cumulative trauma	Repetitive microtrauma overtime results in structural weakening, or breakdown of connective tissue
Trauma with subsequent microtrauma	Results in a condition that never completely heals and the involved region becomes more susceptible to injury
Scarring	Since scar tissue is not as compliant as undamaged tissue, it is unable to sustain the stresses that normal, healthy tissue can sustain
Adaptive shortening of connective tissues	Connective tissue contractures can become stressed with repeated or vigorous activity
Imbalance between length and strength of muscles	This can lead to faulty mechanics of joint motion and/or abnormal forces through the muscles
Training errors	Improper performance and equipment coupled with the condition of the participant and an inappropriate intensity of the exercise can lead to abnormal stresses. In addition, a sudden increase or change in an exercise or training routine may not be tolerated by the connective tissues
Age-related factors	There is a decline in the overall compliance of tissues with aging which reduces their ability to withstand sustained stress
Excessive repeated eccentric demand	There is a marked increase in the proportion of disrupted muscle fibers after eccentric as compared with concentric exercise. Eccentric exercise is also linked to morphologic and metabolic signs of muscle alteration: myofibrillar damage along the Z-band
Muscle weakness	Muscle fatigue results in a decrease in contractility and shock absorbing capabilities
Faulty biomechanics and anatomical malalignment	Any biomechanical or anatomical asymmetries, particularly in the lower extremities can lead to structural breakdown through compensation

compensated for along the kinematic chain. T is hypermobility should be addressed using joint stabilization techniques (see Chapter 14). T e more common overuse injuries are described in the relevant chapters.

Rehabilitation Modalities

Clinicians have at their disposal a battery of physical agents and electrotherapeutic modalities for use in the acute phase and once the acute stage of healing has subsided. T e modalities used during the acute phase involve the application of cryotherapy, electrical stimulation, pulsed ultrasound, and iontophoresis. Modalities used during the later stages of healing include thermotherapy, phonophoresis, electrical stimulation, ultrasound, iontophoresis, and diathermy (Tables 8-3 and 8-4).

At present, with the exception of cryotherapy, there is insufficient evidence to support or reject the use of modalities.[73–75] However, the absence of evidence does not always mean that there is evidence of absence (of effect), and there is always the risk of rejecting therapeutic approaches that are valid.[76]

CLINICAL PEARL

It is important that the clinician have an understanding of the principles that relate to a particular modality so that the modality is used when indicated, and the maximum therapeutic benefit may be derived from its use.

If modalities have a place in the clinic, it is during the acute phase of healing, when there is little the clinician can do in the form of manual techniques or therapeutic exercise. In the remodeling or functional phase, thermal modalities may be used to promote blood flow to the healing tissues and to prepare the tissues for exercise or manual techniques. However, at the earliest opportunity, the patient should be weaned away from these modalities, and the focus of the intervention should shift to the application of movement and the repeated and prolonged functional restoration of the involved structures.

Two categories of modalities are recognized:

1. Physical agents and mechanical modalities
2. Electrotherapeutic modalities

TABLE 8-3 Clinical Decision Making on the Use of Various Therapeutic Modalities in Treatment of Acute Injury

Phase	Approximate Time Frame	Clinical Picture	Possible Modalities Used	Rationale for Use
Initial acute	Injury—day 3	Swelling, pain to touch, and pain on motion	CRYO ESC IC LPL Rest	↓ Swelling, ↓ pain ↓ Pain ↓ Swelling ↓ Pain
Inflammatory response	Days 1–6	Swelling subsides, warm to touch, discoloration, pain to touch, and pain on motion	CRYO ESC IC LPL Range of motion	↓ Swelling, ↓ pain ↓ Pain ↓ Swelling ↓ Pain
Fibroblastic repair	Days 4–10	Pain to touch, pain on motion, and swollen	THERMO ESC LPL IC Range of motion Strengthening	Mildly ↑ circulation ↓ Pain–muscle pumping ↓ Pain Facilitate lymphatic flow
Maturation-remodeling	Day 7—recovery	Swollen, no more pain to touch, and decreasing pain on motion	ULTRA ESC LPL SWD MWD Range of motion Strengthening Functional activities	Deep heating to ↑ circulation ↑ Range of motion, ↑ strength ↓ Pain ↓ Pain Deep heating to ↑ circulation

CRYO, cryotherapy; ESC, electrical stimulating currents; IC, intermittent compression; LPL, low-power laser; MWD, microwave diathermy; SWD, shortwave diathermy; THERMO, thermotherapy; ULTRA, ultrasound; ↓, decrease; ↑, increase.

TABLE 8-4 Indications and Contraindications for Therapeutic Modalities

Therapeutic Modality	Physiologic Responses (Indications for Use)	Contraindications and Precautions
Electrical stimulating currents	Pain modulation	Pacemakers
High voltage	Muscle reeducation Muscle pumping contractions Retard atrophy Muscle strengthening Increase ROM Fracture healing Acute injury	Thrombophlebitis Superficial skin lesions
Low voltage	Wound healing Fracture healing Iontophoresis	Malignancy Skin hypersensitivities Allergies to certain drugs
Interferential	Pain modulation Muscle reeducation Muscle pumping contractions Fracture healing Increase ROM	Same as high voltage
Russian	Muscle strengthening	Pacemakers
Micro-electric nerve stimulation	Fracture healing Wound healing	Malignancy Infections
Shortwave diathermy and microwave diathermy	Increase deep circulation Increase metabolic activity Reduce muscle guarding and spasm Reduce inflammation Facilitate wound healing Analgesia Increase tissue temperatures over a large area	Metal implants Pacemakers Malignancy Wet dressings Anesthetized areas Pregnancy Acute injury and inflammation Near eyes Areas of reduced blood flow Anesthetized areas
Cryotherapy (cold packs and ice massage)	Acute injury Vasoconstriction and decreased blood flow Analgesia Reduce inflammation Reduce muscle guarding/spasm	Allergy to cold Circulatory impairments Wound healing Hypertension
Thermotherapy (hot whirlpool, paraffin, hydrocollator, and infrared lamps)	Vasodilation and increased blood flow Analgesia Reduce muscle guarding and spasm Reduce inflammation Increase metabolic activity Facilitate tissue healing	Acute and post-acute trauma Poor circulation Circulatory impairments Malignancy
Low-power laser	Pain modulation (trigger points) Facilitate wound healing	Pregnancy Near eyes
Ultraviolet	Acne Aseptic wounds Folliculitis Pityriasis rosea Tinea	Psoriasis Eczema Herpes Diabetes Pellagra

TABLE 8-4 Indications and Contraindications for Therapeutic Modalities (Continued)

Therapeutic Modality	Physiologic Responses (Indications for Use)	Contraindications and Precautions
	Septic wounds Sinusitis Increase calcium metabolism	Lupus erythematosus Hyperthyroidism Renal and hepatic insuf ciency Generalized dermatitis Advanced atherosclerosis
Ultrasound	Increase connective tissue extensibility Deep heat Increased circulation Treatment of most soft-tissue injuries Reduce inflammation Reduce muscle spasm	Infection Acute and post-acute injury Epiphyseal areas Pregnancy Thrombophlebitis Impaired sensation Near eyes
Intermittent compression	Decrease acute bleeding Decrease edema	Circulatory impairment

ROM, range of motion.

Physical Agents

Physical agents are sources of energy that are used therapeutically.

Cryotherapy. Cryotherapy, which removes heat from the body, thereby decreasing the temperature of the body tissues, is the most commonly used modality for the intervention of acute musculoskeletal injuries. T e use of ice by itself or in conjunction with compression has been demonstrated to be effective in minimizing the amount of exudate.[77–82] Cryotherapy can be applied in various forms, but crushed ice bags (CIB), cold packs (Fig. 8-1), and cold water immersion (CWI) are frequently used. A more expensive form of cryotherapy can be supplied by a pneumatic cold compression unit such as Game Ready© (Fig. 8-2) that simultaneously delivers active pneumatic compression and adjustable cold therapies to specific areas of the body.

T e physiologic effects of local cold application are principally the result of vasoconstriction, reduced metabolic function, and reduced motor and sensory conduction velocities. T ese effects include the following:

- **A decrease in muscle and intraarticular temperature.** T e decrease in muscle temperature and intraarticular structures occurs because of a decline in local blood flow[55,57,60,68,69] and appears to be most noticeable between the temperatures of 40°C and 25°C.[70] Temperatures below 25°C, which typically occur after 30 minutes of cryotherapy, actually result in an increase in blood flow (Hunting effect),[70] with a consequent unfavorable increase in hemorrhage and an exaggerated acute inflammatory response.[63] T e reduction in muscle and intraarticular temperature is maintained for several hours after removal of the cooling agent.[71] A prolonged application of cold, however, can result in a sympathetically mediated reflex vasodilation in an attempt to rewarm the area, which may actually worsen the swelling.[71,72]
- **Local analgesia.**[75,83–88] T e stages of analgesia achieved by cryotherapy are outlined in Table 8-5.[89] It is worth remembering that the timing of the stages depends on the depth of penetration and the depth of the overlying

FIGURE 8-1 Cold pack.

FIGURE 8-2 Pneumatic cold compression unit.

TABLE 8-5	Stages of Analgesia Induced by Cryotherapy	
Stage	**Response**	**Time after Initiation of Cryotherapy (min)**
1	Cold sensation	0–3
2	Burning or aching	2–7
3	Local numbness or analgesia	5–12
4	Deep tissue vasodilation without increase in metabolism	12–15

Data from Hocutt JE, Jaffee R, Rylander R, et al. Cryotherapy in ankle sprains. Am J Sports Med. 1982;10:316–319.

adipose tissue.[90] The patient should be advised as to these various stages, especially in light of the fact that the burning or aching phase occurs before the therapeutic phases.

- Decreased muscle spasm.[23,75,91–93]
- A decrease in edema.[75,94,95]
- A decrease in nerve conduction velocity (NCV).[96]

Several methods of applying cryotherapy have been examined in different studies. The use of ice chips in toweling has been shown to be more effective in decreasing skin temperature than ice chips in plastic bags, or cold gel packs.[97,98] Findings from another study[99] indicated that ice massage and ice bags are equally effective in decreasing intramuscular temperature and in maintaining the duration of temperature depression. That study also found that ice massage achieves maximal intramuscular temperature decrease sooner than the ice bag.[99] A study by a Rupp et al.[100] using CIB and CWI found there was no difference in time required to reduce intramuscular temperature 8°C 1 cm below adipose tissue but that intramuscular temperature remained significantly colder 90 minutes following CWI.

Cryotherapy is recommended in all of the phases when any inflammation is present, but particularly in the acute phase, because of its effectiveness in reducing both pain and edema.[80,99,101] Ice that has been frozen in a paper cup is applied to the area in small, circular motions for 10–15 minutes before and after activity, up to six times a day.

Cold packs applied directly to the joint area are useful in decreasing pain.[87] Current recommendations are to apply ice for 20–30 minutes every 2 hours.[102]

The application of cold to an area is contraindicated over superficial nerves or healing wounds in patients with Raynaud disease or cold sensitivity and in areas with poor circulation or sensation.[103]

- **Thermotherapy.** Thermotherapy involves the therapeutic application of heat, which involves the transfer of thermal energy. Five types of heat transfer exist:
  1. Convection occurs when a liquid or gas moves past a body part. An example of this type of heat transfer is the whirlpool or fluidotherapy (Fig. 8-3).
  2. Evaporation occurs when there is a change in the state of a liquid to a gas, and a resultant cooling takes place. An example of this type of heat transfer occurs during spray and stretch techniques.

FIGURE 8-3 Fluidotherapy unit.

  3. Conversion occurs when one form of energy is converted into another form. Examples of this type of heat transfer include ultrasound (Fig. 8-4), shortwave diathermy, and microwave diathermy.
  4. Radiation occurs when there are a transmission and absorption of electromagnetic waves.
  5. Conduction occurs when heat is transferred between two objects that are in contact with each other. An example of this type of heat transfer occurs with a paraffin bath (Fig. 8-5), and hydrocollator heating packs (Fig. 8-6).

Thermotherapy is used in the subacute and chronic stages of healing, because the deep heating of structures during the acute inflammatory stage has the potential to destroy collagen fibers and accelerate the inflammatory process,[104] whereas in the later stages of healing, an increase in blood flow to the injured area is beneficial.

FIGURE 8-4 Ultrasound unit.

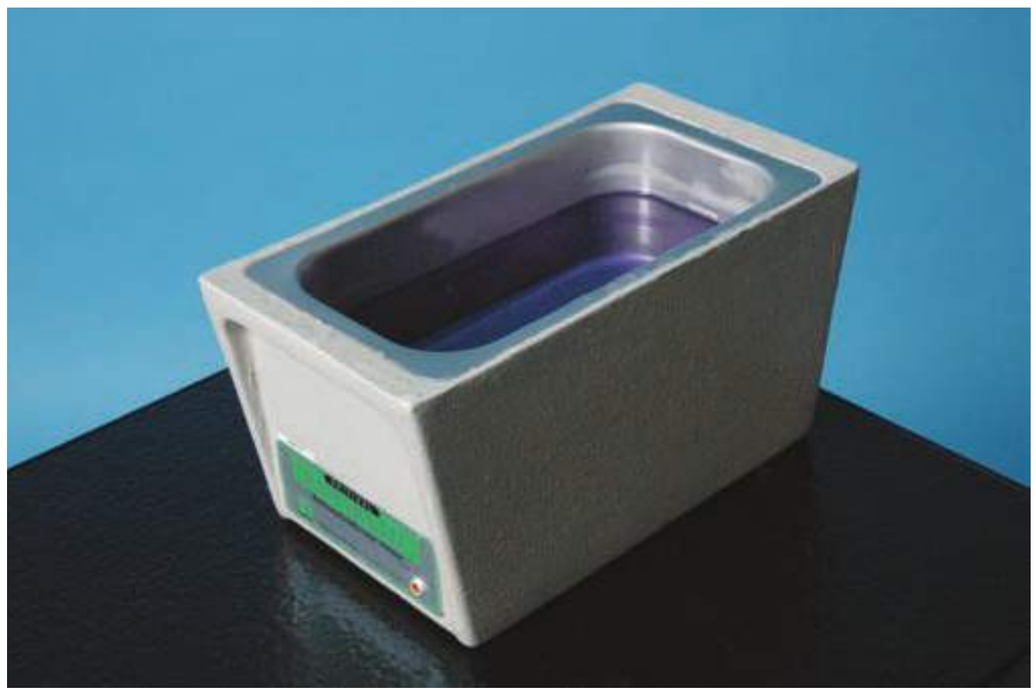

FIGURE 8-5 Paraf n bath.

T e physiologic effects of local heat application include the following:[105–109]

1. Dissipation of body heat through selective vasodilation and shunting of blood via reflexes in the microcirculation, and regional blood flow.[110]
2. Decreased muscle spasm.[85,110–112] T e muscle relaxation probably results from a decrease in neural excitability of the sensory nerves.
3. Increased capillary permeability, cell metabolism, and cellular activity, all of which have the potential to increase the delivery of oxygen and chemical nutrients to the area, while decreasing venous stagnation.[106,113]
4. Increased analgesia through hyperstimulation of the cutaneous nerve receptors.
5. Increased tissue extensibility[110] which has obvious implications for the application of stretching techniques. T e best results are obtained if heat is applied during the stretch and if the stretch is maintained until cooling occurs after the heat has been removed.

CLINICAL PEARL

For a heat application to have a therapeutic effect, the amount of thermal energy transferred to the tissue must be suf cient to stimulate normal function, without causing damage to the tissue.[114]

FIGURE 8-6 Hydrocollator hot pack.

Although the human body functions optimally between 36°C and 38°C, an applied temperature of 40°C, and 45°C is considered effective for a heat intervention. Commercial hot packs, or electric heating pads, are a conductive type of superficial moist heat, and the temperature of the unit is set anywhere between 65°C and 90°C. T e moist heat pack causes an increase in the local tissue temperature, reaching its highest point about 8 minutes after the application.[115] T e depth of penetration for traditional heating pads (and cold packs) is about 1 cm, which results in changes in the cutaneous blood vessels and the cutaneous nerve receptors.[98]

Wet heat produces a greater rise in local tissue temperature compared with dry heat at a similar temperature.[116] However, at higher temperatures, wet heat is not tolerated as well as dry heat.

It is important to assess the patient's sensitivity to temperature, pain, and circulation status prior to the use of thermotherapy. Moist heat should not be applied to an area with decreased sensation, poor circulation, an open wound, or an acute injury.[103] T e application of moist heat to an area of malignancy is also contraindicated because it can increase the temperature of the tumor and increase the rate of growth.[103] Hemophiliacs are also at risk with thermotherapy because of the increased blood flow.

Ultrasound. T e type of ultrasound in physical therapy is primarily used for its ability to deliver heat to deep musculoskeletal tissues such as tendon, muscle, and joint structures using ultrasonic waves. T ese sound waves are delivered through a transducer, which has a piezoelectric crystal, the latter of which vibrates very rapidly, converting electrical energy into acoustical energy. As the energy, which leaves the transducer in a straight line, travels further from the transducer, the waves begin to diverge. T e depth of penetration of the sound waves depends on a number of factors including the absorption and scattering of the beam, the medium being used (gel or lotion), the contact quality of the transducer, the treatment surface, and the tissue type (muscle, skin, fat, etc.).[117,118] Scar tissue, tendon, and ligament demonstrate the highest absorption. Tissues that demonstrate poor absorption include bone, tendinous, and aponeurotic attachments of skeletal muscle, cartilaginous covering of joint surfaces, and peripheral nerves lying close to the bone.[119] T e portion of the sound head that produces the sound wave is referred to as the effective radiating area (ERA). T e ERA is always smaller than the transducer.

Clinical units typically deliver ultrasound of 0.75–3 MHz, with duty cycles ranging from 20% to 100%. T e depth of penetration of the ultrasound is roughly inversely related to its frequency.[120,121] A frequency of 3 MHz is more superficial, reaching a depth of approximately 2 cm, whereas 1 MHz is effective to a depth of 4 or 5 cm.[122] Duty cycles less than 100% are usually termed pulsed ultrasound, whereas a 100% duty cycle is referred to as continuous ultrasound. Continuous-mode ultrasound produces a thermal effect. Pulsed ultrasound does not. T e thermal effects of ultrasound are similar to those previously described for thermotherapy. T e nonthermal or mechanical properties of ultrasound are less well defined but are believed to alter cellular permeability and metabolism and may be important in the promotion of wound healing by reducing edema, pain, and muscle spasms.[123–126]

The beam nonuniformity ratio of ultrasound is the maximal/average intensity (W/cm^2) found in the ultrasound field. Each transducer produces sound waves in response to the vibration of the crystal. This vibration has different intensities at points on the transducer head, having peaks and valleys of intensity. The greater the ratio difference in the beam nonuniformity ratio, the more likely the transducer will have hot spots. Hot spots are areas of high intensity. High intensities have been shown to cause unstable cavitational effects and to retard tissue repair.[126,127] Intensities of 0.1–0.3 W/cm^2 are recommended for acute lesions, whereas 0.4–0.8 W/cm^2 are recommended for chronic lesions.[128]

Treatment times for ultrasound are based on the principle of 1 minute of ultrasound per treatment head area, although account must be taken of the pulse ratio employed. The pulse ratio needs to be higher for more acute lesions (1:4) and lower for more chronic ones (1:1 or continuous).

One study[129] demonstrated that to achieve a tissue temperature of 4°C, using continuous ultrasound, the following parameters and application times are necessary:

- 1 MHz at 1.5 W/cm^2 for 13 minutes
- 3 MHz at 1.5 W/cm^2 for 4.5 minutes

It must be remembered that the effects of ultrasound are predominantly empirical and are based on reported biophysical effects within tissue[130,131] and on anecdotal experience in clinical practice.[132–134] Despite the paucity of documented evidence in terms of randomized control studies,[135] many benefits have been ascribed to ultrasound. These include the following:

- Production of cellular excitation, enhancing cellular activity rather than dampening it, and enhancing the inflammatory cascade, thereby encouraging the tissues to move into their next phase.[119,136–138]
- Decreased swelling when applied in a pulsed format during the inflammatory stage of healing.[128,130,131,139–144]
- Stimulation of the active cells and a maximization of scar production activity and quality, if applied during the neurovascular phase.[144–146] During the latter phase, ultrasound appears to enhance the remodeling of tissue.[127,142,145]
- An alteration of the parameters of ultrasound, which changes the intent of the intervention.[54]

Phonophoresis. Phonophoresis is a specific type of ultrasound application in which pharmacologic agents are introduced.[140,147–153] Phonophoresis has been used clinically since the early 1960s, in an attempt to drive these drugs transdermally into subcutaneous tissues. Theoretically, increases in cell permeability and local vasodilation may result in increased diffusion of the topical agent.[140,148,149]

The efficacy of phonophoresis has not been conclusively established. Some early studies have shown drug penetration as deep as 10 cm,[153–155] but a more recent study has cast doubt on these findings.[156] Other studies have examined the effects of phonophoresis with different corticosteroid concentrations, compared with ultrasound alone, in the intervention of various musculoskeletal conditions. Recent papers have argued that many of the commonly used cream-based preparations do not allow adequate transmission of the acoustic wave.[117,118,143] Gel-based preparations appear to be superior with respect to the transmissivity of ultrasound. Consequently, gel-based corticosteroid compounds might be expected to be superior for phonophoresis applications.

Mechanical Modalities

Traction. Mechanical or manual traction has been advocated throughout the spine despite the lack of evidence for its effectiveness. Traction has been promoted to distract the zygapophyseal joint, to increase the space between the vertebrae, to enlarge the intervertebral foramina, to stretch the joint capsule and ligaments, to improve blood supply (intermittent traction), and to reduce muscle spasms and pain.[157] Manual traction is usually the first form applied as it provides the clinician with information about the patient's reaction to traction and allows the clinician to quantify the amount of force being used. Ideally, the manual traction should be applied specifically by applying longitudinal traction to a segment while stabilizing the below segments using various locking techniques. The two most common modes employed with mechanical traction include the following:

- Sustained or static. This type of traction is applied continuously for a number of minutes and is recommended for patients with joint and/or nerve root irritability, those patients with reasonable developing neurological signs that have been associated with irritability, and those patients with severe arm pain combined with reduced neck movement toward the painful side.
- Intermittent. This type of traction is applied for short periods, with a rest period in between, and is indicated for patients with an acute joint derangement, those requiring generalized joint mobilization, and those with pain coming from muscle spasm.

Contraindications to mechanical traction include impaired cognitive function, rheumatoid arthritis, osteoporosis, evidence of instability, claustrophobia, spinal tumors, spinal infections, spondylolisthesis, vascular compromise, and very old or young patients.

Two types of mechanical traction are described, cervical and lumbar.

Cervical. Cervical traction is applied with the patient in sitting or supine position (Fig. 8-7), although the supine position is generally preferred as it removes the weight of the patient's head and allows the patient to relax better. With intermittent traction, a duty cycle of either 1:1 or 3:1 is used, and the treatment time varies according to the condition being treated—5–10 minutes is recommended for acute conditions and disk protrusion and 15–30 minutes is recommended for other conditions.[158–160] Weights of 25–45 lb appear necessary to produce vertebral separation with cervical traction.[161] Twenty to twenty-five pounds is necessary to straighten the lordotic curvature of the cervical spine. Approximately 8–10 lb or 7–10% of the patient's body weight is recommended initially to treat disk protrusions, muscle spasm, and to elongate soft tissue in acute conditions.[158–160] Less force appears to be necessary when treatment is directed to the upper cervical area.[161]

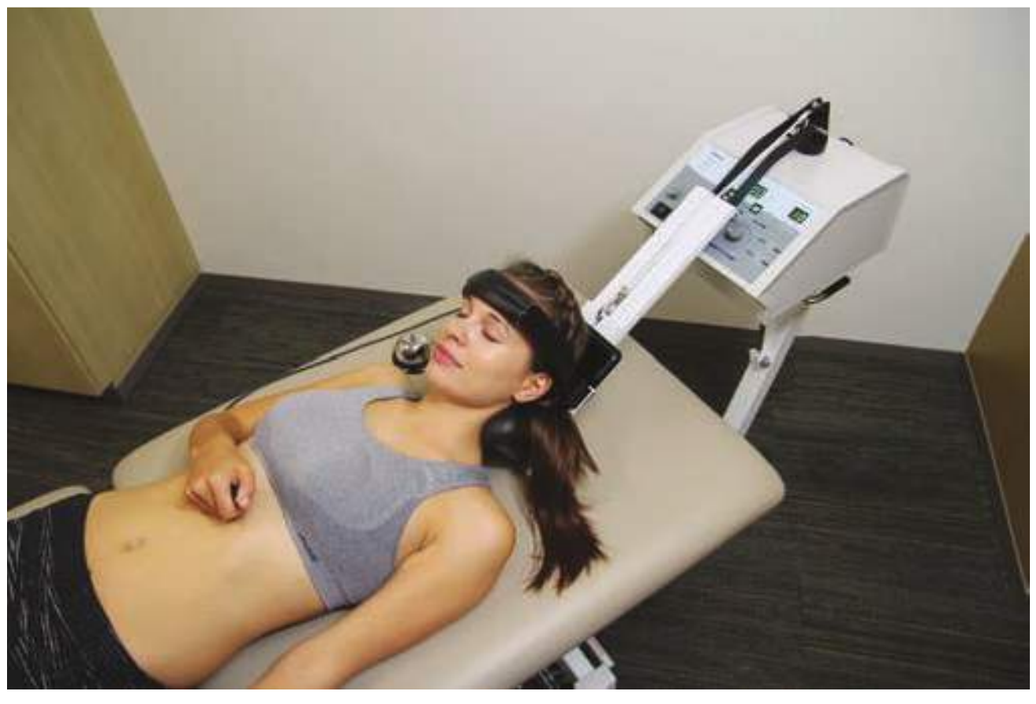

FIGURE 8-7 Cervical traction.

It is possible to apply traction more specifically by varying the angle of neck flexion:[158–160]

- To increase the intervertebral space at the C1–5 levels, approximately 0–5 degrees should be used.
- To increase the intervertebral space at the C5–7 levels, 25–30 degrees of flexion is recommended.
- Twenty-four to thirty-five degrees of flexion is recommended for zygapophyseal joint separation.
- Zero degrees of flexion is recommended for disk dysfunction.

Lumbar. The total treatment times to be used in lumbar traction are only partially research-based and can range from 5 to 30 minutes.[162–164] The traction force necessary to cause effective vertebral separation varies (approximately 50% of the patient's body weight).[162–164]

CLINICAL PEARL

There is conflicting evidence for the efficacy of intermittent lumbar traction for patients with low back pain. Several randomized controlled trials have compared traction to a sham traction intervention, with no significant differences found between groups. Clark et al.,[165] in a systematic review, investigated the use of traction compared to reference treatments, placebo/sham traction, or no treatment, for patients with low back pain. They concluded there was moderate evidence showing no statistically significant differences in short- or long-term outcomes between traction as a single treatment and a placebo, sham, or no treatment. There is preliminary evidence that a subgroup of patients with signs of nerve root compression along with peripheralization of symptoms or a positive crossed straight-leg raise will benefit from intermittent lumbar traction in the prone position.[166] In addition, there is moderate evidence that intermittent or static lumbar traction should not be used for reducing symptoms in patients with acute or subacute, nonradicular low back pain, or in patients with chronic low back pain.[167]

Hydrotherapy. Hydrotherapy is the use of water and its mechanical and thermal effects in the treatment of musculoskeletal dysfunction.

- Whirlpool. A whirlpool may be used in an attempt to facilitate the resorption of effusion. A cold whirlpool is indicated in acute and early subacute conditions, in which gentle exercise of the injured part is permitted. The temperature for a cold whirlpool is in the range of 50–60°F (10–16°C). A warm whirlpool is indicated in chronic conditions. During the treatment, the body part may be exercised. The temperature of a warm whirlpool is in the range of 100–110°F (39–45°C).
- Contrast bath. A contrast bath is a method of treatment that uses an alternating cycle of warm and cold whirlpools to create a cycle of alternating vasoconstriction and vasodilation. Contrast baths are used most often in the management of extremity injuries.[168,169] In a study by Myrer et al.,[170] a contrast bath therapy of 20 minutes had no impact on the intramuscular temperature of the gastrocnemius of their subjects 1 cm below the subcutaneous fat, as measured by a microprobe.
- Prolotherapy. Although prolotherapy is not administered by physical therapists, patients seen in the clinic may have received a course of prolotherapy from their physician, and it is thus included for completeness. Prolotherapy, also known as "proliferation therapy," is a relatively controversial injection-based pain management technique that may be used as an intervention for degenerative or chronic injury to ligaments, tendons, fascia, and joint capsular tissue. Prolotherapy involves the injection of a small volume of an irritant solution (e.g., dextrose 10%, sodium morrhuate, and phenol–glycerine–glucose) at multiple sites on painful ligament and tendon insertions and in adjacent joint spaces.

Prolotherapy is purported to allow rapid production of new collagen and cartilage through stimulation of the immune system's healing mechanism. The number of injections required per intervention is based on the type of injury. Rabago et al.[171] reviewed data from 34 case reports and case series and two nonrandomized control trials and suggested that prolotherapy was efficacious for many musculoskeletal conditions. However, they concluded that further investigation with high-quality randomized controlled trials was required before it would be possible to determine whether or not prolotherapy was effective.

- Sclerosing therapy. Like prolotherapy, sclerosing therapy is not administered by physical therapists, but patients seen in the clinic may have received a course of prolotherapy from their physician, and it is thus included for completeness. Sclerosing injections have been used in patients with various conditions, including chronic low back pain,[172–174] shoulder impingement,[175] tennis elbow,[176] Achilles tendinosis,[177,178] and patella tendinosis[179] with good results. Sclerosing therapy involves the injecting of abnormal vessels that are associated with painful tendons with a sclerosing agent to decrease pain. High-resolution color Doppler ultrasound shows intratendinous Doppler activity in patients with chronic tendinopathy. The affected area is sclerosed with vascular ingrowth. The injected chemical (e.g., Polidocanol) irritates the vascular intima to cause a vessel thrombosis. In addition, it may also sclerose the nerves adjacent to the new vessels, either directly (by destruction) or indirectly (by ischemia), which could explain the reduction in pain following the procedure.

FIGURE 8-8 Electrical stimulation unit.

Electrotherapeutic Modalities

- Electrical stimulation. Historically, many clinicians have advocated electrical stimulation (Fig. 8-8) to assist with strength recovery, muscle reeducation, prevention of atrophy, and reduction of functional limitation.[180] Electrical stimulation is traditionally used to[181]
  - produce a muscle contraction;
  - stimulate sensory nerves to help treat pain. For example, transcutaneous electrical nerve stimulation (TENS); and
  - create an electrical field within the tissues to stimulate or alter the healing process.

In addition to its use in the acute phase, electrical stimulation can be used in the other stages of healing for the reduction of pain and for neuromuscular reeducation.

Electrical current that passes through tissue forces nerves to depolarize. The type of nerve influenced in this way, and the rate at which the fiber is depolarized, determines the physiologic and, therefore, therapeutic effect achieved.[182,183]

The limited studies on postsurgical or acutely injured patients seem to indicate that neuromuscular electrical muscle stimulation (NMES) is either as effective as, or more effective than, isometric exercises at increasing muscle strength and bulk in both atrophied and normal muscles.[184,185]

Several authors have demonstrated the influence of stimulation parameters, such as electrode positioning,[186] current frequency,[187] current amplitude (intensity),[188] stimulus pulse duration,[189] and burst duty cycle of medium frequency alternating current,[190] on electrically induced torque.[180]

CLINICAL PEARL

A burst duty cycle is an important parameter of NMES, as it can directly affect torque production and sensory discomfort in healthy, untrained individuals.[191] In a study by a Liebano et al. a burst duty cycle of 20% of medium-frequency alternating current, compared to burst duty cycles of 35% and 50%, produced higher peak torque of the quadriceps femoris in professional soccer players while producing no difference in discomfort.

- Transdermal iontophoresis. Transdermal iontophoresis is a method by which ionic therapeutic agents are administered through the skin by the application of a low-level electrical current. Iontophoresis has proved to be valuable in the intervention of musculoskeletal disorders. Iontophoresis causes an increased penetration of drugs and other compounds into tissues by the use of an applied current through the tissue. The principle behind iontophoresis is that an electrical potential difference actively causes ions in solution to transfer according to their electrical charge. Ionized medications do not ordinarily penetrate tissues, and, if they do, it is not normally at a rate rapid enough to achieve therapeutic levels.[192] This is problem is overcome by providing a direct current energy source.[192,193]

CLINICAL PEARL

Negatively charged ions are repelled from a negative electrode and attracted toward the positive electrode. In contrast, the positive ions are repelled from the positive electrode and attracted toward the negative electrode.[192,193]

Iontophoresis has, therefore, been used for the transdermal delivery of systemic drugs in a controlled fashion.[194] The factors affecting the quality of the transdermal iontophoretic transport include pH; the intensity of the current, or current density, at the active electrode; ionic strength; concentration of drug; molecular size; and the duration of the current flow (continuous or pulse current).

Iontophoresis can be performed using a wide range of chemicals (Table 8-6). If the ionic source is in an aqueous solution, it is recommended that a low concentration be used (2–4%) to aid in the dissociation.[195] Although electrons flow from negative to positive, regardless of electrode size, having a larger negative pad than a positive one will help shape the direction of flow.

Current intensity is recommended to be at 5 mA or less. The duration of the treatment can vary from 10 to 20 minutes. Longer durations have been shown to produce a decrease in the skin impedance, thus increasing the likelihood of burns from an accumulation of ions under the electrodes.[196] An accumulation of negative ions under the positive electrode produces hydrochloric acid. An accumulation of positive ions under the negative electrode produces sodium hydroxide.

Other complications have included prolonged erythema that resolved in 24 hours, tingling, burning, and pulling sensations that were especially apparent at the start of the current or if the amperage was turned up too rapidly. The visible erythema demonstrates the clear increase in blood flow and the influence of the iontophoresis.

Currently, research has been focused on the development of iontophoretic patches for the systemic delivery of drugs as (1) they provide the option to monitor and control the power supplied during use, (2) can detect the number of times the patch has been used, and (3) the controller can be rendered unusable to avoid abuse, once the drug is exhausted.

Extracorporal Shock Wave Therapy. High-energy extracorporeal shock waves have been used in urology for the disintegration of stone concretion for almost 15 years. For the past 10 years, this technology has emerged as a treatment modality for managing pain caused by a broad range of

TABLE 8-6 Various Ions Used in Iontophoresis

Ion	Polarity	Solution	Purpose/Condition
Acetate	−	2–5% acetic acid	Calcium deposits[171]
Atropine sulfate	+	0.001–0.01%	Hyperhidrosis
Calcium	+	2% calcium chloride	Myopathy and muscle spasm
Chlorine	−	2% sodium chloride	Scar tissue and adhesions
Copper	+	2% copper sulfate	Fungus infection
Dexamethasone	+	4 mg/mL dexamethasone Na–P	Tendonitis and bursitis[172]
Lidocaine	+	4% lidocaine	Trigeminal neuralgia[173]
Hyaluronidase	+	Wydase	Edema[174]
Iodine	−	Iodex ointment	Adhesions and scar tissue[175]
Magnesium	+	2% magnesium sulfate (Epsom salts)	Muscle relaxant[176] and bursitis
Mecholyl	+	0.25%	Muscle relaxant
Potassium iodide	−	10%	Scar tissue
Salicylate	−	2% sodium salicylate	Myalgia and scar tissue
Tap water	±	—	Hyperhidrosis

+, positive; −, negative.

musculoskeletal conditions. T ese conditions include tendinopathies and nonunion and delayed union of fractures.[197–199] Currently, the therapeutic mechanisms of shock waves in musculoskeletal problems or their specific biologic effects on the various musculoskeletal tissues (bone, cartilage, tendon, and ligament) are not fully understood.[200] T e extracorporeal shock wave is an acoustic wave characterized by high positive pressures of more than 1,000 bar (100 MPa), which can be developed within an extremely short rise time (10^{-9} seconds) and followed by a low-pressure phase of tensile stress equivalent to 100 bar (10 Mpa).[201] A clinically applicable shock wave represents nothing more than a controlled explosion, producing a sonic pulse in much the same way as a fast-flying aircraft may produce a sonic boom.[200] When the shock wave enters the tissue, it may be dissipated and reflected so that the kinetic energy is absorbed according to the integral structure of the tissues or structures that are exposed to the shock waves.[200] However, because the duration of the shock wave is so short (3–5 microseconds) and is generated at low frequencies, no thermal effect is generated. For shock waves to be effective in the clinical situation, the maximally beneficial pulse energy must be concentrated at the point at which treatment is to be provided. T ere are three mechanisms by which extracorporeal shock wave therapy (ESWT) units generate the shock waves: electromagnetic, electrohydraulic, and piezoelectric. T e electromagnetic and piezoelectric units tend to generate lower energy shock waves than the electrohydraulic units.[202] Medically useful shock waves usually are generated through a fluid medium (water) and a coupling gel to facilitate transmission into biologic tissues. T e energy flux density (ED) refers to the shock wave energy "flow" through an area perpendicular to the direction of propagation[202]; 1,000–2,000 shock waves of an ED from 0.01 to 0.4 mJ/mm^2 are usually applied two to three times at weekly intervals.[201] Pulse duration is usually fixed at 3–5 microseconds and the calculation of dose (total energy delivered) depends on the choice of energy level and the total number of shock wave impulses delivered.[202] Most patients report a sharp pain sensation during the application of ESWT, necessitating a skin sensation test prior to its use.

A meta-analysis by Ogden et al.[203] reported that, of various applications of ESWT on musculoskeletal conditions, the use of ESWT for treating chronic, recalcitrant heel pain syndrome was the most credible.

ESWT is contraindicated for use in patients suffering from hemophilia (because it may cause microvascular disruption) and malignancy, and ESWT should not be applied to growth plates or where exposure to lung tissue may occur (clavicle or first rib).[200,202]

Transcutaneous Electrical Nerve Stimulation. TENS was first introduced in the early 1950s to determine the suitability of patients with pain as candidates for the implantation of posterior (dorsal) column electrodes. TENS has since been shown to be an effective, inexpensive, and noninvasive intervention in providing pain relief in the early stages of healing following surgery[204–209] and in the remodeling phase.[210–213]

T e percentage of patients who benefit from short-term TENS pain intervention has been reported to range from 50% to 80%, and good long-term results with TENS have been observed in 6–44% of patients.[210,212,214,215] However, most of the TENS studies rely solely on subjects' pain reports to establish efficacy and rarely on other outcome measures such as activity, socialization, or medication use.

TENS units typically deliver symmetric or balanced asymmetric biphasic waves of 100- to 500-millisecond pulse duration, with zero net currents to minimize skin irritation,[216] and may be applied for extended periods.

T ree modes of action are theorized for the efficacy of this modality (see Chapter 3):

1. Gate control mechanism. Spinal gating control through stimulation of the large, myelinated A-alpha fibers inhibits transmission of the smaller pain transmitting unmyelinated C fibers and myelinated A-delta fibers.[207,217]
2. Endogenous opiate control. When subjected to certain types of electrical stimulation of the sensory nerves, there may be a release of enkephalin from local sites within the central nervous system and the release of β-endorphin from the pituitary gland into the cerebrospinal fluid.[216,218,219] A successful application can produce an analgesic effect that lasts for several hours.
3. Central biasing. Intense electrical stimulation, approaching a noxious level, of the smaller C or pain fibers, produces a stimulation of the descending neurons.

Diathermy. Diathermy is a therapeutic modality that generates a form of an electromagnetic wave (a combination of both electrical and magnetic fields) that has frequency ranges that can be categorized as either microwave or shortwave. Diathermy is generally used to decrease pain, increase metabolic functions, increase deep tissue temperature, and increase ROM. Contraindications to diathermy include application over metal, metabolic conditions, and pacemakers.

- Shortwave diathermy. T is is also described as either continuous shortwave diathermy or pulsed shortwave diathermy.
- Microwave diathermy. Microwave diathermy delivers shorter waves of higher-frequency electromagnetic waves than shortwave diathermy.

Variation in the strength of the electromagnetic wave is dependent upon several factors including the frequency of the unit, and characteristics of the applicator. Although there is some evidence to support the clinical use of diathermy,[220–225] there is also evidence that does not support its use.

Hyperbaric Oxygen Therapy

Hyperbaric oxygen therapy (HBOT) is the medical use of oxygen at a level higher than atmospheric pressure, which produces an excess of oxygen in the body. T is increased dissolved oxygen in the plasma has been shown to more effectively reach injured tissues than oxygen-bound hemoglobin.[226] T e current literature includes studies of treatment of numerous different orthopaedic conditions using HBOT, including delayed onset muscle soreness, chronic wounds, fibromyalgia, complex regional pain syndrome, migraine and cluster headaches, and edema.[226] T e only absolute contraindication to HBOT is untreated pneumothorax.

Aquatic Therapy

Current research shows aquatic therapy to be beneficial in the treatment of everything from orthopaedic injuries to spinal cord damage, chronic pain, cerebral palsy, multiple sclerosis, and many other conditions. Among the psychological aspects, water motivates movement because painful joints and muscles can be moved more easily and painlessly in water.

T e indications for aquatic therapy include instances when partial weight-bearing ambulation is necessary, to increase ROM, when standing balance needs to be improved, when endurance/aerobic capacity needs to be improved, or when the goal is to increase muscle strength via active-assisted, gravity-assisted, active or resisted exercise.

Contraindications to aquatic therapy include uncontrolled incontinence, urinary tract infections, water and airborne infections or diseases (e.g., influenza, and gastrointestinal infections), unprotected open wounds, menstruation without internal protection, heat intolerance, severe epilepsy/seizures disorder, uncontrolled diabetes, unstable blood pressure, or severe cardiac and/or pulmonary dysfunction (e.g., incipient cardiac failure, unstable angina, and a vital capacity of less than 1 L). In general, pregnant women are quite sensitive to core temperature elevations and should, therefore, exercise in cool to neutral temperatures. T e same can be said for patients with heat intolerant multiple sclerosis. However, a few studies have reported benefits for this patient population if the water temperature is controlled.[227–229]

Physical Properties and Resisted Forces

T ere are several physical properties of water, which make exercising in water differ from that on land:

- Density. Although the human body is mostly water, the body's density is slightly less than that of water, which has a specific density of 1.0 kg/m^3, and averages a specific gravity of 0.974 kg/m^3, with men averaging higher density than women. Any object with a specific gravity less than that of water will float. T e buoyant values of different body parts vary according to a number of factors:
  - Bone to muscle weight. Lean body mass, which includes bone, muscle, connective tissue, and organs, has a typical density near 1.1 kg/m^3.
  - T e amount and distribution of fat. Fat mass, which includes both essential body fat plus fat in excess of essential needs, has a density of about 0.9 kg/m^3.
- Hydrostatic pressure: hydrostatic pressure is the pressure exerted by the water on immersed objects with the pressure being directly proportional to both the liquid density and to the immersion depth when the fluid is incompressible. Water exerts a pressure of 22.4 mm Hg/ft of water depth, which translates to 1 mm Hg/1.36 cm (0.54 in) of water depth. T us, a human body emerged to a depth of 48 in is subjected to a force equal to 88.9 mm Hg, slightly greater than normal diastolic blood pressure.[230] T e effects of hydrostatic pressure, which is the force that aids resolution of edema in an injured body part, begin immediately on immersion, causing plastic deformation of the body over a short period. T is results in a superior displacement of blood, a rise in right atrial pressure, an increase in pleural surface pressure, compression of the chest wall, and a superior displacement of the diaphragm.
- Surface tension: Surface tension is a result of the cohesive forces among liquid molecules that causes fluid to act as a membrane under tension. From a clinical perspective, using equipment at the surface of the water increases the resistance. In addition, and it is more difficult for a patient

to move an extremity through the surface than moving the extremity underwater.

- Buoyancy: the human body displaces a volume of water weighing slightly more than the body, forcing the body upward by a force equal to the volume of the water displaced, as discovered by Archimedes. T is buoyancy force is responsible for the main advantage of exercising in water. As the body is gradually immersed, water is displaced, creating the force of buoyancy. Buoyancy can provide a feeling of relative weightlessness. A human with a specific gravity of 0.974 kg/m^3 reaches floating equilibrium when 97% of his or her total body volume is submerged.[230] Adjusting the depth of immersion has been described as an effective way of controlling the loads acting on body structures.[231]
  - With neck depth immersion, only about 15 lb of compressive force is exerted on the spine, hips, and knees.
  - With immersion up to the symphysis pubis, 40% of the body weight is effectively of oaded.
  - With immersion up to the umbilicus, 50% of the body weight is effectively of oaded.
  - With immersion up to the xiphoid, 60% or more (depending on whether the arms are overhead or beside the trunk) of the body weight is effectively of oaded.
  - Compared to stationary running on land, running in water that is hip level decreases forces applied to the body by nearly 40%, while running in water that is chest level decreases the forces by almost 50%.[232]
- Viscosity refers to the magnitude of internal friction specific to a fluid in motion. A limb moving relative to water is subjected to the various resistive effects of the fluid:[230]
  - Drag force: It is a factor of the shape of an object and its speed of movement. Objects that are more streamlined (minimizing the surface area at the front of the object) produce less drag force. Moving water past the patient, or using aquatic equipment such as a paddle or board, requires the patient to work harder.
  - Laminar flow: movement in which all molecules move parallel to each other.
  - Turbulence: movement in which molecules do not move parallel to each other. Under turbulent flow conditions, resistance increases as a log function of velocity.

Viscous resistance increases as more forces are exerted against it, but that resistance drops to zero almost immediately on the cessation of force.

Thermodynamics

Specific heat is the amount of heat required to raise the temperature of 1g of a substance by 1°C. T e heat capacity of water is 1,000 times greater than the equivalent volume of air. T e therapeutic utility of water depends greatly on both its ability to retain heat and its ability to transfer heat energy. Heat transfer begins immediately on immersion, and as the heat capacity of the human body is less than that of water (0.83 vs. 1.00), the body equilibrates faster than the water does.

CLINICAL PEARL

Water is an ef cient conductor, transferring heat 25 times faster than air. This thermal conductive property, in combination with the high specific heat of water, makes the use of water in rehabilitation very versatile because water retains heat or cold while delivering easily to the immersed body part.[230]

Design and Special Equipment

Certain characteristics of the pool should be taken into consideration if it is to be used for rehabilitation purposes:

- T e pool (Fig. 8-9) should not be smaller than 10′ × 12′.
- T e pool should have both a shallow (1.25 m/2.5 ft) and a deep (2.5 m/5 ft plus) area (Fig. 8-9) to allow for standing exercises and swimming or non-standing exercise.
- T e pool bottom should be flat and the depth gradations clearly marked.
- A pneumatic chair lift (Fig. 8-10) can be used to help a patient access the water.

Variable temperature control for the water should be available (water that is too warm can lead to fatigue, or even heat exhaustion because evaporation of perspiration is not possible in water, whereas water that is too cool can cause shivering, increase muscular tension, or produce hypothermia):

- Cold plunge tanks are often used at temperatures of 10–15°C to produce a decrease in muscle pain and speed recovery from an overuse injury.
- Most public and competitive pools operate in the range of 27–29°C.
- Typical therapy pools operate in the range of 33.5–35.5°C.
- Hot tubs are usually maintained at 37.5–41°C.

Rescue tubes, inner tubes, and wet vests should be purchased to assist in floatation activities. Hand paddles and pull buoys can be used for strengthening the upper extremity. Kick boards and fins are useful for strengthening the lower extremity.

FIGURE 8-9 An aquatherapy pool.

FIGURE 8-10 A pneumatic chairlift to aid a patient.

Advantages

Aquatic therapy offers a number of advantages over traditional land-borne exercises:

- The buoyancy of the water allows active exercise while providing a sense of security and causing little discomfort. Deepwater running drills, using a buoyancy vest, can be used to maintain fitness during recovery from lower limb injury and as a form of cross-training to reduce impact with the aim of reducing overuse injuries.
- Early in the rehabilitation process, aquatic therapy is useful in restoring ROM and flexibility using a combination of the water's buoyancy, resistance, and warmth.
- The buoyancy provides support. An aquatic exercise program can be designed to vary the amount of gravity loading by using buoyancy as a counterforce. Shallow water vertical exercises generally approximate closed chain exercises, albeit with reduced joint loading because of the counterforce produced by buoyancy. Deepwater exercises more generally approximate the open-kinetic chain system, as do horizontal exercises. Paddles and other resistive equipment (Fig. 8-11) tend to "close" the kinetic chain.
- The slow-motion effect of moving in water provides extra time to control movement and to react. Aquatic exercise protocols have been successfully used to improve balance and coordination in older individuals, who face an increased risk of falling.[233]
- The water provides tactile stimulation and feedback.

FIGURE 8-11 Examples of exercise equipment for use in aquatherapy.

- The buoyancy of the water can be used to provide a gradual transition from non–weight-bearing to full–weight-bearing exercises by adjusting the amount the body is submerged. For example, acute injury programs typically start at non–weight-bearing depths, limiting activity below pain onset, and then progress to weight-bearing levels as symptoms permit.
- The intensity of exercise can be controlled by manipulating the body's position or through the addition of exercise equipment. During aquatic treadmill running, oxygen consumption is three times greater at a given speed of ambulation than on land. Thus, the training effect may be achieved at a significantly slower speed than on land.[234]

Disadvantages

The disadvantages of aquatic therapy include:

- The cost of building and maintenance.
- Difficulty in treating patients with an inherent fear of water.
- Potential adverse effects on the cardiovascular system. Because an individual immersed in water is subject to external water pressure in a gradient, which within a relatively small depth exceeds venous pressure, blood is displaced upward to the venous and lymphatic systems, first into the thighs, then into the abdominal cavity vessels, and finally into the great vessels of the chest cavity and into the heart.[230] The following cardiovascular changes can occur with immersion of the body:
  - An increase in central venous pressure.
  - An increase in pulse pressure as a result of the increased cardiac filling and decreased heart rate during thermoneutral or cool immersion.
  - An increase in central blood volume.
  - An increase in cardiac volume, cardiac output, and stroke volume.
  - A decrease in sympathetic vasoconstriction, resulting in a reduction in both peripheral venous tone and systemic vascular resistance.
- Potential adverse effects on the pulmonary system. Immersion of the body to the level of the thorax causes

a shifting of blood into the chest cavity and increased compression of the chest.[230] T e combined effect is to alter pulmonary function, increase the work of breathing, and change respiratory dynamics. However, while care must be taken with patients who have inspiratory muscle weakness due to conditions such as congestive heart failure and chronic obstructive lung disease, respiratory strengthening can also be an important aspect of high-level athletic performance.

Aquatic Therapy Protocols

Many of the therapeutic activities that are traditionally land based can be performed in water. T ese include manual stretching, extremity strengthening exercises, core stabilization, and aerobic conditioning. In contrast to gravity, buoyancy works in the opposite direction but, like gravity, can be manipulated by changing the direction in which an exercise is performed, or how much support the patient is given. For example, most ROM and stretching exercises can be performed with the patient supported in supine using a variety of buoyancy aids. Strengthening exercises can be progressed by working parallel to the buoyancy force to working perpendicular to the buoyancy force—moving the segment toward the bottom of the pool.

Postsurgical Rehabilitation

Traditional interventions for postsurgical patients have involved adhering to exercise protocols designed by the surgeon performing the operation in order to limit postsurgical stress to the healing tissues. T is has led to an emphasis on interventions based solely on exercises linked to time frames, a sort of "cookbook" approach, rather than a comprehensive approach designed in conjunction with the physical therapist based on clinical findings and individual consideration.

Among the key factors that must be considered in the postsurgical rehabilitation are:[235]

- type of surgery;
- patient's age;
- patient's physical status, including weight, and other medical conditions, such as any history of cardiovascular or peripheral vascular disease (PVD), or diabetes;
- the social lifestyle of the patient;
- preoperative joint contracture or muscle atrophy;
- the method of surgical fixation;
- surrounding soft tissues involved;
- the degree of correction of biomechanical alignment;
- functional and recreational goals of the patient; and
- frequency of visits during the episode of care.

T ese factors may influence the rate at which the patient progresses through the rehabilitation process, as well as determine the extent of functional return that can be expected in the long term.

T e stages of healing described in Chapter 2 should not be viewed as distinct entities or as rigid templates but as a continuum that must be modified on the basis of clinical findings and subjective responses. For example, responses to an intervention that indicate an overly aggressive approach include:

- increased area of pain;
- pain at rest that lasts longer than 2 hours after exercising;[236]
- pain that alters the performance of an activity or exercise in a detrimental manner.[236]

Each surgical procedure is different, as is the healing capacity of each individual. In addition, each surgeon has his or her opinion as to the intensity of the postsurgical intervention. T ese opinions must always be respected. Although estimated timetables are typically provided with each protocol, the point at which the various tools of intervention can be used following surgery may vary.

Realistic goal setting is important following surgery. Postsurgical rehabilitation goals should be based on the status of the uninvolved body parts, and the patient should be involved in the goal-setting process whenever possible.

Patient/Client-Related Instruction

Patient/client-related instruction forms the cornerstone of every intervention. During the physical therapy visits, the clinician and the patient work to alter the patient's perception of the functional capabilities. Together, the patient and clinician discuss the parts of the patient's life that he or she can and cannot control and then consider how to improve those parts that can be changed. It is imperative that the clinician spends time educating the patient about his or her condition, so that the patient can fully understand the importance of his or her role in the rehabilitation process and become an educated consumer. Educating the patient about strategies to adopt in order to prevent recurrences and to self-manage his or her condition is also very important. Discussions about intervention goals must continue throughout the rehabilitative process and must be mutually acceptable.

Oftentimes, the physician relies on the physical therapist to give a broader explanation about the condition and to answer questions and concerns related to the rehabilitative process. T e aim of patient instruction is to create independence, not dependence, and to foster an atmosphere of learning in the clinic. A detailed explanation should be given to the patient in a language that he or she can understand. T is explanation should include:

- the name of the structure(s) involved, the cause of the problem, and the effect of the biomechanics on the area. Whenever possible, an illustration or anatomical model of the involved structure should be shown to the patient. Anatomic models can also be used to explain biomechanical principles in layperson's terms.
- information about tests, diagnosis, and any interventions that are planned.
- the prognosis of the problem and a discussion about the patient's functional goals. An estimation of healing time is useful for the patient so that he or she does not become frustrated at a perceived lack of progress.
- what patients can do to help themselves. T is includes the permitted use of the joint or area, a brief description of the relevant stage of healing, and the vulnerability

of the various structures during the pertinent healing phase. T is information makes the patient aware and more cautious when performing activities of daily living, recreational activities, and the home exercise program. Emphasis should be placed on dispelling the myth of "no pain, no gain," and patients should be encouraged to respect pain. Patients often have misconceptions about when to use heat and ice, and it is the role of the clinician to clarify such issues.

- home exercise program. Before prescribing a home exercise program, the clinician should take into consideration the time that will be needed to perform the program. In addition, the level of tolerance and motivation for exercise vary among individuals and are based on their diagnosis and stage of healing. A short series of exercises, performed more frequently during the day, should be prescribed for patients with poor endurance or when the emphasis is on functional reeducation. Longer programs, performed less frequently, are aimed at building strength or endurance. Each home exercise program needs to be individualized to meet the patient's specific needs. Although two patients may have the same diagnosis, the examination may reveal different positive findings and stages of healing, both of which may alter the intervention.

T ere are probably as many ways to teach as there are to learn. It is not within the scope of this text to discuss all of the theories on learning, but an overview of the major concepts is merited. Motor learning and skill acquisition is described in Chapter 3.

Litzinger and Osif[237] organized individuals into four main types of learners, based on instructional strategies:

1. Accommodators. T is type looks for the significance of the learning experience. T ese learners enjoy being active participants in their learning and will ask many questions, such as, "What if?" and "Why not?"
2. Divergers. T is type is motivated to discover the relevancy of a given situation and prefers to have information presented in a detailed, systematic, and reasoned manner.
3. Assimilators. T is type is motivated to answer the question, "What is there to know?" T ese learners like accurate, organized delivery of information, and they tend to respect the knowledge of the expert. T ey are perhaps less instructor intensive than some other types of learners and will carefully follow prescribed exercises, provided a resource person is clearly available and able to answer questions.
4. Convergers. T is type is motivated to discover the relevancy, or "how," of a situation. T e instructions given to this type of learner should be interactive, not passive.

A patient's learning style can be identified by asking how he or she prefers to learn. Some patients will prefer a simple handout with pictures and instructions; others will prefer to see the exercises demonstrated and then be supervised while they perform the exercises. Some may want to know why they are doing the exercises, which muscles are involved, why they are doing three sets of a particular exercise, and so on. Others will require less explanation.

If the clinician is unsure about the patient's learning style, it is recommended that each exercise first be demonstrated by the clinician and then by the patient. T e rationale and purpose behind each of the exercises must be given, as well as the frequency and intensity expected.

Compliance

Compliance is vitally important in the healing process. Compliance can be defined as engaging in behavior as instructed or prescribed.[238] Another term "adherence," which can be defined as continuing to engage in behaviors, is similar in that both vary from patient to patient, and both are related to motivation. Motivation, a psychological feature that drives an organism toward a desired goal, is considered vital to maintaining behavior. Motivation has been classified as either intrinsic (internal) or extrinsic (external). A number of motivational theories have been proposed (Table 8-7).

Anecdotally, unmotivated patients may progress more slowly. Much literature has conceptualized or reported poor motivation in rehabilitation as secondary to patient-related factors, including depression, apathy, cognitive impairment, low self-efficacy (e.g., low confidence in one's ability to successfully rehabilitate), fatigue, and personality factors.[239] Various studies have found that average compliance with medication regimens occurs only in 50–60% of patients, and compliance with physical therapy programs is approximately 40%.[240] Other reports have found that compliance was decreased if the physical therapists did not provide their patients with positive feedback.[241]

Several considerations should be made to increase compliance:

- T e patient's age—older individuals tend to adhere to exercise programs more than younger individuals;[242]
- T e patient's marital status—singles tend to have lower rates of adherence to physical activity/exercise than married couples;[243]
- T e patient's education—individuals with high levels of education show more compliance to exercise programs than those who are uneducated;[243]
- T e patient's gender—males report greater levels of total and vigorous activity than females;[243]
- T e patient's biomedical status—poorer health tends to lead to decreased adherence;[244]
- T e patient's socioeconomic status—an individual's income bracket tends to influence the ability to access medical care, as well as exercise equipment and venues;[245–247]
- T e patient's ethnicity—Caucasians appear to participate in more physical activities than other racial or ethnic groups, regardless of age.[243]

Finally, a number of factors have been outlined to improve compliance; including:[248–250]

- involving the patient in the intervention planning and goal setting;
- realistic goal setting for both short- and long-term goals;
- promoting high expectations regarding final outcome;
- promoting perceived benefits;
- projecting a positive attitude;

TABLE 8-7 Motivational Theories

Theory	Proponents	Description
Social cognitive	Bandura[a]	Individuals act as contributors to their own motivation, behavior, and development. Behavior and characteristics are modified by environment. Primary mediators include self-efficacy and the ability to self-regulate. Mastery is the best way to create a strong sense of efficacy.
Self-determination	Lepper et al.[b]	Choices made are based on experiences, thoughts, contemplations, and interactions with others. Essential psychological needs include competence, relatedness, and autonomy. Comprised of five minitheories[c]: ▯ Cognitive Evaluation Theory (CET): intrinsic motivation is a lifelong creative wellspring. CET highlights the critical roles played by competence and autonomy in fostering intrinsic motivation. ▯ Organismic Integration Theory: extrinsic motivation is behavior that aims toward outcomes extrinsic to the behavior itself. Highlights supports for autonomy and relatedness as critical to internalization. ▯ Causality Orientations Theory: describes individual differences in people's tendencies to orient toward environments and regulate behavior in various ways based on rewards, gains, and approval. ▯ Basic Psychological Needs Theory: psychological well-being and optimal functioning is predicated on meeting the needs of autonomy, competence, and relatedness. ▯ Goal Contents Theory: Goals are seen as differentially affording basic need satisfactions and are thus differentially associated with well-being.
Health belief model	Ajzen[d] and Fishbein[e]	An individual's attitude, social norms, and perceived control are accurate predictors of behavioral intentions. Involves the TRA and the TPB: ▯ TRA is most successful when applied to behavior under an individual's voluntary control. ▯ TPB theorizes that if an individual's perceived control, self-efficacy, or self-esteem is low, the perception and belief that he or she can influence behavior in a positive manner is undermined.
Humanistic	Maslow[f]	Based on the concept that there is a hierarchy of biogenic and psychogenic needs that humans must progress through. Hypothesizes that the higher needs in this hierarchy only come into focus once all the needs that are lower down are mainly or entirely satisfied.
Transtheoretical model	Prochaska and DiClemente[g]	Describes five stages of change: ▯ Precontemplation: defined by a lack of intention to take action. ▯ Contemplation: defined by the individual thinking about engaging in a behavior or activity in the near future. ▯ Preparation: defined by the individual intending to take action in the immediate future. ▯ Action: defined by the individual actively engaged in the behavior or change. ▯ Maintenance: defined by an individual who has engaged in a behavior or change for longer than 6 months.

TPB, theory of planned behavior; TRA, theory of reasoned action.

- providing clear instructions and demonstrations with appropriate feedback;
- keeping the exercises pain free or with a low level of pain; and
- encouraging patient problem solving.

Progress and Reexamine

The selection of intervention procedures, and the intervention progression, must be guided by continuous reexamination of the patient's response to a given procedure, making the reexamination of patient dysfunction before, during, and after each intervention essential.[251]

At each visit, the clinician must reexamine the patient's status. To evaluate progress, comparisons are made between the findings from the initial examination and subsequent visits. There are three possible scenarios following a reexamination:

1. The patient's *f*unction has improved. In this scenario, the intensity of the intervention may be incrementally increased.
2. The patient's *f*unction has diminished. In this scenario, the intensity and the focus of the intervention must be changed. Further review of diagnosis and working hypothesis may be needed. The patient may require further education on activity modification and the use of heat and ice at home.
3. There is no change in the patient's *f*unction. Depending on the time that has elapsed since the last visit, there may be a reason for the lack of change. This finding may also indicate the need for a change in the intensity of the intervention. If the patient is in the acute or subacute stage of healing, a decrease in the intensity may be warranted to allow the tissues more of an opportunity to heal. In the chronic stage, an increase in intensity may be warranted.

The developing healthcare system of the last decade has dramatically limited patients' access to rehabilitation services and has increased the accountability of the healthcare provider.[252] This development has placed a burden on the physical therapy profession to make the necessary changes to deal effectively with healthcare reform, so that physical therapists become more accountable for their professional performance and more cost-effective in their provision of patient care.[252] It is important that examination and intervention techniques continue to be verified through peer-reviewed research, patient outcome databases, and an increased efficiency and effectiveness.[253,254]

Health Promotion, Wellness, and Physical Fitness

In 1996, the Surgeon General's report on physical activity and health highlighted the importance of engaging in an active lifestyle to prevent the insidious onset of chronic disease and illness.[255] More recently, the office of disease prevention and health promotion in the Department of Health and Human Services introduced an agenda through Healthy People 2020 that established goals for promoting a healthy lifestyle for individuals in the United States.[256]

The World Health Organization has defined health promotion as "the process of enabling people to increase control over their health and its determinants, and thereby improve their health."*

The National Wellness Institute has delineated six components of wellness:†

- Social. This includes contributing to one's environment and community and emphasizing the interdependence between others and nature.
- Occupational. This includes satisfaction and enriching life through work.
- Spiritual. This includes an appreciation of the depth of an expansive life and having meaning in one's life.
- Physical. This includes awareness of the need for regular physical activity, good diet, and nutrition and avoiding habits that are harmful to wellness.
- Intellectual. This includes being able to solve problems, expand knowledge and skills, and have an openness to new ideas.
- Emotional. This includes awareness and acceptance of one's feelings and thinking of oneself positively.

Physical therapists serve as major providers of health promotion, wellness, and fitness by making patients and clients more aware of lifestyle changes, particularly in the areas of physical activity, lifelong health promotion, and creating an environment that supports health practices leading to a healthy lifestyle.[257] Evidence exists that when healthcare professionals counsel patients about risk reduction, those patients are more likely to change poor health habits, thus enhancing a healthier lifestyle.††

The effects of physical activity and exercise on various physiological and psychological parameters across the lifespan support the use of exercise prescriptions and their role in preventing disease and improving function and health. This is particularly relevant in promoting mobility and dependence of the elderly, the older old, and the frail elderly.[257]

Pharmacology for the Orthopaedic Physical Therapist

CHAPTER 9

CHAPTER OBJECTIVES

At the completion of this chapter, the reader will be able to:

1. Differentiate between pharmacokinetics and pharmacodynamics.
2. Describe the process of drug development, regulation, and distribution.
3. Describe controlled substances and their potential for abuse.
4. Recognize the three different names used for drugs.
5. Describe the various modes of action of drugs.
6. Describe the various drug receptor sites within the body.
7. Outline the different administration routes used for drug delivery.
8. Understand the potential effects of physical agents and exercise on drug delivery.

OVERVIEW

Pharmacology is the broad area of study that deals with how chemical substances affect living tissue on a molecular level and how drugs affect specific patient populations (Table 9-1). Drug therapy is one of the mainstays of modern treatments, and physical therapists often encounter patients who are taking various medications. The Guide to Physical Therapist Practice[1] identifies clinical pharmacology as an essential component of appropriate patient monitoring, modality delivery, and communication among medical professionals. It is therefore important for the physical therapist to have a working knowledge of pharmacology because of the number of drugs currently on the market and the number of physical therapy patients that are likely to have been prescribed medications. As physical therapists attempt to account for the effects of their interventions, it becomes apparent that they must also understand the effect and potential interactions of all available and reasonable resources, including pharmacological interventions, offered by other members of the healthcare team.[2] The prescription-drug-writing privileges exercised by select military therapists and the evolution of the physical therapy profession promote consideration of an expanded pharmacological role in physical therapy practice.[3] Although the dispensing of medications is currently out of the scope of practice for the vast majority of physical therapists, questioning the patient about prescribed medication use can reveal medical conditions that the patient might not consider related to his or her present problem, as the prescribed medications may be for pre-existing conditions that are not directly related to the condition being treated with physical therapy. In addition, this information can also provide the clinician with possible reactions that the patient may have to exercise or other treatment procedures, and the impact on clinical findings. For example:

Pain medications, muscle relaxants, and nonsteroidal anti-inflammatory drugs (NSAIDs) can mask signs and symptoms, thereby affecting examination findings and increasing the potential for injury during the performance of prescribed exercises.[4] However, if the patient has a significant amount of pain, appropriate use of these medications may enhance treatment, allowing a more rapid progression than would otherwise be possible. However, as the patient improves, the need for this medication should lessen.

- Certain medications can produce changes in musculoskeletal structures. For example, prolonged use of corticosteroids may produce osteoporosis and weakening of connective tissues.[5]
- A patient undergoing anticoagulant therapy has a reduced clotting ability and is more susceptible to bruising or hemarthrosis. It is worth remembering that aspirin and aspirin-based products have an anticoagulant effect.

Clinical Pearl

While the importance of a pharmacologically integrated approach to comprehensive patient management cannot be over emphasized, it is worth remembering that while some drugs can enhance physical therapy interventions, many can have negative consequences.

TABLE 9-1 Pharmacology Terms and Definitions

Term	Definition
Drug	Any substance that can be used to modify a chemical process or processes in the body, e.g., to treat an illness, relieve a symptom, enhance a performance or ability, or to alter states of mind. The word "drug" is etymologically derived from the Dutch/Low German word "droog," which means "dry," since in the past, most drugs were dried plant parts.
Pharmacology	The science of studying both the mechanisms and the actions of drugs, usually in animal models of disease, to evaluate their potential therapeutic value.
Pharmacy	The mixing and dispensing of drugs. The monitoring of drug prescriptions for appropriateness and the monitoring of patients for adverse drug interactions.
Pharmacotherapeutics	The use of chemical agents to prevent, diagnose, and cure disease.
Pharmacokinetics	The study of how the body absorbs, distributes, metabolizes, and eliminates a drug.
Pharmacodynamics	The study of the biochemical and physiologic effects of drugs and their mechanisms of action at the cellular or organ level.
Pharmacotherapy	The treatment of a disease or condition with drugs.
Pharmacogenetics	The study of how variation in human genes leads to variations in our response to drugs and helps direct therapeutics according to a person's genotype.
Toxicology	A study of the negative effects of chemicals on living things, including cells, plants, animals, and humans.

PHARMACOKInETICS

Pharmacokinetics is the study of the physicochemical factors involved as the body absorbs, distributes, metabolizes, and eliminates a drug. To have a desirable effect, a drug must have an appropriate concentration at the site of action. The physicochemical properties of drugs, their dosage formulations, and routes of administration determine the level of drug absorption and the response that occurs. Absorption is the process by which a drug is made available to the body fluids that distribute the drug to the organ systems. The primary routes of administration include oral, buccal, sublingual, rectal, parenteral, topical, and inhalational (Table 9-2). As the target cells become exposed to increasing concentrations of the drug, increasing numbers of receptors become activated, and the magnitude of the response increases until there is a maximal response. In pharmacology, the term bioavailability is used to describe the rate and extent of a therapeutically active drug that reaches the systemic circulation and is available at the site of action. Bioavailability is one of the essential tools in pharmacokinetics, as bioavailability must be considered when calculating dosages. The concept of equivalence among drug products is also important in making clinical decisions:

- Chemical equivalence refers to drug products that contain the same compound in the same amount.
- Bioequivalence refers to chemical equivalents that, when administered to the same person in the same dosage regimen, result in equivalent concentrations of drug in the blood and tissues.
- Therapeutic equivalence refers to drug products that, when administered to the same person in the same dosage regimen, provide essentially the same therapeutic effect or toxicity. Bioequivalent products are expected to be therapeutically equivalent.

Thus, the physicochemical properties of a drug govern its absorptive potential, but the properties of the dosage form (which partly depend on its design and manufacture) and the mode of administration can largely determine drug bioavailability.

TABLE 9-2 Methods for Drug Administration

Method	Description
Enteral	
Oral	Chewed, sucked, or swallowed
Sublingual or buccal	Placed under the tongue or in the cheek
Rectal	Placed in the rectum as a suppository or enema
Parenteral	
Intravenous	Direct placement of a drug into the bloodstream
Intramuscular	Injected into the muscle
Intraarticular	Administered directly into the synovial fluid of a joint
Subcutaneous	Administered below the dermis
Intrathecal	Injected into the subarachnoid or subdural spaces to bypass the blood–brain barrier
Epidural	Administered into the epidural space
Other	
Inhalational	
Topical	
Transdermal	

The volume of distribution is used to indicate how a systemic dose of the medication is ultimately dispersed throughout the body. The volume of the distribution represents how much of the drug appears in the plasma relative to the total amount of drug administered, thus having important implications as to the amount of drug that reaches the target tissue. Because of high levels of blood flow, well-perfused organs such as the heart, liver, kidney, and brain rapidly receive most of the drug during the first few minutes after absorption.[6] Tissues with less vascular perfusion such as muscle, skin, and fat require several minutes longer to achieve a steady state. The process of absorption, distribution, biotransformation, and excretion of a drug as related to passage across cell membranes is dependent upon the characteristics of the drug's molecular size, shape, solubility, site of absorption, degree of ionization, and relative lipid solubility of its ionized and nonionized forms.[6] Clearance is the rate at which the active form of the drug is removed or eliminated from the body. It is the time that it takes to clear the drug from blood plasma. The rate of the process to inactivate a drug or eliminate it from the circulation is referred to as the elimination half-life (see later).

TRANSPORT ACROSS CELL MEMBRANES

When administered by most routes (excluding intravenously), a drug must traverse semipermeable cell membranes at several locations before reaching the systemic circulation (Fig. 9-1). These membranes are biologic barriers that selectively inhibit the passage of drug molecules and are composed primarily of a bimolecular lipid matrix, containing mostly cholesterol and phospholipids. The lipids provide stability to the membrane and determine its permeability characteristics. Globular proteins of various sizes and composition are embedded in the matrix; they are involved in transport and function as receptors for cellular regulation. Drugs may cross a biologic barrier by a number of methods: (1) diffusion through the water-filled channels or specialized ion channels, (2) passive diffusion through the lipid membrane, (3) facilitated diffusion, (4) active transport, or (5) pinocytosis.

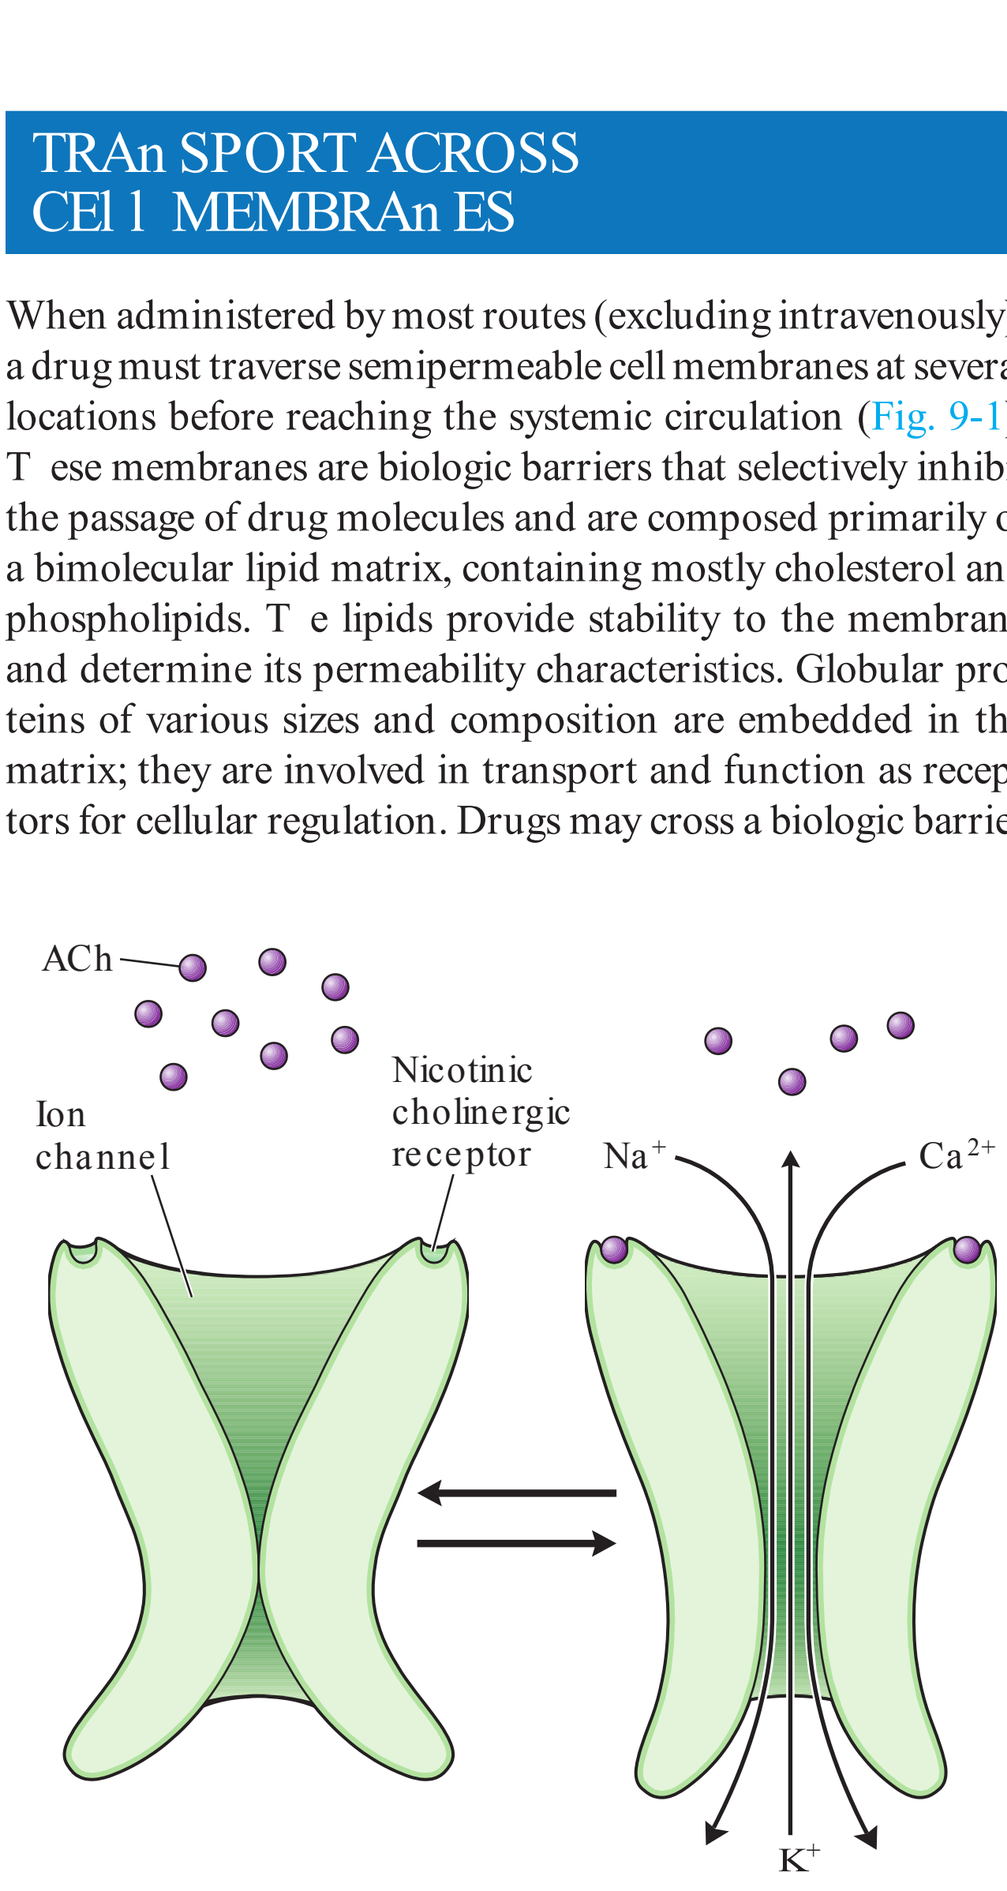

FIGURE 9-1 Drug transfer across a cell membrane.

Diffusion. Most drugs are weak organic acids or bases, existing in nonionized and ionized forms in an aqueous environment. The nonionized form is usually lipid soluble and diffuses readily across cell membranes. However, the ionized form cannot penetrate the cell membrane easily because of its low lipid solubility and the high electrical resistance provided by the lipid portion of the membrane. Steroids are nonionized (lipid soluble), the receptors for which are located inside the cell rather than on the external surface of the cell. Distribution of an ionizable drug across a membrane at equilibrium is determined by the drug's pKa (the pH at which concentrations of nonionized and ionized forms of the drug are equal) and the pH gradient, when present. For a weak acid, the higher the pH, the lower the ratio of nonionized to ionized forms. In plasma (pH, 7.4), the ratio of nonionized to ionized forms for a weak acid (e.g., with a pKa of 4.4) is 1:1,000; in gastric fluid (pH, 1.4), the ratio is reversed (1,000:1). When the weak acid is given orally, the concentration gradient for a nonionized drug between stomach and plasma tends to be large, favoring diffusion through the gastric mucosa. At equilibrium, the concentrations of a nonionized drug in the stomach and in the plasma are equal because only the nonionized drug can penetrate the membranes; the concentration of an ionized drug in the plasma would then be about 1,000 times greater than that in the stomach. For a weak base with a pKa of 4.4, the outcome is reversed. Thus theoretically, weakly acidic drugs (e.g., aspirin) are more readily absorbed from an acid medium (stomach) than are weak bases (e.g., quinidine).

Passive Diffusion. In this process, transport across a cell membrane depends on the concentration gradient of the solute. Most drug molecules are transported across a membrane by simple diffusion from a region of high concentration (e.g., gastrointestinal [GI] fluids) to one of low concentration (e.g., blood). Because drug molecules are rapidly removed by the systemic circulation and distributed into a large volume of body fluids and tissues, drug concentration in blood is initially low compared with that at the administration site, producing a large gradient. The diffusion rate is not only directly proportional to the gradient but also depends on the molecule's lipid solubility, the degree of ionization, and the size and area of the absorptive surface. Because the cell membrane is composed of lipids, lipid-soluble drugs diffuse across the membrane more rapidly than relatively lipid-insoluble drugs. Small molecules tend to penetrate membranes more rapidly than large ones.

Facilitated Passive Diffusion. For certain molecules (e.g., glucose), the rate of membrane penetration is greater than predicted due to their low lipid solubility. One theory is that a carrier component combines reversibly with the substrate molecule at the cell membrane exterior, and the carrier–substrate complex diffuses rapidly across the membrane, releasing the substrate at the interior surface. Carrier-mediated diffusion is characterized by selectivity and saturability: The carrier transports only those substrates with a relatively specific molecular configuration, and the process is limited by the availability of

carriers. T e process does not require energy expenditure, and transport against a concentration gradient does not occur.

Active Transport. T is process requires energy expenditure by the cell. Substrates may accumulate intracellularly against a concentration gradient. Active transport appears to be limited to drugs structurally similar to endogenous substances. T ese drugs are usually absorbed from sites in the small intestine. Active transport processes have been identified for various ions, vitamins, sugars, and amino acids.

Pinocytosis. T is process occurs when a cell engulfs fluid or particles. T e cell membrane invaginates (encloses) the fluid or particles, then fuses again, forming a vesicle that later detaches and moves to the cell interior. T is mechanism requires energy expenditure and probably plays only a minor role in drug transport, except in the case of protein drugs.

DISTRIBu TIOn Of DRu g S

T e distribution of a drug refers to the movement or transport of a drug to the site of action. Once a drug enters the systemic circulation, it is distributed to different parts of the body including the interstitial and intracellular fluid, and extravascular tissues. T e rate at which this occurs depends on a variety of factors including the following:[7]

- T e rate of organ blood flow.
- T e degree of drug ionization in different compartments.
- T e binding of a percentage of the drug molecules to serum protein. T e primary protein that binds drug molecules is serum albumin. Binding prevents the drug from exerting any pharmacologic action. T e unbound molecules are the portions of the drug that can penetrate capillary walls to reach the site of action.
- T e number of competing drugs within the system. Some drugs compete for the same binding sites. T is competition may result in higher levels of the unbound drug acting on the body.
- Molecular weight.
- Blood–brain barrier. Many drugs that easily penetrate other body organs do not appreciably enter the brain because of the sieve-like action of the blood–brain barrier.
- Lipid solubility.
  - Lipid-soluble drugs are more likely to penetrate the blood–brain barrier than other drugs because they pass through the cell membrane.
  - Lipid-soluble drugs may be stored in adipose tissue, which acts as a drug repository.
- Any local metabolism that occurs in any tissue other than the target organ.

METABOl ISM Of DRu g S

Metabolism refers to the process of transforming a drug into a compound that can be excreted. Metabolism occurs primarily in the liver, which reduces the drugs pharmacological activity and lipid solubility. Drug metabolism involves two processes or phases:

- Phase I. T ese reactions are catabolic and involve oxidation, reduction, full hydrolysis reactions, with oxidation occurring most frequently.
- Phase II. During this phase, the drug undergoes conjugation reactions.

DRu g El IMIn ATIOn

Drugs are eliminated from the body by a variety of routes including elimination in fluids (urine, breast milk, saliva, tears, and sweat), through the GI tract in the feces, and expelled in exhaled air through the lungs. T e kidney is the primary organ for the excretion of drugs that have been inactivated by the liver into water-soluble metabolites.[8] Excretion of a drug by the kidneys occurs by two processes[7]:

- Glomerular filtration, in which drugs are filtered through the glomerulus and then carried through the tubule into the urine. T e rate of drug excretion depends upon renal blood flow. Renal blood flow may be diminished with kidney pathology and the aging process.[9]
- Active secretion of the drug by the tubule into the urine.

DRu g HAl f -l If E

T e rate at which a drug disappears from the body, through metabolism, excretion, or a combination is called the hal*f*-li*f*e. It is the amount of time required for half of the drug that is in the body to be eliminated. Two terms are used to describe half-life:

- Elimination half-life.
  - T e time in which the concentration of the drug in the plasma falls to one-half of its original amount.
  - A drug's rate of disappearance from the body, whether by metabolism, excretion, or a combination of both.
- Biological half-life.
  - T e time in which the duration of action falls to one-half of its original duration.
  - T e time of the drug's response rather than its plasma concentration.

Cl In ICAl PEARl

The half-life is the amount of time required for half of the drug that is in the body to be eliminated.

Knowing the half-life of a drug is critical in determining how often and in what dosage a drug must be administered to achieve and maintain therapeutic levels of concentration. T e dosage interval (time between administrations of the drug) is equal to the half-life of a particular drug. T e shorter the half-life, the more often the patient must take the medication. T eoretically a steady state will be reached when the amount of the drug taken will equal the amount that is excreted. A

steady state is usually reached after five half-lives of the drug have occurred. T us, a drug with a long half-life may take several days to weeks to reach a steady state.

DRu g Al l ERg y An D DRu g -In Du CED Il l n ESSES

Drug allergies or hypersensitivities range from mild presentations to very severe life-threatening events. For a drug to produce a reaction, it must have antigenic effects and stimulate antibody formation or the formation of sensitized T-lymphocytes, which is immune-related. Drug allergies are generally classified into four types:

- *T*ype I (anaphylactic reactions). Anaphylaxis is the most severe allergic reaction and involves the skin and pulmonary and cardiovascular systems, producing cardiovascular and respiratory collapse. T e signs and symptoms associated with anaphylactic shock, which usually occur within minutes after antigen exposure, but may still occur up to 1 hour later, include:
  - Neurological: dizziness, weakness, and seizures.
  - Ocular: pruritus, lacrimation, edema around the eyes.
  - Respiratory: nasal congestion, hoarseness, stridor, cough, dyspnea, tachypnea, bronchospasm, and respiratory arrest.
  - Cardiac: tachycardia, hypotension, arrhythmias, myocardial infarction.
  - Integumentary: flushing, erythema, urticaria.
  - GI: nausea, vomiting, and diarrhea.

Cl In ICAl PEARl

Anaphylaxis is the most severe form of allergic reaction and can often be life threatening.

- *T*ype II (cytotoxic reaction). T e antigens adhere to the target cell and begin to destroy the target tissue. T e clinical manifestations include:
  - Fever
  - Arthralgia
  - Rash
  - Splenomegaly
  - Lymph node enlargement
- *T*ype III (autoimmune reaction). A complex-mediated hypersensitivity reaction in which the body has difficulty in eliminating antigen–antibody complexes. Manifestations include serum sickness, glomerulonephritis, vasculitis, and pulmonary disorders.
- *T*ype IV (cell-mediated hypersensitivity). T is type of reaction is mediated through T-lymphocytes as opposed to antibodies. Manifestations include local or tissue reaction.

THE Ef f ECTS Of Ex ERCISE On PHARMACOKIn ETICS

T e effects of exercise on drug distribution are complex and are dependent on factors that pertain to the characteristics of each drug as well as exercise-related factors such as exercise intensity, mode, and duration.[10] Exercise increases muscular blood flow and temperature and the subsequent enhancement of absorption through molecular diffusion across biological membranes. T e bioavailability of drugs can be altered with exercise primarily because of its influence on the drug's absorption site.[11] For example, there is an increased binding of digoxin (a heart medication that reduces the ventricular rate) in the skeletal muscle.[11] On the other hand, exercise may sequester some drugs such as propranolol (a medication used to treat hypertension) in muscle and reduce the availability of the drug for elimination. In addition, exercise decreases the clearance of highly extracted drugs and increases their plasma concentration. Hepatic blood flow has been found to be reduced as much as 50% with an exercise intensity level of 70% of maximal oxygen uptake.[12] Decreasing hepatic blood flow could potentially decrease the clearance of drugs that are metabolized as a function of blood through the liver. In a similar fashion, since exercise reduces renal blood flow, the plasma concentrations of those drugs that are primarily eliminated by the kidneys may increase.[12]

Exercise does appear to enhance absorption from intramuscular, subcutaneous, transdermal (iontophoresis, phonophoresis), and inhalation sites. However, exercise at the site of administration also increases cutaneous blood flow which, in the case of iontophoresis and phonophoresis, could be therapeutically unfavorable as the target site of drug administration could become diluted below therapeutic levels.[9]

THE Ef f ECTS Of PHy SICAl Ag En TS On PHARMACOKIn ETICS

Similar to exercise, physical therapy modalities have the potential to alter the pharmacokinetics of locally and systemically administered drugs, primarily by affecting blood flow and tissue kinetic and metabolic activity.[9,13] T ermal agents that increase regional blood flow can theoretically increase delivery of a drug to a specific tissue site although there are a few studies that have documented whether these changes have any clinical relevance. However, application of local heat to the site of the drug administration will almost certainly increase dispersion of the drug away from the delivery site.[10] In contrast, cold can theoretically restrict drug delivery by causing vasoconstriction at the cryotherapy site.[10]

THE Ef f ECTS Of MAn u Al TECHn Iq u ES On PHARMACOKIn ETICS

Manual techniques that increase blood flow to an area, such as massage, increase drug absorption from local subcutaneous

injection sites. Whether manual techniques have an effect on the delivery of systemically administered drugs is not known at present.

In conclusion, because some physical therapy interventions are capable of producing complex changes in the pharmacokinetics of certain drugs, any variation in the clinical response that is observed during or after a physical therapy session, should raise the suspicion about the potential pharmacokinetic effect of a drug.[9] In addition, if maintaining the plasma concentration of a drug at a certain level is important, consideration should be given to alternative drugs if the patient is to receive treatment that may affect the absorption, distribution, and metabolism of a drug.[13]

PHARMACOTHERAPy

An understanding of the potential effects of certain types of drugs commonly encountered during the rehabilitation process is essential.

Mu SCu l OSKEl ETAl PHARMACOl Og y

Drugs are widely used in the management of both acute and chronic pain and inflammation. By far the most frequently encountered and/or prescribed drug agents in physical therapy practice are those that are prescribed to control pain and/or inflammation.

Opioid Analgesics

Most of the narcotics used in medicine are referred to as opioids, as they are derived directly from opium or are synthetic opiates.[14] Examples of these opioids include codeine, Darvon (propoxyphene hydrochloride), morphine, and Demerol (meperidine) (see "Narcotic Analgesics"). Opioid analgesics are more effective in controlling pain of a constant duration versus sharp intermittent pain.[15]

nonopioid Analgesics

Nonopioid analgesics comprise a heterogeneous class of drugs including the salicylates (aspirin and diflunisal), para-aminophenol derivatives (primarily acetaminophen), and the NSAIDs, such as ibuprofen, Motrin, and many others. Despite their diverse structures, nonopioid analgesics have similar therapeutic effects, oral efficacy, and similar side-effect profiles. Nonopioid analgesics are better tolerated compared to opioids by ambulatory patients, have less sedative effects, and are much less likely to produce tolerance or dependence. Conversely, the hazards of long-term administration of these drugs are recognized.

Para-Aminophenol Derivatives. Of the para-aminophenol derivatives, only acetaminophen (Tylenol) is widely used. Acetaminophen is not typically classified as an NSAID because of its lack of an anti-inflammatory effect (it does not inhibit prostaglandin synthesis in peripheral tissues). Acetaminophen is primarily centrally acting yet exerts its analgesic and antipyretic effects peripherally by weak inhibition of both isoforms of cyclooxygenase through an unknown mechanism.[16]

Nonsteroidal Anti-inf ammatory Drugs. NSAIDs are distinguished from true steroid agents such as cortisone (cortisol), prednisone (see later), and from the opiate-derived analgesics. NSAIDs have antipyretic, anticlotting (nonselective NSAIDs only), analgesic, and anti-inflammatory effects and are by far the most frequently encountered form of drug in physical therapy practice. NSAIDs are the first-line drug choice for the treatment of mild-to-moderate pain, soft-tissue injury, osteoarthritis, gout, and inflammatory rheumatic disorders.[3] Of those patients seeing physical therapists, 25–40% are taking prescription anti-inflammatory agents, with about 40% of those using multiple NSAIDs concomitantly.[3,17,18] Aspirin, an acetylsalicylic acid, has been recognized for its pharmaceutical properties for centuries. T e pharmacology of aspirin is quite consistent with that of other NSAIDs, and it remains the prototype for comparisons of the efficacy and safety of new medications in its class. Aspirin continues to be the first-line drug for a variety of conditions, including mild pain, fever, osteoarthritis, rheumatoid arthritis, stroke prevention therapy, and potential reduction in prostate cancer incidence.[19] Other NSAIDs differ from aspirin in kinetics, duration of action, and patient tolerance, but the overall efficacy is very similar.

Cl In ICAl PEARl

While it has been shown that NSAIDs may be of benefit in muscle and tendon healing, there is growing evidence of impairment of bone and cartilage healing due to NSAIDs.[3]

T e analgesic and anti-inflammatory activity of NSAIDs is primarily due to the inhibition of arachidonic acid metabolism.[20] Arachidonic acid is present on cell membranes throughout the body and acts as a substrate for prostaglandin, prostacyclin, and thromboxane synthesis.[3] Arachidonic acid is released from cell membranes in response to physical, chemical, hormonal, and bacterial or other stimuli.[3]

NSAIDs also seem to promote the inhibition of the release of cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2) and the synthesis of prostaglandins at an injury site.[20]

- COX-1 inhibitors. COX-1 is constitutively present in virtually all tissues under normal conditions.[3] T e inhibition of COX-1 by NSAIDs has a tendency to produce a number of adverse effects on multiple organ systems, including GI inflammation, ulceration, bleeding, and increased potential for perforation.[21] Other possible side effects include an alteration of normal function in the GI mucosa and kidney blood flow, delayed wound healing, edema, nausea, dyspepsia, and fluid retention. NSAIDs may also alter kidney blood flow by interfering with the synthesis of prostaglandins in the kidney involved in the autoregulation of blood flow and glomerular filtration.[22]

- COX-2 inhibitors. Much attention has been given to the selective COX-2 inhibitors, such as celecoxib (Celebrex), which were developed to provide NSAID benefits without affecting the GI mucosa, renal tissue, or platelet aggregation.[3] COX-2 is typically not found on cell membranes under baseline conditions but is induced and upregulated by cytokines, such as interleukin-1 in the presence of cell stress or injury.[3] Because COX-2 inhibitors do not produce the same GI effects as COX-1 inhibitors, they are safer to use in patients who are predisposed to gastric or kidney malfunctions. COX-2 drugs block only the COX-2 enzyme, which is responsible for triggering pain and inflammation.[20] Because COX-1 is not affected, the patient's stomach lining is protected, and bleeding tendencies are avoided. However, the enthusiasm for the coxibs have been somewhat tempered by data suggesting they are associated with a higher risk of cardiovascular events than the nonselective NSAIDs, which led to the withdrawal from the market of two widely distributed drugs: Vioxx and Bextra.[23]

T e pharmacokinetics of NSAIDs have been studied extensively:[3]

- Absorption. NSAIDs are typically lipid-soluble weak acids and are ideally suited for rapid absorption from the acidic stomach and duodenum. After ingestion, most NSAIDs will exhibit an effect within 15–30 minutes. T e time interval to perceive symptom relief varies with the rate of enzymatic breakdown of previously synthesized prostaglandins and the time required for the ingested drug agent to inhibit replacement. Once in the bloodstream NSAIDs, except for aspirin, are heavily bound to plasma proteins. Despite the high level of NSAID protein binding, a therapeutic effect is exerted by the constant dissociation of the drug from its binding protein and release as free or active fraction within the serum. Because of NSAIDs' high-protein affinity they may displace other more weakly protein-bound drugs unintentionally, such as warfarin (Coumadin), sulfonylurea hypoglycemic agents, and methotrexate.
- Distribution. NSAIDs are widely distributed throughout most body tissues.
- Metabolism. T e liver is responsible for the metabolism and bioconversion of NSAIDs. Integration of the NSAID half-life data into the clinician's therapeutic modality selection allows for maximal drug benefit and a minimization in any adverse impact on therapy. It is worth noting that drugs with longer half-lives are associated with the highest risk for adverse effect. T e effect of a given NSAID will vary among individual patients, sometimes leading to a trial of several different agents in an effort to obtain the best therapeutic effect. In clinical practice, 7–10 days are generally long enough to ascertain the effect of a given drug.
- Elimination. NSAIDs are eliminated by renal excretion. Alterations in urine pH can affect the level of ionized or nonionized drug residue and, therefore, rates of elimination.

Cl In ICAl PEARl

Excess ingestion of salicylate, including topical products containing salicylates (e.g., Ben-Gay, and oil of wintergreen), is a common cause of poisoning. Symptoms can include respiratory failure, "sepsis-like syndrome," a potentially lethal complication of salicylate toxicity, altered mental status, and signs and symptoms of respiratory alkalosis and metabolic acidosis.

Local Anesthetics. Local anesthetics decrease sensation in a body part without a loss of consciousness or impairments of vital functions that are associated with the use of a general anesthetic.[15] All local anesthetics are membrane stabilizing drugs that act by reversibly decreasing the rate of depolarization and repolarization of nociceptor membranes by inhibiting sodium influx through sodium-specific ion channels in the neuronal cell membrane. When the influx of sodium is interrupted, an action potential cannot arise, and signal conduction is inhibited. T e local adverse effects of anesthetic agents include neurovascular manifestations such as prolonged anesthesia and paresthesia, which are symptoms of localized nerve impairment. Depending on the local tissue concentrations of local anesthetics, there may be excitatory or depressant effects on the central nervous system (CNS), which can include generalized convulsions, coma, respiratory arrest, and death.

Corticosteroids. Corticosteroids can be classified as natural or synthetic. T e natural form (mineralocorticoids) is produced by the adrenal glands, under the control of the hypothalamus, and is involved in maintaining fluid and electrolyte balance. Glucocorticoids (cortisol, and drugs such as prednisone), are used primarily for the treatment of a range of immunological and inflammatory musculoskeletal conditions. Although glucocorticoids affect nearly every major organ system in the body, their primary role is to regulate blood glucose. Corticosteroids exert their anti-inflammatory effects by binding to a high-affinity intracellular cytoplasmic receptor present in all human cells,[24] which in turn interact with discrete nucleotide sequences to alter gene expression. Because most steroid receptors in target cells are located in the cytoplasm, they need to get into the nucleus to alter gene expression. T e side effects from excess corticosteroids are associated with a number of negative side effects, including a catabolic effect on all types of supportive joint tissue. Exogenous steroid use leads to Cushing's syndrome:[25]

- Cutaneous manifestations. Cutaneous manifestations of hypercortisolism include delayed wound healing, acanthosis nigricans (a velvety, thickened, hyperpigmented plaque that usually occurs on the neck or in the axillary region), acne, ecchymosis after minor trauma, hyperpigmentation, hirsutism, petechia, and striae.
- Hypokalemia. Hypokalemia (a potentially fatal condition in which the body fails to retain sufficient potassium to maintain health) is a well-recognized side effect of corticosteroid therapy and is probably related

to the mineralocorticoid effect of hydrocortisone, prednisone, and prednisolone. Dexamethasone has no mineralocorticoid effect.

- Myopathy. T ere are two recognized forms of corticosteroid-induced myopathy: acute and chronic. Acute myopathy may in part be caused by hypokalemia, although corticosteroids (especially massive dosages) may have a direct effect on skeletal muscle. Both proximal and distal muscle weakness occur acutely, usually with an associated and significant elevation in serum creatinine phosphokinase, which is indicative of focal and diffuse muscle necrosis. In the more chronic form of myopathy, weakness is more insidious in onset and primarily involves the proximal muscle groups.
- Hyperglycemia. Hyperglycemia is a condition in which an excessive amount of glucose circulates in the blood plasma. When hyperglycemia is combined with the immunosuppressive effect of corticosteroids, there is a significant increase in the risk for infection.
- Neurological impairments. T ese can include vertigo, headache, convulsions, and benign intracranial hypertension.
- Osteoporosis. Corticosteroids inhibit bone formation directly via inhibition of osteoblast differentiation and type I collagen synthesis and indirectly by inhibition of calcium absorption and enhancement of urinary calcium excretion.
- Ophthalmologic side ef ects. Corticosteroids increase the risk of glaucoma by increasing intraocular pressure, regardless of whether administered intranasally, topically, periocularly, or systemically.
- Growth suppression. Corticosteroids interfere with bone formation, nitrogen retention, and collagen formation, all of which are necessary for anabolism and growth.

Disease-Modifying Antirheumatic Drugs. Disease-modifying antirheumatic drugs (DMARDs), sometimes referred to as slow-acting antirheumatic drugs (SAARDs), are a group of drugs that appear to decrease inflammation, though they are not categorized as anti-inflammatory drugs. DMARDs differ from NSAIDs as they do not decrease prostaglandin production, do not directly relieve pain, nor reduce fever. In effect, DMARDs slow the disease process by modifying the immune system. DMARDs are most commonly used in the treatment of rheumatoid arthritis when combined with anti-inflammatory agents, and corticosteroids, but some are also used for ankylosing spondylitis, psoriatic arthritis, and lupus. Studies throughout the years have shown DMARDs to be very effective drugs, with uncommonly observed serious side effects. T e newest DMARDs are biological agents that specifically target and block interleukin-1 or tumor necrosis factor, both of which are cytokines that play a role in the inflammatory process in diseases such as rheumatoid arthritis.

Skeletal Muscle Relaxants. Skeletal muscle relaxants are thought to act by decreasing muscle tone without causing impairment in motor function, and by acting centrally to depress polysynaptic reflexes. As muscle guarding and spasm accompany many musculoskeletal injuries, it was originally thought that these drugs, by eliminating the spasm and guarding, would facilitate the progression of a rehabilitation program. However, other drugs with sedative properties, such as barbiturates, also depress polysynaptic reflexes, making it difficult to assess if centrally acting skeletal muscle relaxants are actually muscle relaxants as opposed to nonspecific sedatives.[26] T ere presently exists a discrepancy between the common clinical use of skeletal muscle relaxants and the results of controlled clinical trials evaluating their efficacy in comparison with placebo. Supporting evidence does not exist for their efficacy in the pain of myogenic origin nor is it clear if they provide an additive effect with exercises aimed at muscle relaxation.

Because nearly all of the oral skeletal muscle relaxants have the potential to produce drowsiness, sedation, or muscle weakness, these agents can have an effect on the patient's ability to perform motor-related tasks or participate in therapy programs.[15]

Ex AMP1 ES Of DISEASE-SPECIf IC DRu g S

Musculoskeletal System Pharmacology

Osteoporosis. While estrogen therapy is still used in the treatment of osteoporosis, there are a number of medication options presently being used. T e current drug options for osteoporosis fall into four categories:[15]

1. Bisphosphonates. T ese are antiresorptive agents that decrease osteoclastic bone resorption. T e results are decreased bone remodeling, indirectly increased bone mass and a reduced risk of fractures.
2. Calcitonin. T is is a calcium lowering hormone secreted by the thyroid gland that exerts its effects by direct inhibition of osteoclast activity, and promotion of renal excretion of calcium and other minerals.
3. Selected receptor molecules. T is type of nonhormonal medication acts as an estrogen agonist in the bone to suppress bone remodeling without unfavorable stimulation of the estrogen receptors located in the breast tissue or the uterus.
4. Strontium Ranelate. A drug that offers the dual mechanisms of action of combining the antiresorptive effect with the anabolic effect of new bone formation.

Gout. T e medications prescribed to treat gout usually depend on whether the patient produces too much uric acid or does not excrete uric acid properly. If the body produces too much uric acid, a drug such as allopurinol is used to slow uric acid production. In the case where the body does not excrete uric acid well, another drug such as probenecid can be used.

neurologic System Pharmacology

Antianxiety Medications

Selective Serotonin Reuptake Inhibitors. Selective serotonin reuptake inhibitors (SSRIs) are commonly prescribed psychotherapeutic agents. Serotonin is a neurotransmitter synthesized from the amino acid L-tryptophan. Synthesis is necessary for both the central and peripheral nervous systems (PNSs) because serotonin cannot cross the blood–brain barrier. Once

synthesized, serotonin is either stored in neuronal vesicles or metabolized by monoamine oxidase (MAO) to 5-hydroxyindoleacetic acid. The most serious drug-related adverse effect of SSRIs is the potential to produce serotonin syndrome (SS). SS, characterized by mental status changes, neuromuscular dysfunction, and autonomic instability, is thought to be secondary to excessive serotonin activity in the spinal cord and brain. Symptoms attributed to serotonin excess may include:

- restlessness
- hallucinations
- shivering
- diaphoresis
- nausea
- diarrhea
- headache

Monoamine Oxidase Inhibitors (MAOIs).[27] Neurotransmitters are generally monoamines. When released into the synaptic space, neurotransmitters are either reabsorbed into the proximal nerve or destroyed by MAO in the synaptic cleft. The two types of MAO are MAO-A and MAO-B. MAO-A is found primarily in the liver and GI tract with some found in the monoaminergic neurons. MAO-A present in the liver is involved in the elimination of ingested monoamines, such as dietary tyramine. Circulating monoamines such as epinephrine, norepinephrine, and dopamine are inactivated when they pass through a liver rich in MAO-A. MAO-B, on the other hand, is found primarily in the brain and in platelets.

MAOIs act by inhibiting the activity of MAO preventing the breakdown of monoamine neurotransmitters (norepinephrine, serotonin, and dopamine) thereby increasing the available monoamines available within the CNS.

Benzodiazepines.[28] Benzodiazepines (BZDs) are sedative/hypnotic agents that are used for a variety of situations, including seizure control, anxiety, alcohol withdrawal, insomnia, control of drug-associated agitation, as muscle relaxants (antispasticity agents), and as preanesthetic agents. They also are combined frequently with other medications for conscious sedation before procedures or interventions.

γ-Aminobutyric acid (GABA) is the major inhibitory neurotransmitter in the CNS. Two types of GABA receptors called A and B types, are found in the brain and spinal cord neurons. BZDs exert their action by potentiating the activity of GABA. They bind to a specific receptor on the $GABA_A$ receptor complex, which facilitates the binding of GABA to its specific receptor site. BZD binding causes increased frequency of opening of the chloride channel complexes with the $GABA_A$ receptor. The reversal potential for $GABA_A$/chloride complexes is negative to the threshold for generating an action potential. In this way, activation of the $GABA_A$ receptor/chloride pore is inhibitory.

Clinical Pearl

GABA has two types of receptors:

- $GABA_A$. $GABA_A$ receptor is stimulated and chloride channels open to allow the influx of negative ions (i.e., chloride). The $GABA_A$ receptors have multiple binding sites for BZDs, barbiturates, and others substances such as picrotoxins, bicuculline, and neurosteroids.
- $GABA_B$. The $GABA_B$ receptor is linked to a potassium channel.

Enhanced GABA neurotransmission results in sedation, striated muscle relaxation, anxiolysis, and anticonvulsant effects. Stimulation of PNS GABA receptors may cause decreased cardiac contractility, vasodilation, and enhanced perfusion.

β-blockers. β-blockers are a class of drugs used for various indications, including the management of cardiac arrhythmias, hypertension, cardio-protection after myocardial infarction, and to block the autonomic response in persons with social phobia.

Sedatives/Hypnotics. Sedative/hypnotics are a group of drugs that cause CNS depression and are mainly used in the treatment of insomnia, but can also be used to treat anxiety, depression, and psychosis. BZDs, which are nonbarbiturates (see above), are the most commonly used agents in this class.[29] Although barbiturates produce a sedative-hypnotic effect, the associated rapid development of tolerance carries with it a high risk of physical and psychological dependence, withdrawal syndromes, and fatalities by overdose. For these reasons, barbiturates are not routinely prescribed. BZDs induce sleep by decreasing the number of arousals between the different stages of sleep thereby allowing for more continuous total sleep time. Most sedative/hypnotics stimulate the activity of GABA, the principal inhibitory neurotransmitter in the CNS. γ-Hydroxybutyric acid (GHB) is a sedative/hypnotic recently banned for sale to the public because of frequent abuse and serious adverse toxic effects. GHB is a neuroinhibitory neurotransmitter or neuromodulator in the CNS. It also appears to increase $GABA_B$ receptor activity and dopamine levels in the CNS.

Mild toxicity of sedative/hypnotics resembles ethanol intoxication and can include excessive drowsiness, impaired psychomotor coordination, decreased concentration, and cognitive deficits.[29] Moderate poisoning leads to respiratory depression and hyporeflexia. Severe poisoning leads to flaccid areflexic coma, apnea, and hypotension.

Occasionally, hyperreflexia, rigidity, clonus, and Babinski signs are present. Miosis is common, but mydriasis may be present with certain agents. The nonbarbiturates, such as methyprylon and glutethimide, more commonly present with mydriasis. Hypotension is usually secondary to vasodilation and negative cardiac inotropic effects.

Narcotic Analgesics. The term narcotic specifically refers to any substance that induces sleep. In current practice, narcotic refers to any of the many opioids or opioid derivatives.

Activation of the opiate receptors results in the inhibition of synaptic neurotransmission in the CNS and PNS. Opioids bind to opiate receptors thereby inducing a postsynaptic response. The physiological effects of opioids are mediated principally through μ and κ receptors in the CNS and periphery. μ-receptor effects include analgesia, euphoria, respiratory depression, and miosis. κ-receptor effects include analgesia, miosis, respiratory depression, and sedation. Two other opiate

receptors that mediate the effects of certain opiates include σ and δ sites. σ receptors mediate dysphoria, hallucinations, and psychosis; δ-receptor agonism results in euphoria, analgesia, and seizures.

Common classifications divide the opioids into agonist, partial agonist, or agonist–antagonist agents and natural, semisynthetic, or synthetic. Opioids decrease the perception of pain, rather than eliminate or reduce the painful stimulus. Inducing slight euphoria, opioid agonists reduce the sensitivity to exogenous stimuli. T e GI tract and the respiratory mucosa provide easy absorption for most opioids.

Peak effects are generally reached in 10 minutes with the IV route, 10–15 minutes after nasal insuf ation, 30–45 minutes with the IM (intramuscular) route, 90 minutes with the PO (by mouth) route, and 2–4 hours after dermal application. Following therapeutic doses, most absorption occurs in the small intestine. Toxic doses may delay absorption because of delayed gastric emptying and slowed gut motility.

Most opioids are metabolized by hepatic conjugation to inactive compounds that are excreted readily in the urine. Certain opiates are more lipid soluble and can be stored in the fatty tissues of the body. All opioids have a prolonged duration of action in patients with liver disease (e.g., cirrhosis) because of impaired hepatic metabolism. T is may lead to drug accumulation and opioid toxicity. Renal failure also leads to toxic effects from accumulated drug or active metabolites.

Opioid toxicity characteristically presents with a depressed level of consciousness. Opiate toxicity should be suspected when the clinical triad of CNS depression, respiratory depression, and pupillary miosis is present. Drowsiness, conjunctival injection (redness of the white sclera of the eye), and euphoria are seen frequently. Other important presenting signs are ventricular arrhythmias, acute mental status changes, and seizures.

Antidepressants

Tricyclic Antidepressants.[30] Tricyclic antidepressants (TCAs) are used in the treatment of depression, chronic pain, and enuresis (involuntary discharge of urine, especially while asleep). Patients with depression and those with chronic pain are at high risk for abuse, misuse, and overdosing of these drugs.

TCAs affect the cardiovascular, pulmonary, and GI systems, and the CNS. T e toxic effects on the myocardium are related to the blocking of fast sodium channels, which involves the same mechanism as type IA antiarrhythmics (e.g., quinidine). T e result is a slowing myocardium depolarization that leads to arrhythmia, myocardial depression, and hypotension. Hypotension also results from the peripheral α-adrenergic blockade, which causes vascular dilatation. Inhibition of norepinephrine reuptake and subsequent depletion causes further hypotension. T e effects on the pulmonary system include pulmonary edema, adult respiratory distress syndrome, and aspiration pneumonitis. T e etiologies of the first two remain unclear, but the third, aspiration pneumonitis, is secondary to an altered mental status.

T e anticholinergic effects of TCAs cause a slowing of the GI system, which results in delayed gastric emptying, decreased motility, and prolonged transit time.

CNS toxicity results from the anticholinergic effects and direct inhibition of biogenic amine reuptake. An excitation syndrome is the initial result and manifests as confusion, hallucinations, ataxia, seizures, and coma.

Parkinson Disease and Parkinsonian Syndrome

Parkinson disease (PD) is a progressive neurodegenerative disease affecting every 100–150 per hundred thousand individuals, or about 1% of those over 60 years of age, in the U.S. population.[31–33] PD is characterized clinically by tremor, bradykinesia, rigidity, and postural instability. T e basal ganglia motor circuit modulates cortical output necessary for normal movement.

Levodopa, coupled with a peripheral decarboxylase inhibitor (PDI), remains the criterion standard for symptomatic treatment for PD, as it provides the greatest antiparkinsonian benefit with the fewest adverse effects.[30]

Dopamine agonists provide symptomatic benefit comparable to levodopa/PDI in early disease but lack sufficient efficacy to control signs and symptoms by themselves in later disease.

Medications for PD usually provide good symptomatic control for 4–6 years. Whether levodopa has a toxic or protective effect in the brain with PD is unknown. As PD progresses, fewer dopamine neurons are available to store and release levodopa-derived dopamine. T e patient's clinical status begins to fluctuate more and more closely in concert with plasma levodopa levels. Fluctuating levodopa-derived dopamine concentrations in association with advancing disease, therefore, may be responsible for the development of motor fluctuations and dyskinesia.[30]

In contrast to levodopa, the long-acting dopamine agonists provide relatively smooth and sustained receptor stimulation.[30]

T e selection of medication depends in part on the nature and cause of the disability. If the disability is due solely to tremor, a tremor-specific medication, such as an anticholinergic agent, is often used. Anticholinergic medications provide good tremor relief in approximately 50% of patients, but do not improve bradykinesia or rigidity.[30] Because tremor may respond to one anticholinergic medication and not another, a second anticholinergic usually is tried if the first is not successful. T ese medications are usually introduced at a low dose and escalated slowly to minimize adverse effects, which include memory difficulty, confusion, and hallucinations. Adverse cognitive effects are relatively common, especially in the elderly.

If the disability is due to a dopamine-responsive symptom such as bradykinesia, rigidity, decreased dexterity, slow speech, or shuf ing gait, a dopaminergic medication (dopamine agonist or levodopa/PDI) are typically introduced.[30] Symptomatic medications are started at a low dose, escalated slowly, and titrated to control symptoms. Most patients require symptomatic dopaminergic therapy to ameliorate bradykinesia and rigidity within 1–2 years after diagnosis.

For patients younger than 65 years, symptomatic therapy is normally initiated with a dopamine agonist and then add levodopa/PDI when the dopamine agonist alone no longer controls symptoms adequately.[30] Dopamine agonists provide antiparkinsonian efficacy comparable to levodopa/PDI for 6–18 months or longer and may control symptoms adequately for several years.

For patients who are demented or those older than 70 years, who may be prone to adverse effects from dopamine agonists, and for those likely to require treatment for only a few years, physicians may elect not to use a dopamine agonist but depend

TABLE 9-3 The Ischemic Cascade

Lack of oxygen causes the neuron's normal process for making ATP for energy to fail.

The cell switches to anaerobic metabolism, producing lactic acid.

ATP-reliant ion transport pumps fail, causing the cell to become depolarized, allowing ions, including calcium (Ca^{++}), to flow into the cell.

The ion pumps can no longer transport calcium out of the cell, and intracellular calcium levels get too high.

The presence of calcium triggers the release of the excitatory amino acid neurotransmitter glutamate.

Glutamate stimulates AMPA receptors and Ca^{++}-permeable NMDA receptors, which open to allow more calcium into cells.

Excess calcium overexcites cells and causes the generation of harmful chemicals like free radicals, reactive oxygen species, and calcium-dependent enzymes such as calpain, endonucleases, ATPases, and phospholipases. Calcium can also cause the release of more glutamate.

As the cell's membrane is broken down by phospholipases, it becomes more permeable, and more ions and harmful chemicals flow into the cell.

Mitochondria break down, releasing toxins, and apoptotic factors into the cell.

The caspase-dependent apoptosis cascade is initiated, causing cells to "commit suicide."

If the cell dies through necrosis, it releases glutamate and toxic chemicals into the environment around it. Toxins poison nearby neurons, and glutamate can overexcite them.

If and when the brain is reperfused, a number of factors lead to reperfusion injury.

An inflammatory response is mounted, and phagocytic cells engulf damaged but still viable tissue.

Harmful chemicals damage the blood–brain barrier.

Cerebral edema occurs because of leakage of large molecules like albumin from blood vessels through the damaged blood–brain barrier. These large molecules pull water into the brain tissue after them by osmosis. This "vasogenic edema" causes compression of and damage to brain tissue.

AMPA, α-amino-5-hydroxy-3-methyl-4-isoxazole propionic acid; NMDA, N-methyl-D-aspartate.

on levodopa/PDI as the primary symptomatic therapy.[30] For patients aged 65–70 years, a judgment is made based on general health and cognitive status.

Medications for Cerebrovascular Accidents. The ischemic cascade is a series of biochemical reactions that take place in the brain and other aerobic tissues after seconds to minutes of ischemia (inadequate blood supply; Table 9-3).[34] Since the ischemic cascade is a dynamic process, the efficacy of interventions to protect the ischemic cascade also may prove to be time dependent.

Theoretically, calcium channel blockers should have the narrowest window of therapeutic opportunity since calcium influx is one of the earliest events in the ischemic cascade.

Neuroprotectants affecting later events in the ischemic cascade include free-radical scavengers and neuronal membrane stabilizers. Monoclonal antibodies against leukocyte adhesion molecules also are being evaluated as late neuroprotectants.

Anticoagulants are considered as potential treatments for cerebrovascular accidents (CVA). However, although heparin prevents recurrent cardioembolic strokes and may help inhibit ongoing cerebrovascular thrombosis, no definitive evidence exists to show that initiating anticoagulation reduces brain injury in acute ischemic stroke.

Anticoagulation drug treatment is not without risk. Overall, intracranial hemorrhage occurs in 1–4% of patients who receive an anticoagulant for TIA or acute stroke. Accordingly, uncontrolled hypertension, intracranial hemorrhage, and uncontrolled bleeding at another site are contraindications to anticoagulation.

Several new oral anticoagulant medications are in the final stages of clinical trials for use in the prophylaxis of ischemic thromboembolic stroke. Once approved for use, the potential of such drugs in the arena of stroke treatment may be significant.

Antiepileptic Drugs. Many structures and processes are involved in the development of a seizure, including neurons, ion channels, receptors, glia, and inhibitory and excitatory synapses.[35] The antiepileptic drugs (AEDs) are designed to modify these processes to favor inhibition over excitation in order to stop or prevent seizure activity. The AEDs can be grouped according to their main mechanism of action, although many of them have several actions and others have unknown mechanisms of action. The main groups are as follows.

Sodium channel blockers. The sodium channel blockade is the most common and the most well-characterized mechanism of currently available AEDs. AEDs that target these sodium channels prevent the return of the channels to the active state by stabilizing their inactive form. In doing so, repetitive firing of the axons is prevented. The presynaptic and postsynaptic blockades of sodium channels of the axons cause stabilization of the neuronal membranes, block and prevent posttetanic potentiation, limit the development of maximal seizure activity, and reduce the spread of seizures.

Cl In ICAl PEARl

Anticonvulsants in mood disorders have four major effects:

- Increasing of the seizure threshold
- Decreasing the seizure duration
- Decreasing the neurometabolic response to an episode
- Decreasing the phenomena of amygdaloid kindling

Essentially, they make it more dif cult for the postsynaptic neuron to reach its excitation threshold either electrically or neurochemically, and once it has been reached, decrease the widespread effects.

Side effects and toxicity. AEDs can produce dose-related adverse effects, which include dizziness, diplopia, nausea, ataxia, and blurred vision. Rare idiosyncratic adverse effects include aplastic anemia, agranulocytosis, thrombocytopenia, and Stevens–Johnson syndrome. Asymptomatic elevation of liver enzymes is observed commonly during the course of therapy in 5–10% of patients. Rarely, severe hepatotoxic effects can occur.

GABA receptor agonists. Direct binding to $GABA_A$ receptors can enhance the GABA system by blocking presynaptic GABA uptake, by inhibiting the metabolism of GABA by GABA transaminase, and by increasing the synthesis of GABA.

Side effects and toxicity. The most common effect is sedation. Other adverse effects include dizziness, ataxia, blurred vision, diplopia, irritability, depression, muscle fatigue, and weakness.

GABA reuptake inhibitors. At least four specific GABA-transporting compounds help in the reuptake of GABA; these carry GABA from the synaptic space into the neurons and glial cells, where it is metabolized. Nipecotic acid and tiagabine (TGB) are inhibitors of these transporters; this inhibition makes increased amounts of GABA available in the synaptic cleft, which serves to prolong GABA-mediated inhibitory postsynaptic potentials (IPSPs).

Side effects and toxicity. The most common adverse effects include dizziness, asthenia, nervousness, tremor, depressed mood, and emotional lability. Diarrhea also was significantly more frequent among TGB-treated patients than placebo-treated patients. Other adverse effects included somnolence, headaches, abnormal thinking, abdominal pain, pharyngitis, ataxia, confusion, psychosis, and skin rash.

GABA transaminase inhibitor. GABA is metabolized by transamination in the extracellular compartment by GABA-transaminase (GABA-T). Inhibition of this enzymatic process leads to an increase in the extracellular concentration of GABA. Vigabatrin (VGB) inhibits the enzyme GABA-T.

Side effects and toxicity. The most common adverse effect is drowsiness. Other important adverse effects include neuropsychiatric symptoms, such as depression (5%), agitation (7%), confusion, and, rarely, psychosis. Minor adverse effects, usually at the onset of therapy, include fatigue, headache, dizziness, increase in weight, tremor, double vision, and abnormal vision.

Glutamate blockers. Glutamate and aspartate are the most two important excitatory neurotransmitters in the brain. The glutamate system is a complex system with macromolecular receptors with different binding sites (i.e., AMPA, kainate, NMDA, glycine, metabotropic site).

Side effects and toxicity. Common adverse effects include insomnia, weight loss, nausea, decreased appetite, dizziness, fatigue, ataxia, and lethargy. Polytherapy is associated with increases in adverse effects.

Neuroleptics (Antipsychotics). The term neuroleptic refers to the effects on cognition and behavior of antipsychotic drugs that reduce confusion, delusions, hallucinations, and psychomotor agitation in patients with psychoses.[36] Also known as major tranquilizers and antipsychotic drugs, neuroleptic agents comprise a group of the following classes of drugs:

- Phenothiazines
- Aliphatics
- Piperidines
- Piperazines
- Thioxanthenes
- Butyrophenones
- Dibenzoxazepines
- Dihydroindolone
- Diphenylbutylpiperidine
- Benzisoxazole

The adverse effects of neuroleptics are not confined to psychiatric patients. Neuroleptics also are used as sedatives, for their antiemetic properties, to control hiccups, to treat migraine headaches, as antidotes for drug-induced psychosis, and in conjunction with opioid analgesia.

The major tranquilizers have complex CNS actions that are incompletely defined. Their therapeutic action is thought to be primarily an antagonism of central dopaminergic (D-2 receptor) neurotransmission, although they also have antagonist effects at muscarinic, serotonergic, α_1-adrenergic, and H_1-histaminergic receptors.

Although all antipsychotic preparations share some toxic characteristics, the relative intensity of these effects varies greatly, depending on the individual drug. Generally, all neuroleptic medications are capable of causing the following symptoms:

- **Hypotension:** Phenothiazines are potent α-adrenergic blockers that result in significant orthostatic hypotension, even in therapeutic doses for some patients. In overdose, the hypotension may be severe.
- **Anticholinergic effects:** Neuroleptic agent toxicity can result in tachycardia, hyperthermia, urinary retention, toxic psychosis, and hot, dry flushed skin.
- **Extrapyramidal symptoms:** Alteration in the normal balance between central acetylcholine and dopamine transmission can produce dystonia, oculogyric crisis, torticollis, acute parkinsonism, akathisia, and other movement disorders. Chronic use of major tranquilizers is associated with buccolingual dysplasia (tardive dyskinesia, TD), parkinsonism, and akathisia.
- **Neuroleptic malignant syndrome:** All of the major tranquilizers have been implicated in the development of neuroleptic malignant syndrome (NMS)—a life-threatening derangement that affects multiple organ systems and results in significant mortality.
- **Seizures:** Most major tranquilizers lower the seizure threshold and can result in seizures at high doses and in susceptible individuals.
- **Hypothermia:** Certain major tranquilizers prevent shivering, limiting the body's ability to generate heat.
- **Cardiac effects:** Prolongation of the QT interval and QRS can result in arrhythmias.
- **Respiratory depression:** Hypoxia and aspiration of gastric contents can occur in children and in mixed overdose.

Spasticity. Spasticity is a motor disorder characterized by a velocity-dependent increase in tonic stretch reflexes with exaggerated tendon jerks, resulting from hyperexcitability of the stretch reflex, as one component of the upper motor neuron syndrome (see Chapter 3).[37,38] The drugs used to reduce spasticity work as agonists or antagonists at both of the GABA receptors.
